The dominant SM backgrounds in the signal regions originate from $t\bar{t}$+jets, single top quark production, multijet events that have jets produced through the strong interaction, and the W+jets and Z+jets processes. Data-driven methods are employed to estimate the background contributions to the signal regions. Control regions are used to isolate a process to be estimated, defined by modifying one or more signal selection criteria. After applying the signal and control region selections, resulting data and MC event distributions are scaled to the HL-LHC cross sections and integrated luminosities. For data, a procedure is designed to mimic both the statistical precision and potential modifications in shape due to different levels of cross section scaling in the various contributing processes. After scaling all distributions, background estimates in the signal regions are obtained by multiplying the observed data yields, binned in M_R and R^2, by the simulation transfer factors computed as the ratios of the yields of background MC simulation events in the signal regions to the yields in control regions. Other SM processes that contribute less significantly, such as diboson, triboson, and $\mathrm{t\bar{t}V}$, are estimated directly from the simulation. The simulated events used for obtaining both the transfer factors and the direct estimates were corrected using various data-to-simulation correction factors and event weights. The uncertainties in these correction factors and weights were taken into account as systematic uncertainties. Three different scenarios for systematic uncertainties are considered, in which the systematic uncertainties are i) taken as they are in the original analysis, (Run-2) ii) scaled down according to the expected improvements in the detector and theory calculations (YR18), and iii) neglected in order to test a case with statistical uncertainties only (stat-only). Statistical uncertainties are scaled down by $1/\sqrt{\mathcal{L}_{HL-LHC}/\mathcal{L}_{2016}}$.

The overall background estimation for the W 4-5 jet, W 6 jet, and Top categories along with distributions for several signal benchmark scenarios versus a one-dimensional representation of the bins in M_R and R^2 are shown in Figure 2.1.5, considering the YR18 systematic scenario. The most dominant systematic uncertainties on the total background estimate come from W/top tagging ($\sim 1-4\%$), b-tagging ($\sim 3\%$), jet energy scale (JES) ($\sim 3\%$), and pile-up ($\sim 1-3\%$) variations along with QCD multijet background shape uncertainties ($\sim 3-7\%$). For the simulated signal event yields, the largest contributions come from W/top tagging ($\sim 8\%$), jet energy scale (JES) ($\sim 3\%$) and b-tagging ($\sim 2\%$) variations.

The results are used to set expected upper limits on the production cross sections of various SUSY simplified models. Figure 2.1.6 shows the expected upper limits on the signal cross sections for the T5ttcc, T1tttt and T2tt simplified models for the combination of the W 4-5 jet, W 6 jet, and Top categories for the HL-LHC projection based on the YR18 scenario. Additionally, lower limits on gluino/top squark versus neutralino masses are shown for the cases of Run-2 systematic uncertainties, YR18 sys-

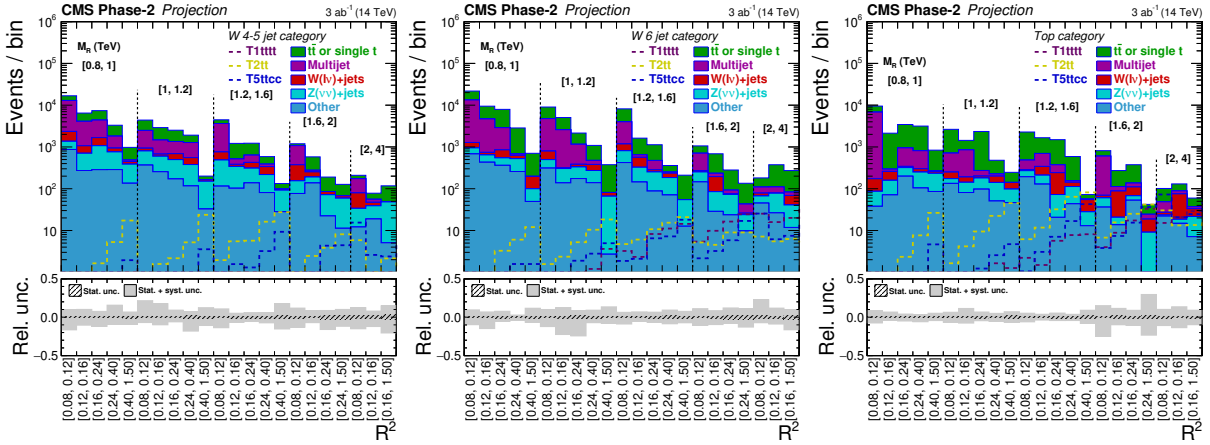

Fig. 2.1.5: M_R-R^2 distributions shown in a one-dimensional representation for background predictions obtained for the W 4-5 jet (upper left), W 6 jet (upper right), and Top (lower) categories for the HL-LHC. Statistical and systematic uncertainties for the YR18 scenario are shown with the hatched and shaded error bars, respectively. Also shown are the signal benchmark models T5ttcc with $m_{\tilde{g}} = 2$ TeV, $m_{\tilde{t}} = 320$ GeV and $m_{\tilde{\chi}^0_1} = 300$ GeV; T1tttt with $m_{\tilde{g}} = 2$ TeV and $m_{\tilde{\chi}^0_1} = 300$ GeV; and T2tt with $m_{\tilde{t}} = 1.2$ TeV and $m_{\tilde{\chi}^0_1} = 100$ GeV.

tematic uncertainties, and statistical-only scenarios for the HL-LHC case. Furthermore, projections of expected discovery sensitivity in the presence of a signal were computed. The p-values for the signal plus background and background-only hypotheses were used to obtain the expected significances in terms of number of standard deviations. Figure 2.1.7 shows the projected expected significance for the T5ttcc, T1tttt, and T2tt models based on the YR18 systematic uncertainties, along with the discovery upper bounds on the gluino/top squark versus neutralino masses for the three uncertainty scenarios for the HL-LHC.

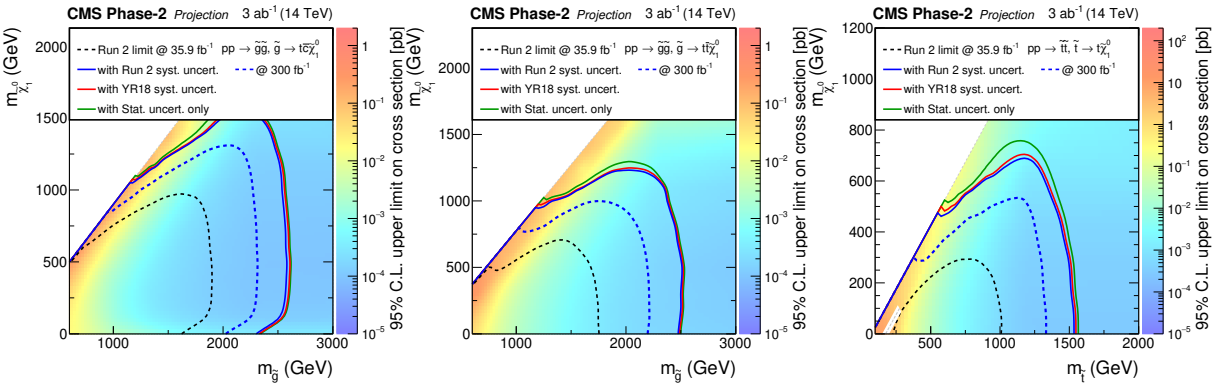

Fig. 2.1.6: Projected expected upper limits on the signal cross sections for the HL-LHC using the asymptotic CLs method versus gluino/top squark and neutralino masses for the T5ttcc (top left), T1tttt (top right), and T2tt (bottom) models for the combined W 4-5 jet, W 6 jet, and Top categories for the YR18 scenario. The contours show the expected lower limits on the gluino/top squark and neutralino masses based on the Run-2 systematic uncertainties, YR18 systematic uncertainties, and statistical-only scenarios, along with the 2016 razor boost limit and the 300 fb^{-1} limit for comparison.

The projection results show that HL-LHC would improve the gluino mass exclusion limits via top-quark by around 750 GeV, while making discovery possible for gluinos up to masses of 2.4 TeV. For top squark pair production, the discovery reach is up to 1.4 TeV, consistent with the ATLAS prospect studies in Section 2.1.2.

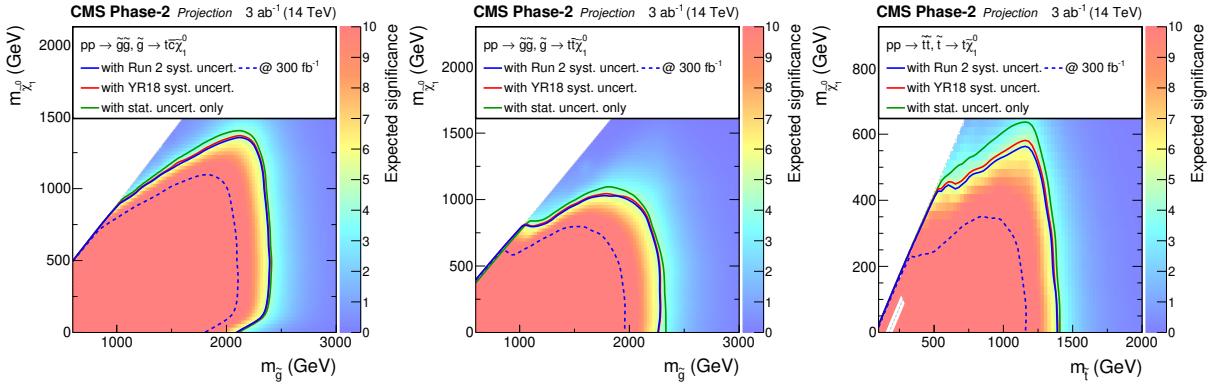

Fig. 2.1.7: Projected expected significance for the HL-LHC versus gluino/stop and neutralino masses for the T5ttcc (top left), T2tttt (top right), and T2tt (bottom) models for the combined W 4-5 jet, W 6 jet, and Top categories for the YR18 scenario. The contours show the expected discovery bounds on the gluino/top squark and neutralino masses based on the Run-2 systematic uncertainties, YR18 systematic uncertainties, and statistical-only scenarios.

2.1.4 Implications of a stop sector signal at the HL-LHC

Contributors: A. Pierce, B. Shakya

The stop sector is intricately tied to the mass of the Higgs boson. A stop sector discovery therefore provides an opportunity to test the Higgs mass relation, as well as predict subsequent signals at the LHC. This section is devoted to illustrations of such scenarios at the HL-LHC, based on the studies in Ref. [76].

The Higgs boson mass at one-loop in the MSSM is [77]

$$\begin{aligned} m_h^2 &= m_Z^2 \cos^2(2\beta) + \frac{3\sin^2\beta\, y_t^2}{4\pi^2}\Big[m_t^2 \ln\left(\frac{m_{\tilde{t}_1} m_{\tilde{t}_2}}{m_t^2}\right) + c_t^2 s_t^2 (m_{\tilde{t}_2}^2 - m_{\tilde{t}_1}^2) \ln\left(\frac{m_{\tilde{t}_2}^2}{m_{\tilde{t}_1}^2}\right) \\ &+ c_t^4 s_t^4 \left\{ (m_{\tilde{t}_2}^2 - m_{\tilde{t}_1}^2)^2 - \frac{1}{2}(m_{\tilde{t}_2}^4 - m_{\tilde{t}_1}^4) \ln\left(\frac{m_{\tilde{t}_2}^2}{m_{\tilde{t}_1}^2}\right) \right\} / m_t^2 \Big], \end{aligned} \tag{2.1.2}$$

where $\tilde{t}_1$ and $\tilde{t}_2$ are the stop mass eigenstates, θ_t is the stop mixing angle, with $\tilde{t}_1 = \cos\theta_t\, \tilde{t}_L + \sin\theta_t\, \tilde{t}_R$, $s_t(c_t) = \sin\theta_t(\cos\theta_t)$, and y_t is the top Yukawa coupling. As the mass splitting between stops increases, the latter two terms in the loop correction grow stronger; in particular, the final term switches sign and becomes negative for $m_{\tilde{t}_2} \gtrsim 2.7 m_{\tilde{t}_1}$, and can dominate for non-vanishing stop mixing and $m_{\tilde{t}_2} \gg m_{\tilde{t}_1}$. Consequently, there exists an *upper* limit on $m_{\tilde{t}_2}$ (as a function of $m_{\tilde{t}_1}$ and θ_t), beyond which it is impossible to accommodate $m_h = 125$ GeV in the MSSM. In other words, a measurement of $m_{\tilde{t}_1}$ and some knowledge of θ_t allows for an upper limit on $m_{\tilde{t}_2}$, and ruling out this window rules out the MSSM. In the following, we discuss some scenarios where such ideas can be implemented at the HL-LHC.

A Sbottom Signal in Multileptons:

Consider a spectrum such that $\tilde{b}_1 \to \tilde{t}_1 W$ (which requires both $\tilde{t}_1$ and $\tilde{b}_1$ to be somewhat left-handed) and $\tilde{t}_1 \to t\chi_0$, the mass splitting $\Delta m_{\tilde{b}_1 \tilde{t}_1}$ is sufficiently large that sbottom decays give visible multilepton signals, but direct $\tilde{t}_1$ discovery is elusive because of a squeezed spectrum. In the MSSM, $m_{\tilde{t}_2}$ is correlated with $\Delta m_{\tilde{b}_1 \tilde{t}_1}$, as shown in Fig. 2.1.8. A large splitting involves a large stop mixing angle (otherwise, $\tilde{b}_1$ is approximately degenerate with $\tilde{t}_1$); in this case, as discussed above, consistency with the Higgs mass enforces an upper limit on $m_{\tilde{t}_2}$, as seen in Fig. 2.1.8. Alternatively, the splitting can be raised by making $\tilde{t}_1$ mostly right-handed; however, in this case, $m_{\tilde{t}_2} \approx m_{\tilde{b}_1}$ and again faces an upper limit. For a sub-TeV sbottom, such limits are particularly sharp, as compatibility with the Higgs mass forces $m_{\tilde{t}_2}$ to lie within a narrow wedge shaped region, as seen in the figure.

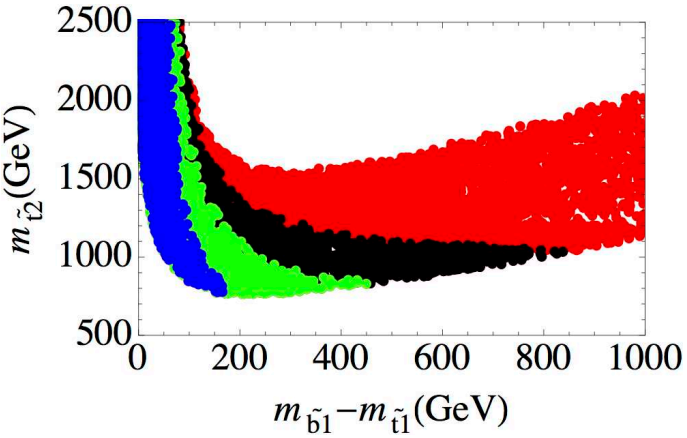

Fig. 2.1.8: $m_{\tilde{t}_2}$ as a function of the mass splitting $m_{\tilde{b}_1} - m_{\tilde{t}_1}$ for points with $120 < m_h < 130$ GeV and $m_{\tilde{t}_1} < 1$ TeV in the MSSM. Red, black, green, and blue points correspond to $m_{\tilde{b}_1} > 1000$ GeV, $750 < m_{\tilde{b}_1} < 1000$ GeV, $500 < m_{\tilde{b}_1} < 750$ GeV, and $m_{\tilde{b}_1} < 500$ GeV respectively.

Detailed analysis of the multilepton excess can shed further light on the properties of $\tilde{t}_2$: inferring $\Delta m_{\tilde{b}_1\tilde{t}_1}$ (from, *e.g.*, the lepton p_T distribution) and the sbottom mass (from, *e.g.*, the signal rate) not only narrows the allowed range of $m_{\tilde{t}_2}$ (Fig. 2.1.8) but also constrains the stop mixing angle. It is therefore possible to not only predict a relatively narrow mass window for $\tilde{t}_2$, but also get a profile of its decay channels. Such a $\tilde{t}_2$ may well be within reach of the LHC, and ruling out such a $\tilde{t}_2$ is sufficient to rule out the MSSM. This concept was implemented in Ref. [76] for a benchmark point with $m_{\tilde{t}_2} = 1022$ GeV, $m_{\tilde{b}_1} = 885$ GeV, $m_{\tilde{t}_1} = 646$ GeV, and $m_{\chi_0} = 445$ GeV. Using existing CMS search strategies for same-sign dileptons [78, 79] as well as multileptons [80, 81], it was shown that the sbottom decay signal could be identified at the HL-LHC at $3-5\sigma$ significance with $3\,\text{ab}^{-1}$of data. As discussed above, the discovery of such a sbottom signal with energetic multileptons imposes an upper limit on $m_{\tilde{t}_2}$ in the MSSM. For this benchmark point, it was also shown that modifications of the aforementioned multilepton search strategy would also allow for a $3-5\sigma$ significance discovery of the heavier stop decay $\tilde{t}_2 \to \tilde{t}_1 Z$ with $3\,\text{ab}^{-1}$of data, illustrating how using the MSSM Higgs mass relation in conjunction with a sbottom signal discovery can lead to predictions and discovery of $\tilde{t}_2$ at the HL-LHC. For details of the analysis, the interested reader is referred to [76].

Using Multiple Decay Channels for the Heavier Stop:

The HL-LHC could enable measurements in multiple channels with significant statistics. In particular, the heavier stop $\tilde{t}_2$ could be observed in multiple channels $\tilde{t}_1 Z$, $\tilde{t}_1 h$, $\tilde{b}_1 W$, and $t\chi_0$, with branching ratios (BRs) determined by the stop masses and mixing angle. We focus on the two decays $\tilde{t}_2 \to \tilde{t}_1 Z$ and $\tilde{t}_2 \to \tilde{t}_1 h$, which give rise to boosted dibosons if the mass splitting between the two stop mass eigenstates is large. In the decoupling limit in the Higgs sector, the ratio of the decay widths into these two channels is [82]:

$$R_{hZ} \equiv \frac{\Gamma(\tilde{t}_2 \to \tilde{t}_1\, h)}{\Gamma(\tilde{t}_2 \to \tilde{t}_1\, Z)} = \left[\left(1 - \frac{m^2_{\tilde{t}_1}}{m^2_{\tilde{t}_2}}\right)\cos 2\theta_{\tilde{t}} + \frac{m^2_W}{m^2_{\tilde{t}_2}}\left(1 - \frac{5}{3}\tan^2\theta_W\right)\right]^2 \approx \left(1 - \frac{m^2_{\tilde{t}_1}}{m^2_{\tilde{t}_2}}\right)^2 \cos^2 2\theta_{\tilde{t}}. \tag{2.1.3}$$

Phase space factors as well as many experimental uncertainties cancel in this ratio, offering a clean dependence on the stop mixing angle if the two stop masses are known from other measurements, enabling a check of the MSSM Higgs mass relation.

The viability of such a strategy was explored in Ref. [76] for a benchmark scenario with $m_{\tilde{t}_2} = 994$ GeV, $m_{\tilde{b}_1} = 977$ GeV, $m_{\tilde{t}_1} = 486$ GeV, and $m_{\chi_0} = 406$ GeV, with $\tilde{t}_2$ decay BRs of

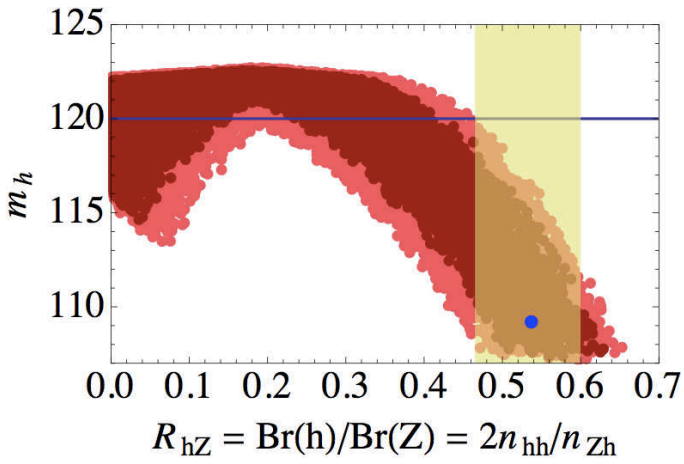

Fig. 2.1.9: MSSM Higgs mass as a function of R_{hZ}. The horizontal blue line denotes $m_h = 120$ GeV, the cutoff below which the Higgs mass is assumed to be inconsistent with the MSSM (see [76] for details). Light (dark) red bands correspond to $440 \leq m_{\tilde{t}_1} \leq 520$ GeV and $930 \leq m_{\tilde{t}_2} \leq 1030$ GeV ($450 \leq m_{\tilde{t}_1} \leq 510$ GeV and $945 \leq m_{\tilde{t}_2} \leq 1015$ GeV). The blue dot denotes the benchmark point in our analysis, which is consistent with all constraints but does not produce the correct Higgs mass in the MSSM. The golden band shows the uncertainty in the calculated value of R_{hZ} with 3 $\text{ab}^{-1}$of data at the HL-LHC.

52% and 28% into $\tilde{t}_1\, Z$ and $\tilde{t}_1\, h$ respectively, using the strategy from Ref. [83] to reconstruct boosted dibosons via fat jets. Note that measuring the ratio R_{hZ} with reasonable precision requires high statistics, motivating searches for the boosted Z and h bosons in their dominant (hadronic) decay channels rather than the cleaner decays into leptons or photons. Assuming that $m_{\tilde{t}_1}$ has been measured to lie in the range 486 ± 40 GeV from monojet or charm-tagged events, while $m_{\tilde{t}_2}$ is known to fall in the 994.2 ± 50 GeV range from various measurements (such as by combining the knowledge of $m_{\tilde{t}_1}$ with information on $p_T(Z)$ in $\tilde{t}_2 \to \tilde{t}_1 Z$ events), the MSSM Higgs mass can be calculated as a function of θ_t using Eq. (2.1.2), which can be converted to a function of the ratio R_{hZ} using Eq. (2.1.3); this relation is plotted in Fig. 2.1.9 in the broad red band for the above stop mass windows. The narrower, darker red band corresponds to narrower windows for the two stop masses, reflecting the improvement in the Higgs mass uncertainty with better knowledge of the stop masses.

The Higgs mass is small for vanishing stop mixing $\theta_t \to 0,\ \pi/2$, which corresponds to $R_{hZ} \sim \cos^2 2\theta_t$ approaching 1. On the other hand, achieving the correct Higgs mass with sub-TeV stops requires large stop mixing, which correlates with a smaller value of R_{hZ}. As seen in Fig. 2.1.9, an inferred value of R_{hZ} above some cutoff value R_0 (≈ 0.45 in this case) is incompatible with the MSSM Higgs mass relation. Such an observation would rule out the MSSM, pointing to the need for additional contributions to the Higgs mass (as is the case for the chosen benchmark point). The golden band encodes the uncertainty in the calculated value of R_{hZ} for the benchmark point that can be achieved at the HL-LHC with 3 $\text{ab}^{-1}$of data (see [76] for details). This benchmark point study illustrates that measurements of the two decay channels can be used as a consistency check of the Higgs mass and possibly rule out the MSSM at the HL-LHC.

2.2 Searches for charginos and neutralinos

The direct production of charginos and neutralinos through EW interactions may dominate the SUSY production at the LHC if the masses of the gluinos and squarks are beyond $3 - 4$ TeV. In this section, the sensitivity at the end of HL-LHC to the direct production of various SUSY partners in the EW sector under the assumption of R-parity conservation is presented. Charginos and heavier neutralinos production processes are considered, assuming they decay into the LSP via on-shell or off-shell W

and Z or Higgs bosons. Final state events characterised by the presence of charged leptons, missing transverse momentum and possibly jets and b-jets are studied and prospects are presented. Dedicated searches for higgsino-like, 'compressed' SUSY models, characterised by small mass splittings between electroweakinos, are also reported, and possible complements with new facilities are illustrated.

2.2.1 Chargino pair production at HL-LHC

Contributors: S. Carra, T. Lari, D. L. Noel, C. Potter, ATLAS

The charged wino or higgsino states might be light and decay via SM gauge bosons. In this search [84], the direct production of $\tilde{\chi}_1^+\tilde{\chi}_1^-$ is studied. The $\tilde{\chi}_1^\pm$ is assumed to be pure wino, while the $\tilde{\chi}_1^0$ is the LSP and is assumed to be pure bino and stable. The $\tilde{\chi}_1^\pm$ decays with 100% branching fraction to $W^\pm$ and $\tilde{\chi}_1^0$. Only the leptonic decays of the W are considered, resulting in final states with two opposite electric charge (OS) leptons and missing transverse energy from the two undetected $\tilde{\chi}_1^0$.

The selection closely follows the strategies adopted in the 8 TeV [85] and 13 TeV [86] searches. Events are required to contain exactly two leptons (electrons or muons) with $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.5$ (2.47 for electrons). The lepton pair must satisfy $m_{\ell\ell} > 25$ GeV to remove contributions from low mass resonances. The two leptons must be OS, pass "tight" identification criteria, and be isolated (the scalar sum of the transverse momenta of charged particles with $p_{\mathrm{T}} > 1$ GeV within a cone of $\Delta R = 0.3$ around the lepton candidate, excluding the lepton candidate track itself, must be less than 15% of the lepton p_{T}). All leptons are required to be separated from each other and from candidate jets defined with $p_{\mathrm{T}} > 30$ GeV and $|\eta| < 2.5$. The latter requirement is imposed to suppress the background from semi-leptonic decays of heavy-flavour quarks, which is further suppressed by vetoing events having one or more jets tagged as originating from b-decays, "b-tagged jets". The chosen working point of the b-tagging algorithm correctly identifies b-quark jets in simulated $t\bar{t}$ samples with an average efficiency of 85%, with a light-flavour jet misidentification probability of a few percent (parametrised as a function of jet p_{T} and η).

The signal region is divided into two disjoint regions with a Same Flavour Opposite Sign (SFOS: e^+e^-, $\mu^+\mu^-$) or Different Flavour Opposite Sign (DFOS: $e^\pm\mu^\mp$) lepton pair to take advantage of the differing SM background composition for each flavour combination. The SFOS and DFOS regions are divided again into events with exactly zero jets or one jet, which target scenarios with large or small $\tilde{\chi}_1^\pm - \tilde{\chi}_1^0$ mass splittings, respectively. One lepton must have $p_{\mathrm{T}} > 40$ GeV to suppress the SM background, and with $p_{\mathrm{T}}^{\ell 1} > 40$ GeV and $p_{\mathrm{T}}^{\ell 2} > 20$ GeV, either the single or double lepton triggers may be used to accept the event at the HL-LHC. Events with SFOS lepton pairs with an invariant mass within 30 GeV of the Z boson mass are rejected to suppress the large $Z \to \ell\ell$ SM background. Events with $E_{\mathrm{T}}^{\mathrm{miss}}$ larger than 110 GeV and $E_{\mathrm{T}}^{\mathrm{miss}}$ significance (defined as $E_{\mathrm{T}}^{\mathrm{miss}}/\sqrt{\sum \vec{p}_{\mathrm{T}}^{\,\mathrm{leptons,\,jets}}}$) larger than $10\ \mathrm{GeV}^{1/2}$ are selected in to suppress Z+jets events with poorly measured leptons.

The stransverse mass m_{T2} is calculated using the two leptons and $E_{\mathrm{T}}^{\mathrm{miss}}$, and used as the main discriminator in the SR selection to suppress the SM background. For $t\bar{t}$ or WW decays, assuming an ideal detector with perfect momentum resolution, $m_{\mathrm{T2}}(\ell, \ell, E_{\mathrm{T}}^{\mathrm{miss}})$ has a kinematic endpoint at the mass of the W boson. Signal models with sufficient mass splittings between the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$ feature m_{T2} distributions that extend beyond this kinematic endpoint expected for the dominant SM backgrounds. Therefore, events in this search are required to have high m_{T2} values. A set of disjoint signal regions "binned" in m_{T2} are used to maximise model-dependent exclusion sensitivity. Each SR is identified by the lepton flavour combination (SFOS or DFOS), number of jets (-0J or -1J) and the range of the m_{T2} interval. Ten high m_{T2} intervals: $[120, 140]$, $[140, 160]$, $[160, 180]$, $[180, 200]$, $[200, 250]$, $[250, 300]$, $[300, 350]$, $[350, 400]$, $[400, 500]$ and $[500, \infty]$, are used to maximise the sensitivity to $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production. After the application of the full selection criteria, no Z+jets or W+jets events remain. The diboson process WW is seen to dominate the total SM background across all signal regions, due to its similarity with the SUSY signal. The stransverse mass m_{T2} of SM and SUSY events in the signal regions is shown

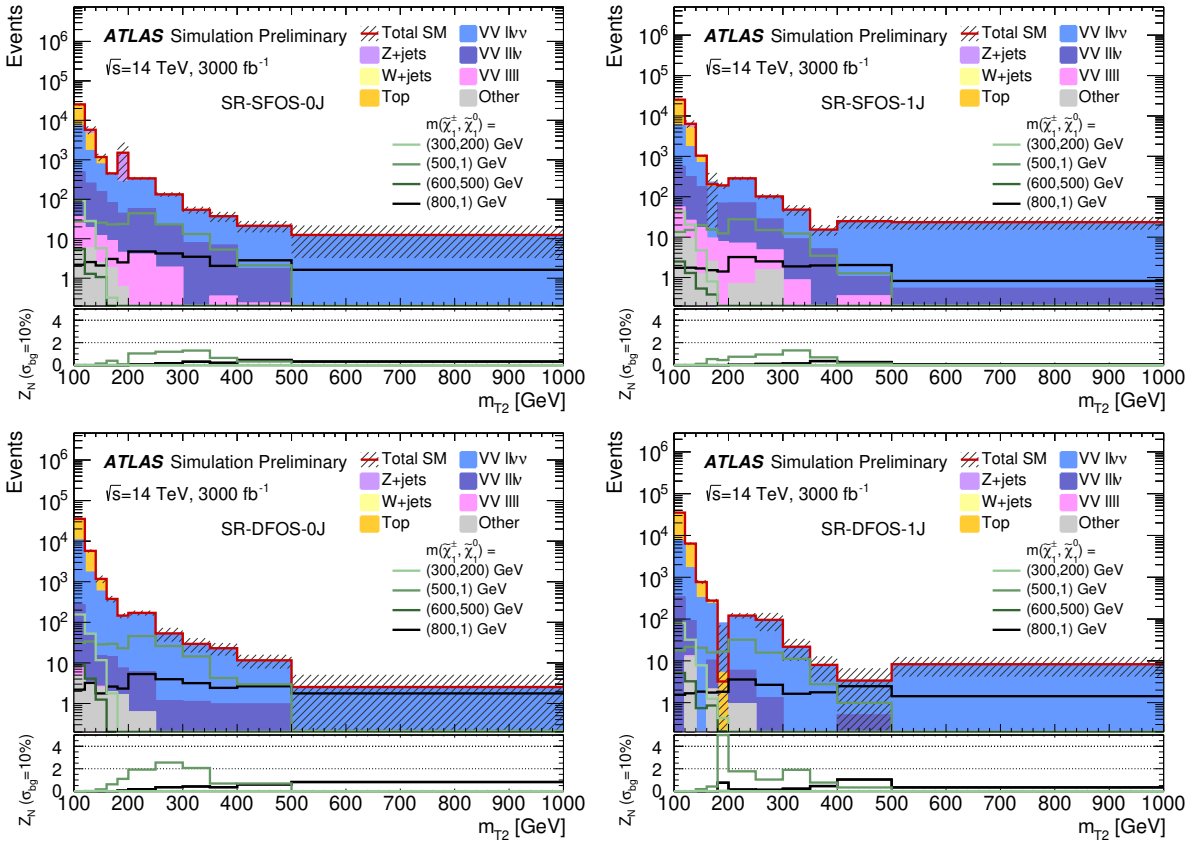

Fig. 2.2.1: Expected number of events from SM and SUSY processes in the signal regions optimised for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production, for the HL-LHC. Uncertainties shown are the MC statistical uncertainties only. The lower pad in each plot shows the significance, Z_N using a background uncertainty of 10%, for a selection of SUSY scenarios in each m_{T2} interval.

in Fig. 2.2.1, for events passing $m_{\mathrm{T2}} > 100$ GeV. The SM background drops off at lower m_{T2} values (around the W mass), while the SUSY signal is seen to have long tails to high m_{T2} values. The 2ℓ diboson SM processes show long m_{T2} tails, which is mostly from $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ production; a small contribution from WW will be present due to the imperfect measurement of the leptons and $E_{\mathrm{T}}^{\mathrm{miss}}$.

To calculate the expected sensitivity to $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production and decay via W bosons, the uncertainties from the normalisation of the WW background are assumed to scale inversely with the increase in luminosity, and thus decrease to $\sim 1\%$, while a better understanding of WW could halve the theoretical uncertainties to $\sim 2.5 - 5\%$. It is assumed that the experimental uncertainties will be understood to the same level, or better, than the 13 TeV analysis [86]. Two scenarios are considered for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production and decay via W bosons at the HL-LHC: the so-called Run-2 scenario, with 5% experimental uncertainty on the signal and SM background, a 10% theoretical uncertainty on the signal, and a 10% modelling uncertainty on the SM background, and the so-called baseline scenario, where the WW theoretical uncertainty can be understood to a better level and modelling uncertainty on SM background halves to 5%.

The statistical combination of all disjoint signal regions is used to set model-dependent exclusion limits. For each of the three uncertainties considered, half of the value is treated as correlated across signal regions, and the other half as uncorrelated. The exclusion potentials for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production and decay via W bosons at the HL-LHC are shown in Fig. 2.2.2 for the baseline scenario. In the absence of an excess, $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production may be excluded up to 840 GeV in $\tilde{\chi}_1^\pm$ mass. For the Run-2, where the modelling uncertainty on the SM background are raised from 5% to 10%, the expected exclusion

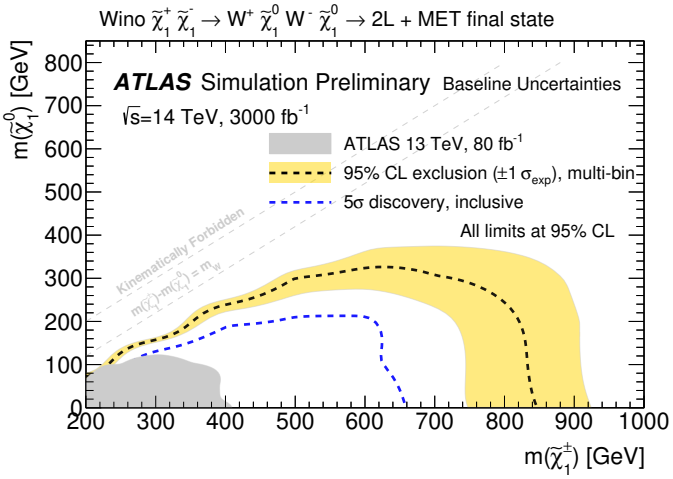

Fig. 2.2.2: The 95% C.L. exclusion and discovery potential for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production at the HL-LHC ($3\,\mathrm{ab}^{-1}$at $\sqrt{s} = 14$ TeV), assuming $\tilde{\chi}_1^\pm \rightarrow W\tilde{\chi}_1^0$ with a BR of 100%, for an uncertainty on the modelling of the SM background of 5% (baseline uncertainty). The observed limits from the analyses of 13 TeV data [86] are also shown.

Table 2.2.1: Signal regions for the chargino/next-to-lightest neutralino production analysis.

potential decreases by 10 GeV in $\tilde{\chi}_1^\pm$ mass and 30 GeV in $\tilde{\chi}_1^0$ mass. To calculate the discovery potential, eleven inclusive signal regions are defined with m_{T2} larger than the lower bound of each m_{T2} interval, and the inclusive signal region with the best expected sensitivity is used. At the HL-LHC, the discovery potential reaches up to 660 GeV in $\tilde{\chi}_1^\pm$ mass with the baseline scenario assumption for the background modelling uncertainty, and it decreases by 30 GeV in $\tilde{\chi}_1^\pm$ mass and 60 GeV in $\tilde{\chi}_1^0$ mass if uncertainties doubled.

2.2.2 Chargino-Neutralino searches in multileptons at HL-LHC

Contributors: A. De Santo, B. Safarzadeh Samani, F. Trovato, ATLAS

Charginos and next-to-lightest neutralinos decaying via W and Z or Higgs bosons and LSP are searched for using three-lepton signatures characterised by large missing transverse momentum [84]. A simplified model describing the direct production of $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ is studied here, where the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ are as-

sumed to be pure wino and equal mass, while the $\tilde{\chi}_1^0$ is the LSP and is assumed to be pure bino and stable. The selection for $\tilde{\chi}_1^\pm\tilde{\chi}_2^0 \to W\tilde{\chi}_1^0 Z\tilde{\chi}_1^0$ at the HL-LHC follows the strategy used in the 13 TeV search [87]. Events are selected with exactly three leptons (electrons or muons) with $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.5$, two of which must form an SFOS pair consistent with a Z boson decay and have $|m_{\ell\ell} - m_Z| < 10$ GeV. To resolve ambiguities when multiple SFOS pairings are present, the transverse mass m_{T} is calculated using the unpaired lepton for each possible SFOS pairing, and the combination that minimises the transverse mass, $m_{\mathrm{T}}^{\mathrm{min}}$, is chosen. The two leading leptons must have $p_{\mathrm{T}} > 25$ GeV, and $m_{\ell\ell\ell}$ must be larger than 20 GeV to reject low mass SM decays. To suppress the $t\bar{t}$ background, events are vetoed if they contain b-tagged jets with $p_{\mathrm{T}} > 30$ GeV, while the Z+jets background is suppressed by requiring $E_{\mathrm{T}}^{\mathrm{miss}} > 50$ GeV.

A set of disjoint signal regions binned in $m_{\mathrm{T}}^{\mathrm{min}}$ and $E_{\mathrm{T}}^{\mathrm{miss}}$ are used to maximise model-dependent exclusion sensitivity. Each SR is identified by the number of jets (-0J or -1J), the range of the $E_{\mathrm{T}}^{\mathrm{miss}}$ interval and the range of the $m_{\mathrm{T}}^{\mathrm{min}}$ interval, as seen in Table 2.2.1. The SRs with at least one jet are defined to extend the sensitivity for the signal benchmark points in which the mass differences between the $\tilde{\chi}_1^+$ and $\tilde{\chi}_1^0$ is small. In such scenarios higher $E_{\mathrm{T}}^{\mathrm{miss}}$in the event is expected when the $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ system recoils against the initial-state-radiation jets. The distribution of $E_{\mathrm{T}}^{\mathrm{miss}}$ and $m_{\mathrm{T}}^{\mathrm{min}}$ in the 0-jet and 1-jet categories are shown in Fig. 2.2.3 for events with $E_{\mathrm{T}}^{\mathrm{miss}} > 150$ GeV and $m_{\mathrm{T}}^{\mathrm{min}} > 150$ GeV.

To calculate the expected sensitivity to $(\tilde{\chi}_1^\pm/\tilde{\chi}_2^0)$ production, a 5% experimental uncertainty on the SM background and signal, a 10% theoretical uncertainty on the signal, and a 10% modelling uncertainty on the SM are assumed. With these uncertainty assumptions, Fig. 2.2.4 shows the expected exclusion for $\tilde{\chi}_1^\pm\tilde{\chi}_2^0 \to W\tilde{\chi}_1^0 Z\tilde{\chi}_1^0$. In the absence of an excess, chargino and neutralino masses up to 1150 GeV may be excluded. The discovery potential is also shown in Fig. 2.2.4, which reaches up to 920 GeV in chargino and neutralino masses.

2.2.3 *Chargino-Neutralino production in the $Wh \to \ell\nu\, b\bar{b}$ channel at HL-LHC*

Contributors: D. Bogavac, M. D'Onofrio, Y. Gao, M. Sullivan, H. Teagle, ATLAS

Chargino and next-to-lightest neutralinos can be searched for in one lepton plus b-jets final state events if the next-to-lightest neutralino decays into a SM-like Higgs boson and the LSP [84]. The Higgs decay mode into two b-quarks is exploited. Signal models with $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ masses up to 1.5 TeV are considered in this search. The analysis is performed separately in three signal regions targeting signal models with different values of mass difference $\Delta m = m(\tilde{\chi}_1^\pm/\tilde{\chi}_2^0) - m(\tilde{\chi}_1^0)$: low ($\Delta m < 300$ GeV), medium ($\Delta m \in [300, 600]$ GeV) and high ($\Delta m > 600$ GeV).

The expected SM background is dominated by top quark pair-production $t\bar{t}$ and single top production, with smaller contributions from vector boson production W+jets, associated production of $t\bar{t}$ and a vector boson $t\bar{t}V$ and dibosons.

The event selection follows a similar strategy as in the previous studies documented in Ref. [88]. Candidate leptons (electrons or muons) are required to have $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.47$ (2.7), and pass "tight" and "medium" identification criteria for electrons and muons respectively. Candidate jets are reconstructed using the anti-k_t algorithm with $R = 0.4$, are required to have p_{T} greater than 25 GeV and $|\eta| < 2.5$. The jets tagged as originating from b-decays are required to pass the jet requirements described previously, and pass the MV2c10 tagging algorithm operating at 77% b-jet tagging efficiency. Candidate jets and electrons are required to satisfy $\Delta R(e, \text{jet}) > 0.2$. Any leptons within $\Delta R = 0.4$ of the remaining jet are removed. The $E_{\mathrm{T}}^{\mathrm{miss}}$ at generator level is calculated as the vectorial sum of the momenta of neutral weakly-interacting particles, in this case neutrinos and neutralinos.

Events containing exactly one lepton, and two or three jets passing the above object definitions are selected. Two of the jets are required to be b-tagged with the criteria defined above. Four key variables are further used to discriminate signal from background: the invariant mass of the two b-tagged jets, m_{bb}, the transverse momentum imbalance in the event, $E_{\mathrm{T}}^{\mathrm{miss}}$, the transverse mass constructed using the leading

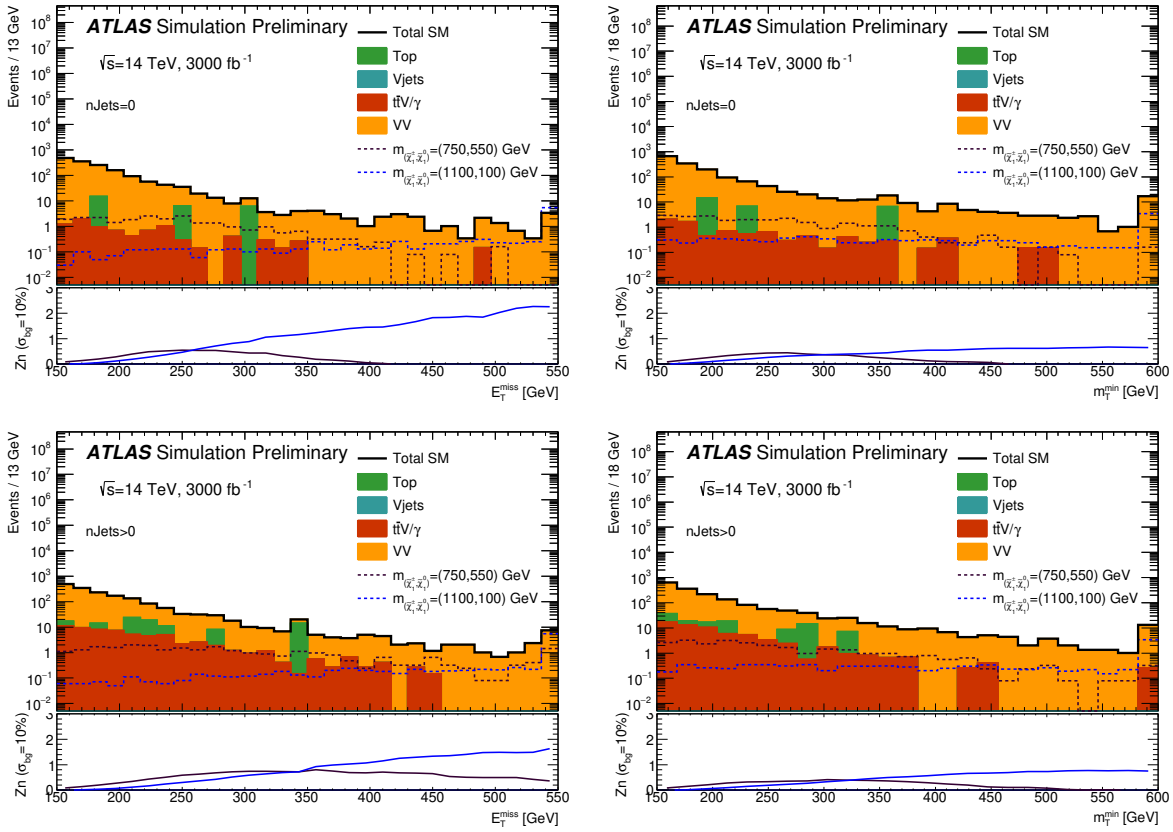

Fig. 2.2.3: Distribution of $E_{\mathrm{T}}^{\mathrm{miss}}$ and $m_{\mathrm{T}}^{\mathrm{min}}$ in the events with zero jets (top) and the events with at least one jet (bottom). All baseline requirements along with the $E_{\mathrm{T}}^{\mathrm{miss}}$ and $m_{\mathrm{T}}^{\mathrm{min}}$ selections of 150 GeV are applied. The lower pad in each plot shows the significance, Z_N using a background uncertainty of 10%, for the SUSY reference points.

lepton p_{T} and the $E_{\mathrm{T}}^{\mathrm{miss}}$, m_{T}, and the contransverse mass constructed using the two b-tagged jets, m_{CT}. The m_{bb} is used to select events which have dijet masses within a window of the Higgs boson mass. The transverse mass variable m_{T}, defined from the $E_{\mathrm{T}}^{\mathrm{miss}}$ and the leading lepton in the event, is effective at suppressing SM backgrounds containing W bosons due to the expected kinematic endpoint around the W boson mass assuming an ideal detector with perfect momentum resolution. The contransverse mass variable m_{CT} is defined for the $b\bar{b}$ system as $m_{\mathrm{CT}} = 2p_{\mathrm{T}}^{b_1}p_{\mathrm{T}}^{b_2}(1+\cos\Delta\phi_{bb})$, where $p_{\mathrm{T}}^{b_1}$ and $p_{\mathrm{T}}^{b_2}$ are transverse momenta of the two leading $b-$jets and $\Delta\phi_{bb}$ is the azimuthal angle between them. It is an effective variable to select Higgs boson decays into $b-$quarks and to suppress the $t\bar{t}$ backgrounds.

A set of common loose requirements, referred to as preselection, are applied first to suppress the fully hadronic multijet and W+jets backgrounds: $m_{\mathrm{T}} > 40$ GeV, $m_{bb} > 50$ GeV, $E_{\mathrm{T}}^{\mathrm{miss}} > 200$ GeV. A multivariate method based on boosted decision trees (BDT) is then chosen for the optimal sensitivity. In this approach, three independent BDTs (referred to as M1, M2 and M3), are trained separately in each signal region for events passing the preselection and within the m_{bb} mass window of $[105, 135]$ GeV. In all regions, the following seven variables are used as inputs: $E_{\mathrm{T}}^{\mathrm{miss}}$, m_{T}, m_{CT}, the leading lepton p_{T}, the leading and sub-leading b-jet p_{T}, as well as the angular separation of the two b-jets $\Delta R(b_1, b_2)$. The BDT output distributions are then used to optimise signal regions maximising the expected significance Z_N of the benchmark signal model. Examples of the BDT output distributions are shown in Fig. 2.2.5. The resulting signal region regions targeting models with low (SR-M1), medium (SR-M3) and high (SR-M3) Δm, are defined by requiring the BDT ranged larger than 0.25, 0.35 and 0.30, respectively.

The SM background is dominated by the top backgrounds, including both the $t\bar{t}$ and single top

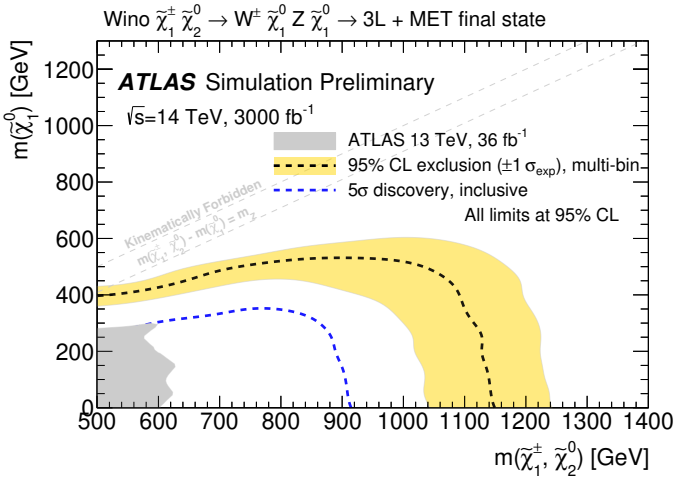

Fig. 2.2.4: Expected exclusion limit and discovery potential on SUSY simplified models for $(\tilde{\chi}_1^\pm/\tilde{\chi}_2^0)$ production with decays via W/Z bosons, assuming 15% uncertainty on the modelling of the SM backgrounds.

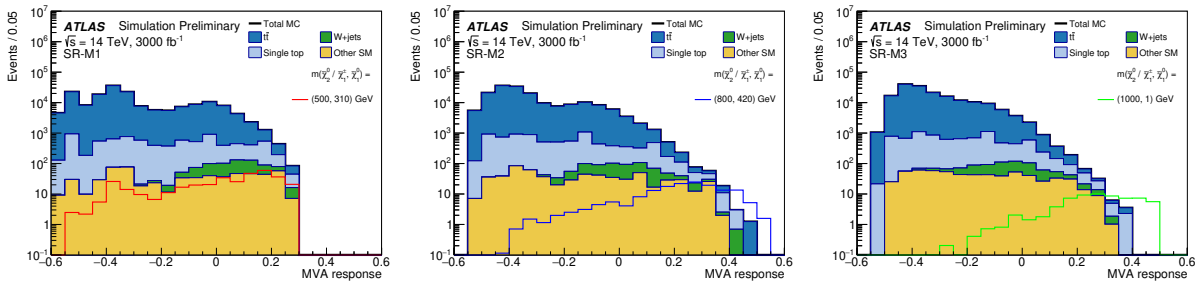

Fig. 2.2.5: Distributions of the BDT responses in the three signal regions for the events that pass the preselection and are within m_{bb} mass window of $[105, 135]$ GeV. The contributions from all SM background are shown as stacked, and the expected distribution from the benchmark signal models are overlaid.

processes. The largest systematic uncertainties arise from the theoretical modelling of the irreducible backgrounds of $t\bar{t}$ and single top, mainly from the generator difference, renormalisation and factorisation scale variations and the interference between the $t\bar{t}$ and single top background. The total theoretical uncertainty is estimated to be about 7%. Experimental uncertainties are dominated by the jet energy scale (JES) and jet energy resolution (JER), on the order of 6%. Figure 2.2.6 shows the expected 95% C.L. exclusion and 5σ discovery contours for the simplified models described earlier. In this model, masses of $\tilde{\chi}_1^\pm/\tilde{\chi}_2^0$ up to about 1280 GeV are excluded at 95% C.L. for a massless $\tilde{\chi}_1^0$. The discovery potential at 5σ can be extended up to 1080 GeV for a massless $\tilde{\chi}_1^0$.

2.2.4 Chargino-Neutralino searches with same-charge dilepton final states at HL-LHC

Contributors: G. Zevi Della Porta, A. Canepa, CMS

This section presents a search from CMS for the pair production of $\widetilde{\chi}_2^\pm$, $\widetilde{\chi}_4^0$ in the final states with two same charge leptons, large $E_{\mathrm{T}}^{\mathrm{miss}}$ and modest jet activity. The search is motivated by radiatively-driven natural supersymmetry (RNS) models, such as those presented in Section 2.4.2. In these models, the mass spectra of the supersymmetric partners of the gauge and Higgs bosons are characterised by low-mass higgsino-like $\widetilde{\chi}_1^0$, $\widetilde{\chi}_2^0$, $\widetilde{\chi}_1^\pm$, and heavier bino-like $\widetilde{\chi}_3^0$ along with mass-degenerate wino-like $\widetilde{\chi}_2^\pm$, $\widetilde{\chi}_4^0$. Two complementary analyses are designed to probe the wino and higgsino sectors of this model. The final states resulting from higgsino production, discussed in Section 2.2.5.1, are characterised by very low p_T SM particles, due to the small mass difference between the low mass states and the $\widetilde{\chi}_1^0$. The

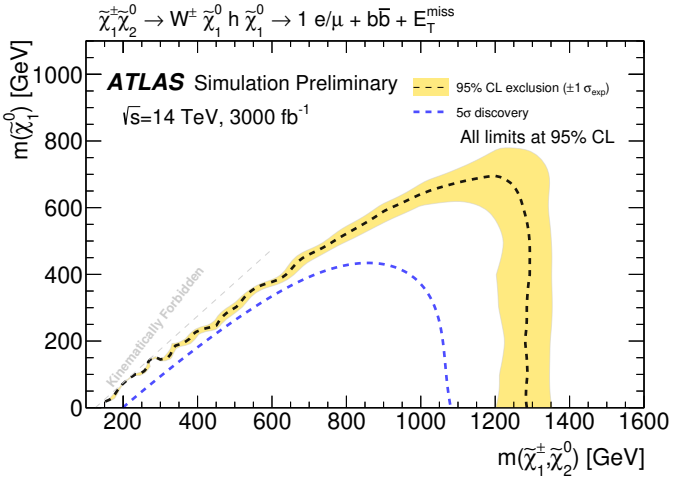

Fig. 2.2.6: Expected 95% C.L. exclusion and 5σ discovery contours in the $m(\tilde{\chi}_1^0), m(\tilde{\chi}_1^{\pm}/\tilde{\chi}_2^0)$ masses plane for the Wh-mediated simplified model.

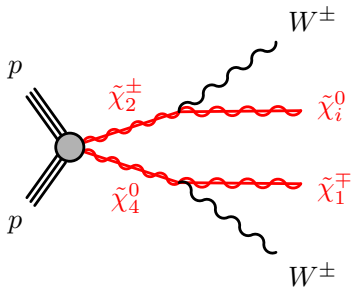

Fig. 2.2.7: Diagram for wino-like $\tilde{\chi}_2^{\pm}\tilde{\chi}_4^0$ pair-production and decay into a final state with two same charge W bosons.

final states resulting from wino production, discussed in this section, are expected to have a significant contribution of events (around 25% of the total BR) where $\tilde{\chi}_2^{\pm}\tilde{\chi}_4^0$ decay into the higgsino sector emitting same-charge W bosons as in Fig. 2.2.7 [89, 90]. This analysis is based on Ref. [91].

Estimates of signal and background yields are based on Monte Carlo samples followed by a DELPHES simulation [33] of the CMS Phase-2 detector. The signal samples are generated by MADGRAPH5_aMC@NLO (v2.3.3) [67] with up to two additional jets at leading order precision. The supersymmetric particles are then decayed by the PYTHIA 8.2 [68] package also providing showering and hadronisation. The cross-sections for SUSY production have been calculated for $\sqrt{s} = 14$ TeV at NLO-NLL using the resumming code from Ref. [59, 60] with CTEQ6.6 and MSTW2008nlo90cl PDFs. The background samples are generated with MADGRAPH 5 at LO, followed by parton showering and hadronisation with PYTHIA 6 [92]. The DELPHES-based yields of processes containing prompt leptons are corrected by the lepton reconstruction, identification and isolation efficiencies measured in Run-2 collision data. For example, the reconstruction efficiency for centrally produced electrons ranges from 60 to 86% for p_T values between 20 and 200 GeV. The DELPHES-based yields of processes containing non-prompt leptons are increased by 25%, based on Ref. [93], to account for events with misidentified leptons from light flavour quarks, which are not included by DELPHES [93].

Candidate signal events are selected if they contain two high quality and isolated leptons with $p_T \geq 20$ GeV, $|\eta| \leq 1.6$, and the same charge. Discrimination from the background processes is achieved by selecting events with no additional leptons with $p_T \geq 5$ GeV and $|\eta| \leq 4.0$ (to suppress multi-boson production), and no $p_T \geq 30$ GeV jets (to suppress events with top quarks). The remaining

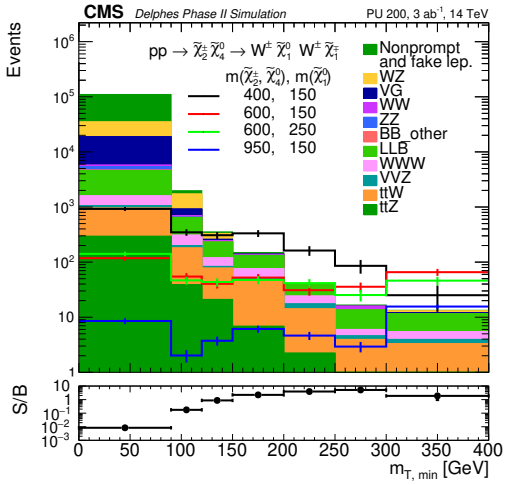

Fig. 2.2.8: Distribution of $m_{\mathrm{T,min}}$ in candidate events satisfying the signal region selection. For coloured lines displaying the signal yields, the first number in the legend refers to the $\widetilde{\chi}_2^{\pm}\widetilde{\chi}_4^0$ mass while the second number refers to the value of the $\widetilde{\chi}_1^0$ mass.

background processes include the pair production of W and Z/Z* bosons, as well as the W+jets and $t\bar{t}$ processes in association with a non-prompt or misidentified lepton. These are suppressed by imposing a tight selection on the $m_{\mathrm{T,min}}$ based on $E_{\mathrm{T}}^{\mathrm{miss}}$ and the p_T of the leptons and defined as

$$m_{T,min} = \min[m_T(p_T^{lep1}, E_{\mathrm{T}}^{\mathrm{miss}}), m_T(p_T^{lep2}, E_{\mathrm{T}}^{\mathrm{miss}})]. \tag{2.2.1}$$

Figure 2.2.8 shows the distribution of the $m_{\mathrm{T,min}}$ observable in events satisfying the signal region selection described above. To maximise the sensitivity, seven signal regions are then defined with $m_{\mathrm{T,min}}$ in the ranges $[0, 90)$, $[90, 120)$, $[120, 150)$, $[150; 200)$, $[200; 250)$, $[250; 300)$, and $[300; \infty)$ GeV.

The search sensitivity is calculated using a modified frequentist approach with the $\mathrm{CL_S}$ criterion and asymptotic results for the test statistic [94, 95]. The systematic uncertainty on the prompt (fake, signal) yields is assumed to be 20% (50%, 20%) based on the estimates computed in the corresponding search carried out in Run-2 collision data [93].

The upper limit on the production cross-section of pair produced $\widetilde{\chi}_2^{\pm}\widetilde{\chi}_4^0$ decaying into a final state with two same charge W bosons with a BR of 25% is shown in Fig. 2.2.9 for two μ scenarios (where $\mu \sim m_{\widetilde{\chi}_1^{\pm}}, m_{\widetilde{\chi}_2^0}, m_{\widetilde{\chi}_1^0}$). The value $\widetilde{\chi}_1^0 = 150$ GeV is representative of the region of parameter space outside the reach of the Run-2 search for direct production of higgsinos in the final states with two same flavour opposite sign leptons [96], while $\widetilde{\chi}_1^0 = 250$ GeV is close to the sensitivity reach of the same search when extrapolated to the HL-LHC (Section 2.2.5.1). As expected, the sensitivity depends only mildly on the value of $\widetilde{\chi}_1^0$ at large $\widetilde{\chi}_2^{\pm}\widetilde{\chi}_4^0$ mass values, while as the $\widetilde{\chi}_2^{\pm}\widetilde{\chi}_4^0$ mass approaches $\widetilde{\chi}_1^0$ the dependence is more significant. Wino-like mass degenerate $\widetilde{\chi}_2^{\pm}\widetilde{\chi}_4^0$ are excluded at 95% C.L. for masses up to 900 GeV in both the $\widetilde{\chi}_1^0 = 150$ GeV and 250 GeV scenarios. This demonstrates that the HL-LHC has the potential to probe most of the natural SUSY parameter space with EW naturalness measure $\Delta_{\mathrm{EW}} \leq 30$ [97].

2.2.5 Searches for SUSY models with compressed electroweakino mass spectra

In several SUSY scenarios, higgsinos could be light, with masses below 1 TeV, and the absolute value of the higgsino mass parameter μ is expected to be near the weak scale, while the magnitude of the bino and wino mass parameters, M_1 and M_2 can be significantly larger, *i.e.* $|\mu| \ll |M_1|, |M_2|$. This results in the three lightest electroweakino states being dominated by the higgsino component. In this scenario, their masses are separated by hundreds of MeV to tens of GeV depending on the composition of these

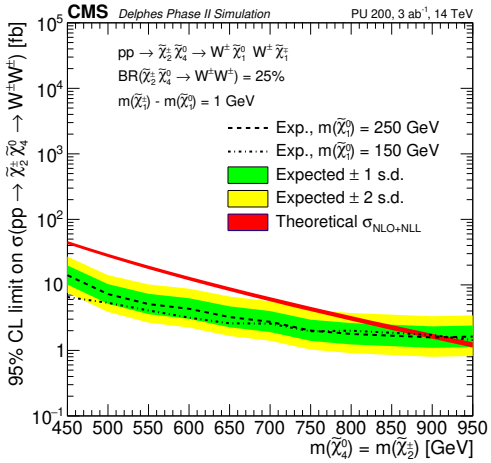

Fig. 2.2.9: Upper limit on the production cross-section of pair produced $\tilde{\chi}_2^{\pm}\tilde{\chi}_4^0$ decaying into a final state with two same charge W boson with a BR of 25% for two assumptions on the $\tilde{\chi}_1^0$ mass.

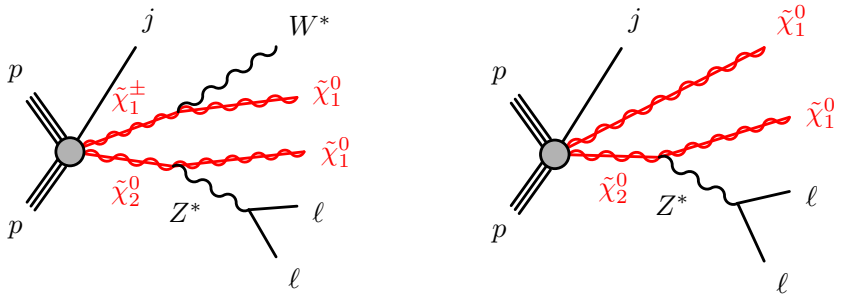

Fig. 2.2.10: Example Feynman diagrams for $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ (left) and $\tilde{\chi}_2^0\tilde{\chi}_1^0$ (right) s-channel pair production, followed by the leptonic decay of the $\tilde{\chi}_2^0$.

mass eigenstates, which is determined by the specific values of M_1 and M_2. Investigating either of these scenarios, with very small mass splitting between the lightest electroweakinos, is particularly challenging at hadron colliders, both due to the small cross-sections and the small transverse momenta of the final state particles. As of writing the ATLAS and CMS collaborations have searched for higgsinos in up to $36\ \mathrm{fb}^{-1}$ of proton-proton collision data [96, 98] and just started probing the parameter space beyond the LEP experiments' limits [99, 100]. By providing $3\ \mathrm{ab}^{-1}$of proton-proton collision data at a c.o.m. energy of $14\ \mathrm{TeV}$, the HL-LHC has the potential to significantly extend the sensitivity to higgsinos and thus to natural SUSY. This is depicted also in Section 2.4.2 of this report.

The model used for the development of the searches for higgsino-like $\tilde{\chi}_i^{\pm}$ and $\tilde{\chi}_j^0$ by ATLAS and CMS is a SUSY simplified model where the higgsino-like $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_2^0$ are assumed to be quasi mass-degenerate and produced in pairs. The model contains both the $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ and the $\tilde{\chi}_2^0\tilde{\chi}_1^0$ production, where $\tilde{\chi}_1^{\pm}$ decays into $\mathrm{W}^*\tilde{\chi}_1^0$ and $\tilde{\chi}_2^0$ into $\mathrm{Z}^*\tilde{\chi}_1^0$, respectively, with a branching fraction of 100% (Fig. 2.2.10).

Both ATLAS and CMS analyses presented in the following exploit the presence of charged leptons with low transverse momenta arising from the off-shell W and Z bosons in the $\tilde{\chi}_1^{\pm} \rightarrow W^*\tilde{\chi}_1^0$ and $\tilde{\chi}_2^0 \rightarrow Z^*\tilde{\chi}_1^0$ decays, and large missing transverse momentum due to the presence of an ISR jet.

2.2.5.1 Higgsino search prospects at HL- and HE-LHC at CMS

Contributors: A. Canepa, J. Hogan, S. Kulkarni, B. Schneider, CMS

The results presented here are from Ref. [101] from the CMS Collaboration. If the $\tilde{\chi}_1^{\pm}$, $\tilde{\chi}_2^0$, and

Observable	Requirement
N_ℓ	$= 2$ (same flavour, opposite charge)
$\Delta R(\ell_1\ell_2)$	≤ 2.0
$N_{\text{b-jet}}$	$= 0$
N_{jet}	≤ 4
N_{ISR}	≥ 1
$\mathbf{p}_{\text{T}}^{\text{miss}}$	≥ 250 GeV
$\Delta\phi(\mathbf{p}_{\text{T}}^{\text{miss}}, p_{\text{T}}(j_{\text{ISR}}))$	≥ 2.0
m_{ℓ_1,ℓ_2}	[5,40] GeV

Table 2.2.2: Definition of the baseline signal region. In the table, N_ℓ is the number of candidate leptons; $\Delta R(\ell_1, \ell_2)$ is the angular separation between the two candidate leptons in the ϕ, η space; $N_{\text{b-jet}}$ is the number of b jets; N_{jet} is the number of candidate jets (including any ISR jet reconstructed in the event); N_{ISR} is the number of ISR jets; $\Delta\phi(\mathbf{p}_{\text{T}}^{\text{miss}}, p_{\text{T}}(j_{\text{ISR}}))$ is the azimuthal distance between the $\mathbf{p}_{\text{T}}^{\text{miss}}$ vector and the j_{ISR} p_T vector; and m_{ℓ_1,ℓ_2} is the invariant mass of the two candidate leptons.

$\widetilde{\chi}_1^0$ are higgsino-like, the mass splitting is just driven by radiative corrections and acquires values up to a few GeV. As a result, pair-produced $\widetilde{\chi}_1^\pm\widetilde{\chi}_2^0$ or pair-produced $\widetilde{\chi}_2^0\widetilde{\chi}_1^0$ can decay promptly into $\widetilde{\chi}_1^0$ only via off-shell W and Z bosons, leading to events with low transverse momentum (p_T) SM particles. In leptonic decays of the Z boson, the events will contain one same-flavour, opposite-charge lepton pair, the invariant mass of which has a kinematic endpoint at $\Delta M(\widetilde{\chi}_2^0, \widetilde{\chi}_1^0) = m(\widetilde{\chi}_2^0) - m(\widetilde{\chi}_1^0)$. Sensitivity to the signal is achieved by requiring at least one jet from initial-state radiation (ISR) that recoils against the two $\widetilde{\chi}_1^0$ and produces significant missing transverse momentum ($\mathbf{p}_{\text{T}}^{\text{miss}}$) in the event.

In the analysis muons (electrons) are selected with $5 \leq p_T \leq 30$ GeV and $|\eta| \leq 2.4\,(1.6)$. Dedicated lepton identification criteria are then applied, providing 40% to 90% efficiency for muons and 20% to 80% efficiency for electrons. Finally, identified leptons are considered candidate leptons if they are isolated. The anti-k_t algorithm with a size parameter of 0.4 is adopted to reconstruct jets. Candidate jets are reconstructed jets with $p_T > 40$ GeV and $|\eta| \leq 4.0$ and are referred to as ISR jets if $p_T > 200$ GeV and $|\eta| \leq 2.4$ (j_{ISR}). Candidate jets consistent with the decay and hadronisation of a B hadron are tagged as b jets with an efficiency of 74%. Spacial separation is imposed between each candidate lepton and jet.

To be considered for this analysis, events are requested to contain at least two low-p_T, same-flavour, opposite-charge candidate leptons, $\mathbf{p}_{\text{T}}^{\text{miss}} \geq 250$ GeV 3and at least one j_{ISR}. To further exploit the boosted topology of the signal, events are accepted only if the $\mathbf{p}_{\text{T}}^{\text{miss}}$ and the ISR candidate jet p_T satisfy $\Delta\phi(\mathbf{p}_{\text{T}}^{\text{miss}}, p_{\text{T}}(j_{\text{ISR}})) \geq 2.0$ and the angular separation between the two candidate leptons satisfies $\Delta R(\ell_1\ell_2) \leq 2.0$. Since minor hadronic activity is expected from the EW production of $\widetilde{\chi}_1^\pm$ and $\widetilde{\chi}_2^0$, an upper bound of 4 is placed on the number of candidate jets N_{jet}.

Several SM processes exhibit a signature similar to that of the signal. One background category consists of prompt processes, where both candidate leptons originate from the prompt decay of W and Z bosons. Another category is misclassified processes, where at least one of the two candidate leptons originates from a semi-leptonic decay of a B hadron, a photon conversion, a decay in flight, or a misidentified quark or gluon. The prompt background is dominated by Drell-Yan (DY), diboson, and $t\bar{t}$ production where both W bosons decay leptonically. The DY contribution is suppressed by requiring significant $\mathbf{p}_{\text{T}}^{\text{miss}}$, while rejecting events with at least one b jet reduces the $t\bar{t}$ background. The dominant misclassified processes are W and $t\bar{t}$ production where one candidate lepton originates from the W boson decay and an additional misclassified lepton is selected in the event. Rejecting events with at least one b jet reduces both contributions. Events satisfying the criteria described above, which are summarised in Table 2.2.2, form the baseline signal region for which relevant distributions are presented in Fig. 2.2.11 and 2.2.12.

The missing transverse momentum, the invariant mass of the two candidate leptons, and the sub-leading lepton $p_{\text{T}}(\ell_2)$ observables are found to provide the best discrimination between signal and

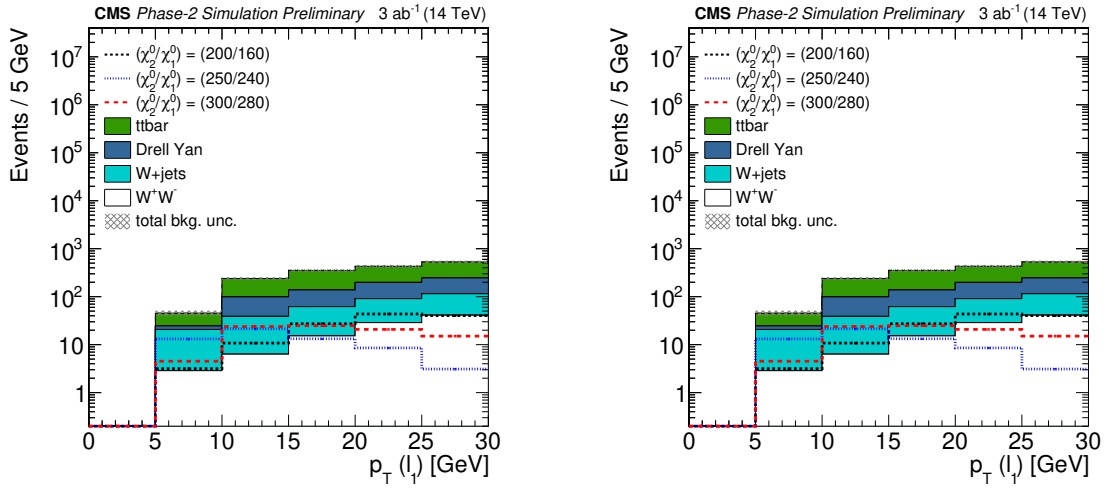

Fig. 2.2.11: Distributions of the p_T of the candidate lepton with the highest p_T (left) and the second-highest p_T (right) for background and signal events in the baseline signal region. Three selected $\widetilde{\chi}_1^{\pm}\widetilde{\chi}_2^0 + \widetilde{\chi}_2^0\widetilde{\chi}_1^0$ signal models are shown, where the first number corresponds to the mass of the $\widetilde{\chi}_2^0$ (and $\widetilde{\chi}_1^{\pm}$) and the second one to the mass of the $\widetilde{\chi}_1^0$. The uncertainty band represents systematical uncertainties.

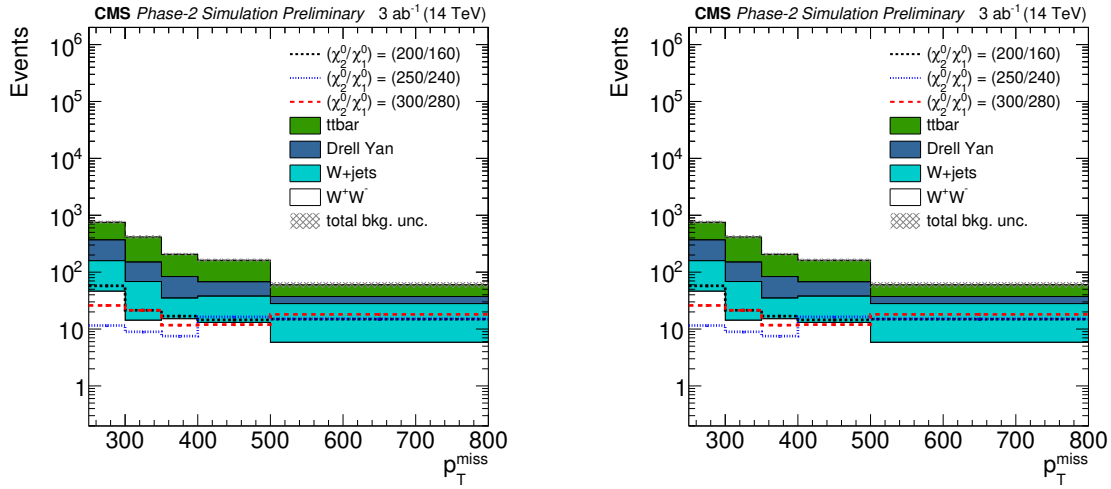

Fig. 2.2.12: Distributions of the $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ (left) and m_{ℓ_1,ℓ_2} (right) for background and signal events in the baseline signal region. Three selected $\widetilde{\chi}_1^{\pm}\widetilde{\chi}_2^0 + \widetilde{\chi}_2^0\widetilde{\chi}_1^0$ signal models are shown, where the first number corresponds to the mass of $\widetilde{\chi}_2^0$ (and $\widetilde{\chi}_1^{\pm}$) and the second one to the mass of $\widetilde{\chi}_1^0$. The uncertainty band represents systematical uncertainties.

background. Events in the baseline signal region are therefore classified in 60 categories with $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ values in $[250, 300, 350, 400, 500, \infty]$ GeV, m_{ℓ_1,ℓ_2} values in $[5, 10, 20, 30, 40]$ GeV, and $p_{\mathrm{T}}(\ell_2)$ in $[5, 13, 21, 30]$ GeV.

Several systematic uncertainties affect the yields of both the background and the signal processes. The dominant experimental uncertainties are those originating from the jet energy corrections ($1-2.5\%$), b-tagging efficiency (1%), lepton identification efficiency and isolation (0.5%, 2.5% for muons and electrons, respectively), and integrated luminosity (1%). An additional systematic uncertainty of 30% on the yield of the misclassified background is also assumed based on the estimate in Ref. [96]. It is assumed that the yields are not affected by the statistical uncertainty deriving from the limited number of generated events. Theoretical uncertainties in the signal cross sections and in the acceptance from the choice of parton distribution functions are considered negligible and are not included. However, a systematic

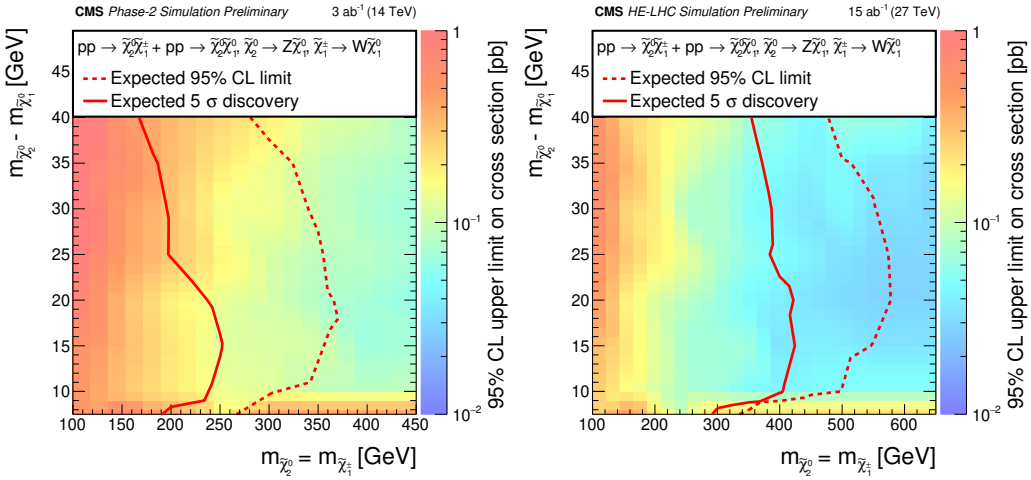

Fig. 2.2.13: 5σ discovery contours and expected 95% C.L. exclusion contours for the combined $\widetilde{\chi}_1^{\pm}\,\widetilde{\chi}_2^0$ and $\widetilde{\chi}_2^0\,\widetilde{\chi}_1^0$ production (left). Projection of the HL-LHC 5σ discovery contours and expected 95% C.L. exclusion contours for the combined $\widetilde{\chi}_1^{\pm}\,\widetilde{\chi}_2^0$ and $\widetilde{\chi}_2^0\,\widetilde{\chi}_1^0$ production for a centre-of-mass energy of 27 TeV and an integrated luminosity of 15 ab^{-1} (HE-LHC). Except for the cross sections and the integrated luminosity, the HL-LHC analysis was not modified (right). Results are presented for $\Delta M(\widetilde{\chi}_2^0, \widetilde{\chi}_1^0) > 7.5$ GeV.

uncertainty of 10% in the signal acceptance, similar to the value from Ref. [96], is included to account for the modelling of the ISR jet.

The upper limit on the cross sections is computed at 95% C.L. and shown in Fig. 2.2.13. Higgsino-like mass-degenerate $\widetilde{\chi}_1^{\pm}$ and $\widetilde{\chi}_2^0$ are excluded for masses up to 360 GeV if the mass difference with respect to the lightest neutralino $\widetilde{\chi}_1^0$ is 15 GeV, extending the sensitivity achieved in Ref. [96] by $\approx$210 GeV. Figure 2.2.13 also shows the 5σ discovery contour, computed using all signal regions without taking the look-elsewhere-effect into account. Under this assumption $\widetilde{\chi}_1^{\pm}$ and $\widetilde{\chi}_2^0$ can be discovered for masses as large as 250 GeV. These results demonstrate that the HL-LHC can significantly improve the sensitivity to natural SUSY.

Figure 2.2.13 also shows the 5σ discovery contours and expected 95% C.L. exclusion contours for the combined $\widetilde{\chi}_1^{\pm}\,\widetilde{\chi}_2^0$ and $\widetilde{\chi}_2^0\,\widetilde{\chi}_1^0$ production for the HE-LHC. The main gain in sensitivity comes from the increased luminosity, since the cross section increase for signal is the same order as that for background. Except for the cross sections and the integrated luminosity, the HL-LHC analysis was not modified for this HE-LHC projection.

2.2.5.2 *Higgsino search prospects at HL-LHC at ATLAS*

Contributors: S. Amoroso, J. K. Anders, F. Meloni, C. Merlassino, B. Petersen, J. A. Sabater Iglesias, M. Saito, R. Sawada, P. Tornambe, M. Weber, ATLAS

The presented dilepton search [102] investigates final states containing two soft muons and a large transverse momentum imbalance, which arise in scenarios where $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^{\pm}$ are produced and decay via an off-shell Z and W boson, as depicted in Fig. 2.2.10. Considering the $Z \to ee$ decay is beyond the scope of this prospect study, but could further improve the sensitivity to these scenarios. Due to the very small mass splitting of the electroweakinos in this scenario, a jet arising from initial-state radiation (ISR) is required, to boost the sparticle system. First constraints surpassing the LEP limits have recently been set by the ATLAS experiment [98], excluding mass splittings down to 2.5 GeV for $m(\tilde{\chi}_1^0) = 100$ GeV.

The search targets scenarios that contain low p_T muons selected with $p_T > 3$ GeV and $|\eta| < 2.5$. Muons that originate from pile up interactions or from heavy flavour decays, referred as fake or non-prompt muons, are rejected by applying an isolation to the muon candidates. The main source of

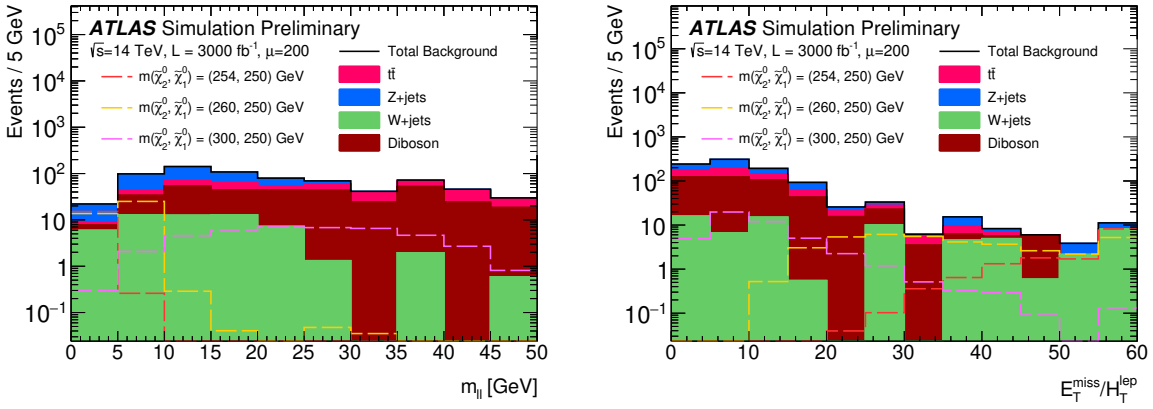

Fig. 2.2.14: Distributions of a selection of kinematic variables used for the SR optimisation in the dilepton search. The variables are presented with the full SR selections implemented aside from the selection on the variable shown. Three signal models with $m(\chi_1^0) = 250$ GeV and different mass splittings ($\Delta m(\chi_2^0, \chi_1^0) = 4,\ 10,$ and 5 GeV) are overlaid.

these fake muons are decays from heavy flavour mesons and baryons created in the quark hadronisation process. The signal region (SR) optimisation is performed by scanning a set of variables which are expected to provide discrimination between the signal scenario under consideration and the expected SM background processes. Only events with two opposite-sign muons are used in the final selection, as the muon reconstruction rate is not expected to fall dramatically and the muon fake rate is not expected to grow largely with increased pile-up. Additional requirements are applied on the leading jet of $p_T(\text{jet}_1) > 100$ GeV, and on the azimuthal separation $\Delta\phi(\text{jet}_1, E_{\text{T}}^{\text{miss}}) > 2.0$. In order to discriminate the signal from SM background processes, kinematic variables are used such as the total number of muons in the event, the total number of jets and b-jets with $p_{\text{T}} > 30$ GeV, the $E_{\text{T}}^{\text{miss}}$, the invariant mass of the dilepton system ($m_{\ell\ell}$), the angular separation between the leptons ($\Delta R(\ell, \ell)$) and more.

Figure 2.2.14 presents a selection of kinematic distributions after the full SR selection is applied, minus the selection on the variable under consideration. The final SR definitions split the $m_{\ell\ell}$ into six non-overlapping SRs, with $m_{\ell\ell}$ selections of $[1, 3]$, $[3.2, 5]$, $[5, 10]$, $[10, 20]$, $[20, 30]$ and $[30, 50]$ GeV.

The leading sources of background in the SR are from $t\bar{t}$, single-top, WW + jets, and $Z/\gamma^*(\to \tau\tau)$ + jets. The dominant source of reducible background arises from processes where one or more leptons are fake or non-prompt, such as in W+jets production. The fake/non-prompt lepton background arises from jets misidentified as leptons, photon conversions, or semileptonic decays of heavy-flavour hadrons. The total uncertainty for the dilepton search is extrapolated to be 30% and are dominated by the modelling of the fake and non-prompt lepton backgrounds, followed by the experimental uncertainties related to the jet energy scale and flavour tagging. The experimental uncertainty is assumed to be fully correlated between the background and the signal.

Figure 2.2.15 shows the 95% C.L. exclusion limits in the $m(\tilde{\chi}_2^0)$, $\Delta m(\tilde{\chi}_2^0, \tilde{\chi}_1^0)$ plane. With $3\ \text{ab}^{-1}$, $\tilde{\chi}_2^0$ masses up to 350 GeV could be excluded, as well as $\Delta m(\tilde{\chi}_2^0, \tilde{\chi}_1^0)$ between 2 and 25 GeV for $m(\tilde{\chi}_2^0) = 100$ GeV. In the figure the blue curve presents the 5σ discovery potential of the search. To calculate the discovery potential a single-bin discovery test is performed by removing the lower bound on $m_{\ell\ell}$ in the SRs previously defined.

2.2.6 Multileptons from resonant electroweakinos in left-right SUSY at HL- and HE-LHC

Contributors: M. Frank, B. Fuks, K. Huitu, S. Mondal, S. Kumar Rai, H. Waltari

Left-right supersymmetric (LRSUSY) models, based on the gauge symmetry $SU(3)_C \times SU(2)_L \times SU(2)_R \times U(1)_{\text{B-L}}$, inherit the attractive features of the left-right (LR) symmetry [103, 104], whereas

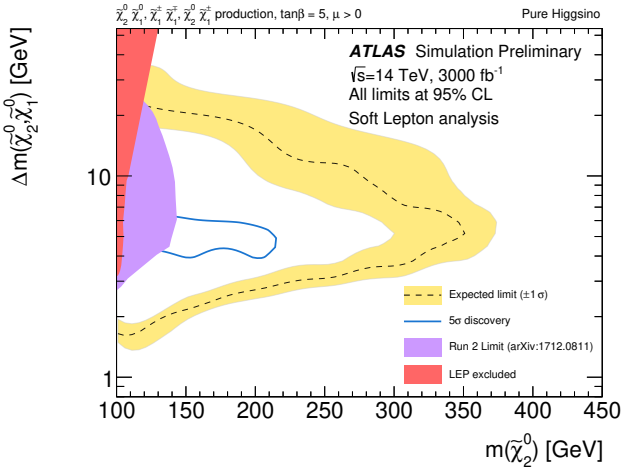

Fig. 2.2.15: Expected exclusion limit (dashed line) in the $\Delta m(\tilde{\chi}_2^0, \tilde{\chi}_1^0)$, $m(\tilde{\chi}_2^0)$ mass plane, at 95% C.L. from the dilepton analysis with 3 $\mathrm{ab}^{-1}$of 14 TeV, proton-proton collision data in the context of a pure Higgsino LSP with $\pm 1\sigma$ (yellow band) from the associated systematic uncertainties. The blue curve presents the 5σ discovery potential of the search. The purple contour is the observed exclusion limit from the Run-2 analysis. The figure also presents the limits on chargino production from LEP. The relationship between the masses of the chargino and the two lightest neutralinos in this scenario is $m(\tilde{\chi}_1^\pm) = \frac{1}{2}(m(\tilde{\chi}_1^0) + m(\tilde{\chi}_2^0))$.

they forbid any R-parity violating operators thanks to the gauged $B-L$ symmetry. To naturally describe the small magnitude of the neutrino masses and preserve R-parity, the model superfield content includes both $SU(2)_L$ and $SU(2)_R$ triplets of Higgs supermultiplets. The neutral component of the $SU(2)_R$ Higgs scalar field then acquires a large vacuum expectation value v_R, which breaks the LR symmetry and makes the $SU(2)_R$ gauge sector heavy. In order to prevent the tree-level vacuum from being a charge-breaking one, we can either rely on spontaneous R-parity violation [105], one-loop corrections [106], higher-dimensional operators [107] or additional $B-L=0$ triplets [108]. Whereas the first two options restrict v_R to be of at most about 10 TeV, the latter ones enforce v_R to lie above 10^{10} GeV. In this work, we rely on radiative corrections to stabilise the vacuum, so that the lightest supersymmetric particle (LSP) is stable and can act as a dark matter candidate.

Two viable LSP options emerge from LRSUSY, neutralinos and right sneutrinos. Out of the 12 neutralinos, gauginos and LR bidoublet, higgsinos can generally be lighter than 1 TeV. The correct relic density can be accommodated with dominantly-bino LSPs with a mass close to $m_h/2$ [109], whilst in the bidoublet higgsinos case (featuring four neutralinos and two charginos that are nearly-degenerate), co-annihilations play a crucial role and impose higgsino masses close to 700 GeV. In this setup, the rest of the spectrum is always heavier, so that SUSY could be challenging to discover. Right sneutrino LSP annihilate via the exchange of an s-channel Higgs boson through gauge interactions stemming from the D-terms [109]. Without options for co-annihilating, the LSP sneutrino mass must lie between 250 and 300 GeV. However, potential co-annihilations with neutralinos enhance the effective annihilation cross section so that the relic density constraints can be satisfied with heavier sneutrinos. The fully degenerate sneutrinos and higgsinos case impose an upper limit on the sneutrino mass of 700 GeV. Additionally, right neutrinos can also be part of the dark sector, together with the LSP [110].

Direct detection constraints imposed by the XENON1T [111] and PANDA [112] collaborations put light DM scenarios under severe scrutiny. Hence, in LRSUSY, in order to account for the relic density and direct detection constraints simultaneously, we need to focus on various co-annihilation options. In this work, we consider one right sneutrino and one higgsino LSP scenario and highlight the corresponding implications for W_R searches at the LHC. A robust signal of left-right symmetry consists in the discovery of a right gauge boson W_R, possibly together with a right neutrino N_R. Both

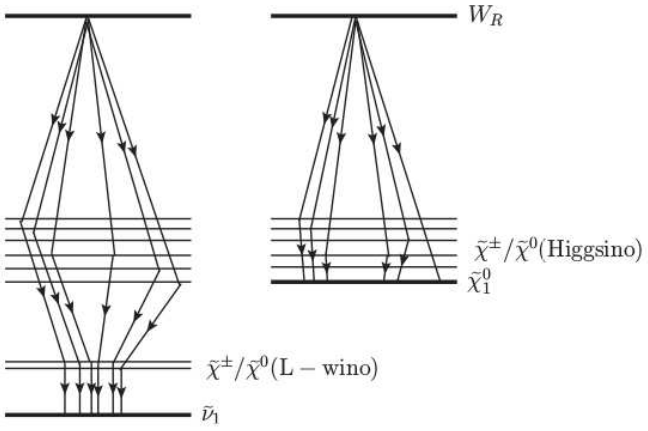

Fig. 2.2.16: The two LRSUSY spectra chosen for our study. Left: sneutrino LSP spectrum, where the W_R boson decays into multiple higgsino-like chargino-neutralino pairs, each electroweakino subsequently decaying into the sneutrino LSP either directly or through an intermediate $SU(2)_L$ wino-like chargino-neutralino pair. Right: neutralino LSP spectrum, where the W_R bosons decays into higgsino-like chargino-neutralino pairs, the electroweakinos subsequently decaying into the lightest (higgsino-like) neutralino.

the ATLAS and CMS collaborations have looked for a W_R signal in the $\ell\ell jj$ channel, excluding W_R masses up to about 4.5 TeV when at least one right-handed neutrino is lighter than the W_R-boson [113]. These exclusion limits nevertheless strongly depend on the spectrum and could be weakened or even evaded, for instance when $M_{N_R} \simeq M_{W_R}$ or for $M_{N_R} \lesssim 150$ GeV and $M_{W_R} > 3$ TeV. In addition, dijet resonance searches yield $M_{W_R} \gtrsim 3.5$ TeV [114, 115], even if these bounds can once again be relaxed by virtue of the supersymmetric W_R decay modes. On different grounds, dark matter considerations lead to favoured LRSUSY scenarios in which several neutralinos and charginos are light (so that they could co-annihilate). This motivates the investigation of a new W_R search channel where decays into pairs of electroweakinos are considered. In many LRSUSY setups, the corresponding combined BR can be as large as 25%, so that the production of multileptonic systems featuring a large amount of missing transverse momentum is enhanced. Whilst such a multilepton signal with $E_{\rm T}^{\rm miss}$ is a characteristic SUSY signal, it also provides an additional search channel for W_R-bosons at the LHC. Moreover, the resonant production mode offers the opportunity to reconstruct the W_R-boson mass through kinematic thresholds featured by various transverse observables.

In order to illustrate the above features, we perform an analysis in the context of two LRSUSY scenarios respectively featuring a sneutrino and a neutralino LSP. The results are presented for both the high c.o.m. energy ($\sqrt{s}$) and high luminosity ($\mathcal{L}$) cases, $\sqrt{s} = 14$ TeV with $\mathcal{L} = 3\,{\rm ab}^{-1}$ and $\sqrt{s} = 27$ TeV with $\mathcal{L} = 15\,{\rm ab}^{-1}$ options for the future run of the LHC. For the higgsino-like neutralino LSP case, we kept the bidoublet higgsino masses in the $700 - 750$ GeV region. In contrast, for the sneutrino DM case, the LSP mass can be much lower and has been fixed to about 400 GeV, with the second lightest superpartner being an $SU(2)_L$ wino lying about 30 GeV above and the higgsinos being again in the $700 - 750$ GeV regime. These two mass spectra are illustrated in Fig. 2.2.16. The sneutrino DM option is expected to be reachable with a lower luminosity due to the harder charged leptons arising from the cascade decays.

For our study, we followed the CMS search of multileptonic new physics signals as could emerge from electroweakino production [93]. We tested several signal regions introduced in this CMS search, all featuring different lepton multiplicities and selections on transverse kinematic variables like the missing transverse energy, the transverse momenta of various systems, the transverse mass M_T of systems made of one lepton and the missing momentum, the stransverse mass M_{T2} or the dilepton invariant mass $M_{\ell\ell}$. The two signal regions that are most suitable for the considered types of LRSUSY spectra, are listed

Signal Regions	Requirements
SRA44	$N_\ell = 3$, $N_{\rm OSSF} \geq 1$, $N_\tau = 0$, $M_T > 160$ GeV, $\not{E}_T \geq 200$ GeV, $M_{\ell\ell} \geq 105$ GeV
SRD16	$N_\ell = 2$, $N_{\rm OS} = 1$, $N_{\rm SF} = 0$, $N_\tau = 1$, $M_{T2} > 100$ GeV, $\not{E}_T \geq 200$ GeV

Table 2.2.3: The two signal regions of the analysis of Ref. [93] that are the most suitable for discovering our considered LRSUSY W_R-boson signal. Here, $N_{\rm OSSF}$ stands for the number of opposite-sign same-flavour lepton pairs, $N_{\rm OS}$ for the number of opposite-sign lepton pair and $N_{\rm SF}$ for the number of same-flavour lepton pair. Moreover, $\ell \equiv e, \mu$.

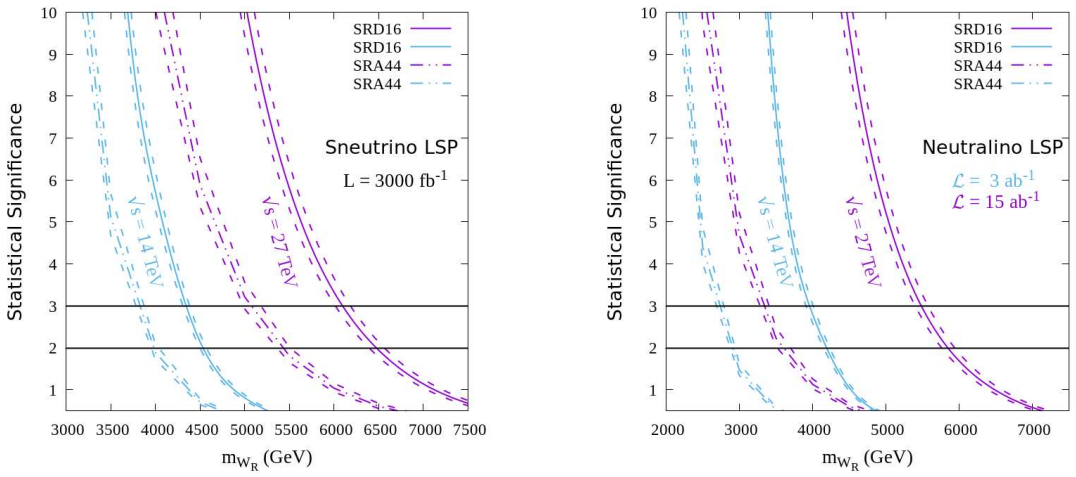

Fig. 2.2.17: Statistical significance of the two signal regions of the analysis of Ref. [93] to a LRSUSY scenarios in the case of a sneutrino (left) and a neutralino (right) LSP setup. We consider c.o.m. energies of $\sqrt{s} = 14$ and 27 TeV, and an integrated luminosities of 3 and 15 ab^{-1}.

in Table 2.2.3. In the **SRA44** region, one requires the presence of three charged leptons (electrons or muons), with at least two of them forming a pair of opposite-sign same-flavour (OSSF) leptons. One further constrains the invariant mass of this OSSF lepton system $M_{\ell\ell}$, relying on the pair that is the most compatible with a Z-boson if several combinations are possible. The transverse mass M_T of the system constructed from the third lepton and the missing momentum is finally constrained, together with the missing transverse momentum. In the **SRD16** region, one instead asks for two opposite-sign leptons (electrons and muons) and one tau-lepton. The stransverse mass M_{T2} originating from the lepton-pair is then constrained, together with the missing transverse energy.

For our simulations, we used the SARAH implementation of the LRSUSY model [116, 117] and generated the particle spectrum by means of SPHENO [118]. DM calculations were performed using MADDM [119] and LHC simulations were performed at the parton-level using MADGRAPH5 (V2.5.5) [67] with the UFO [120] model obtained from SARAH. We used the leading order set of NNPDF parton distribution functions [121]. Showering and hadronisation were performed using PYTHIA 8 [68], and we have used MADANALYSIS 5 (V1.6.40) [122–124] to handle the simulation of the response of the CMS detector (through its interface to DELPHES 3 (V3.4.1) [33] and FASTJET (V3.3.0) [35]) and to recast the CMS analysis of Ref. [93], available from the MadAnalysis 5 Public Analysis Database [125].

The results are presented in Fig. 2.2.17 for c.o.m. energies of 14 and 27 TeV. The two figures depict the reach in the W_R-boson mass M_{W_R} for the two signal regions of Table 2.2.3 for the sneutrino LSP (left) and neutralino LSP (right) scenarios. The two horizontal black lines represent the 2σ (mostly equivalent to a 95% C.L. exclusion) and 3σ statistical significance. For the $14TeV$ analysis, we considered the same SM background as in Ref. [93], appropriately scaled to the required luminosity and assuming relative errors similar to the 35.9 fb^{-1} case. For the 27 TeV analysis, we scaled all background

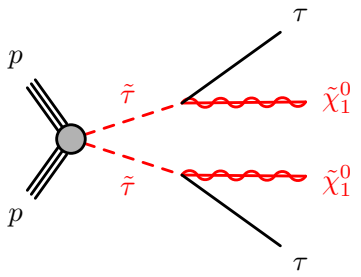

Fig. 2.3.1: Diagram for the $\tilde{\tau}$ pair-production.

contributions by a factor of 3, since the increase in the background cross-sections (for all the dominant channels) is approximately of 3 compared with $\sqrt{s} = 14$ TeV. Whilst this approximation is crude due to lack of information regarding the background contributions from non-prompt leptons and conversions at $\sqrt{s} = 27$ TeV, it allows us to get back-of-the-envelope estimations. As the targeted W_R masses are way larger than the electroweakino masses, the overall cut efficiencies do not change by more than 10%, so that uniform signal selection efficiencies could be considered throughout the entire W_R mass range of $[2, 7.5]$ TeV. We however include in our estimations the effect of a 10% variation on the background uncertainties, as depicted by the dashed lines.

The **SRD16** region proves to be the more favoured channel for both benchmark scenarios mainly because it features an almost background-free environment. It would even be more significant for a tau sneutrino LSP, as this leads to chargino decays into tau leptons. Our calculations however only consider cases where the sneutrino LSP is the electron sneutrino, so that they could be taken as conservative. The reach to sneutrino LSP scenarios is however better, as could be expected from the potentially substantial mass gap featured by the particle spectrum. Multiple hard leptons can indeed arise from the cascade decays, in contrast to the higgsino LSP scenarios where the decay products have softer momenta as the spectrum is more compressed. We observe that for sneutrino and neutralino LSP scenarios, W_R-boson masses up to respectively about 4.5 TeV and 4.2 TeV can be reached while providing enough events for electroweakinos signal sensitivity, when considering 3 ab^{-1} of proton-proton collisions at $\sqrt{s} = 14$ TeV. With $\sqrt{s} = 27$ TeV and $\mathcal{L} = 15$ ab^{-1}, the reach extends to about 6.5 TeV and 5.7 TeV respectively. All the limits are obtained from the sole **SRD16** signal region, so that the **SRA44** region could be used as a confirmatory channel if some excess would be observed.

In conclusion, within the LRSUSY framework, W_R-boson-induced neutralino and chargino production could be used as a probe for dark-matter motivated scenarios. The HL and HE phases of the LHC could hence push the limits on the sensitivity to electroweakino searches as well as on the W_R-boson mass, relying on multilepton production in association with missing transverse momentum.

2.3 Searches for Sleptons: stau pair production at HE- and HL-LHC

Slepton pair production cross sections are less than 1 fb^{-1} for sparticles above 400 GeV at 14 TeV c.o.m. energy, hence searches for these processes will benefit considerably of the large datasets to be collected at the HL-LHC. In many SUSY scenarios with large $\tan\beta$, the stau ($\tilde{\tau}$) is lighter than the selectron and smuon, resulting in tau-rich final states. Co-annihilation processes favour a light stau that has a small mass splitting with a bino LSP, as it can set the relic density to the observed value. Searches for $\tilde{\tau}$ pair production are presented in this section using final state events with at least one hadronically decaying τ lepton as performed by ATLAS and CMS.

The simplified model used for the optimisation of the searches and the interpretation of the results is shown in Fig. 2.3.1. Assumptions on the mixture of left- and right-handed τ leptons as considered by the experiments are detailed where relevant.

Selection	SR-low [GeV]	SR-med [GeV]	SR-high [GeV]	SR-exclHigh [GeV]
$p_{\mathrm{T\,jet}} >$	40	40	20	-
$p_{\mathrm{T}\tau 1} >$	150	200	200	200
$m_{\mathrm{T}\tau 1} + m_{\mathrm{T}\tau 2} >$	500	700	800	800
$m_{\mathrm{T2}}(\tau 1, \tau 2)$	$\in [80, \infty]$	$\in [130, \infty]$	$\in [130, \infty]$	$\in [80, 130]$
				$\in [130, 180]$
				$\in [180, 230]$
				$\in [230, \infty]$

2.3.1 Searches for $\tilde{\tau}$ pair production in the hadronic channel ($\tau_h\tau_h$) at ATLAS at the HL-LHC

Contributors: H. Cheng, D. Xu, C. Zhu, X. Zhuang, ATLAS

In the ATLAS search [84], two models describing the direct production of stau are employed: one considers stau partners of the left-handed τ lepton ($\tilde{\tau_L}$), and a second considers stau partners of the right-handed τ lepton ($\tilde{\tau_R}$). In both models, the stau decays with a branching fraction of 100% to the SM tau-lepton and the LSP. A search for stau production is presented here, which uses a final state with two hadronically decaying τ leptons, low jet activity, and large missing transverse energy ($E_{\mathrm{T}}^{\mathrm{miss}}$) from the $\tilde{\chi}_1^0$ and neutrinos. The SM background is dominated by W+jets, multi-boson production and top pair production.

The event pre-selection is based on that of the previous 8 TeV analysis [126] and 13 TeV analysis [127]. Hadronically decaying taus are selected with $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 4$, while electrons and muons are selected with $p_{\mathrm{T}} > 10$ GeV and $|\eta| < 2.47$ ($|\eta| < 2.5$ for muons). Jets are reconstructed with the anti-k_t algorithm with a radius parameter of 0.4, with $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 4$. To remove close-by objects from one another, an overlap removal based on ΔR is applied. In processes where jets may be misidentified as hadronically decaying taus, each jet is assigned a weight corresponding to the tau fake rate in the HL-LHC detector performance parameterisation.

Events are selected with exactly two tightly identified hadronic taus with $|\eta| < 2.5$, and the two taus must have opposite electric charge (OS). The tight tau algorithm correctly identifies one-prong (three-prong) taus with an efficiency of 60% (45%), with a light-flavour jet misidentification probability of 0.06% (0.02%). Events with electrons, muons, b-jets or forward jets ($|\eta| > 2.5$) are vetoed. The effect of a di-tau trigger is considered by requiring that the leading tau p_{T} is larger than 50 GeV and the sub-leading tau p_{T} is larger than 40 GeV, with an assumed trigger efficiency of 64%. To suppress the SM background, a loose jet veto is applied that rejects events containing jets with $|\eta| < 2.5$ and $p_{\mathrm{T}} > 100$ GeV.

Since the SUSY signal involves two undetected $\tilde{\chi}_1^0$, the resulting $E_{\mathrm{T}}^{\mathrm{miss}}$ spectrum tends to be harder than that for the the major SM backgrounds, thus $E_{\mathrm{T}}^{\mathrm{miss}} > 200$ GeV is required to reject the multi-jet background. A Z veto is imposed, where the invariant mass of the two taus, $m_{\tau\tau}$, is required to be larger than 100 GeV to suppress contributions from $Z/\gamma^* + \mathrm{jets}$ production. To suppress the top quark and multi-jet backgrounds, the sum of the two-tau transverse mass defined using the transverse momentum of the leading (next-to-leading) tau and $E_{\mathrm{T}}^{\mathrm{miss}}$, must be larger than 450 GeV. The transverse mass requirement of $m_{\mathrm{T2}} > 35$ GeV is used to to further suppress the top, W+jets and $Z/\gamma^* + \mathrm{jets}$ backgrounds.

In order to increase the discrimination power between signal and SM backgrounds several kinematic variables are further applied: the p_{T} of the next-to-leading tau, $p_{\mathrm{T}\tau 2} > 75$ GeV, and the angular separation between the leading and next-to-leading tau is required to be $\Delta\phi(\tau 1, \tau 2) > 2$ and $\Delta R(\tau 1, \tau 2) < 3$.

Following these preselection requirements, three signal regions are defined to maximise model-

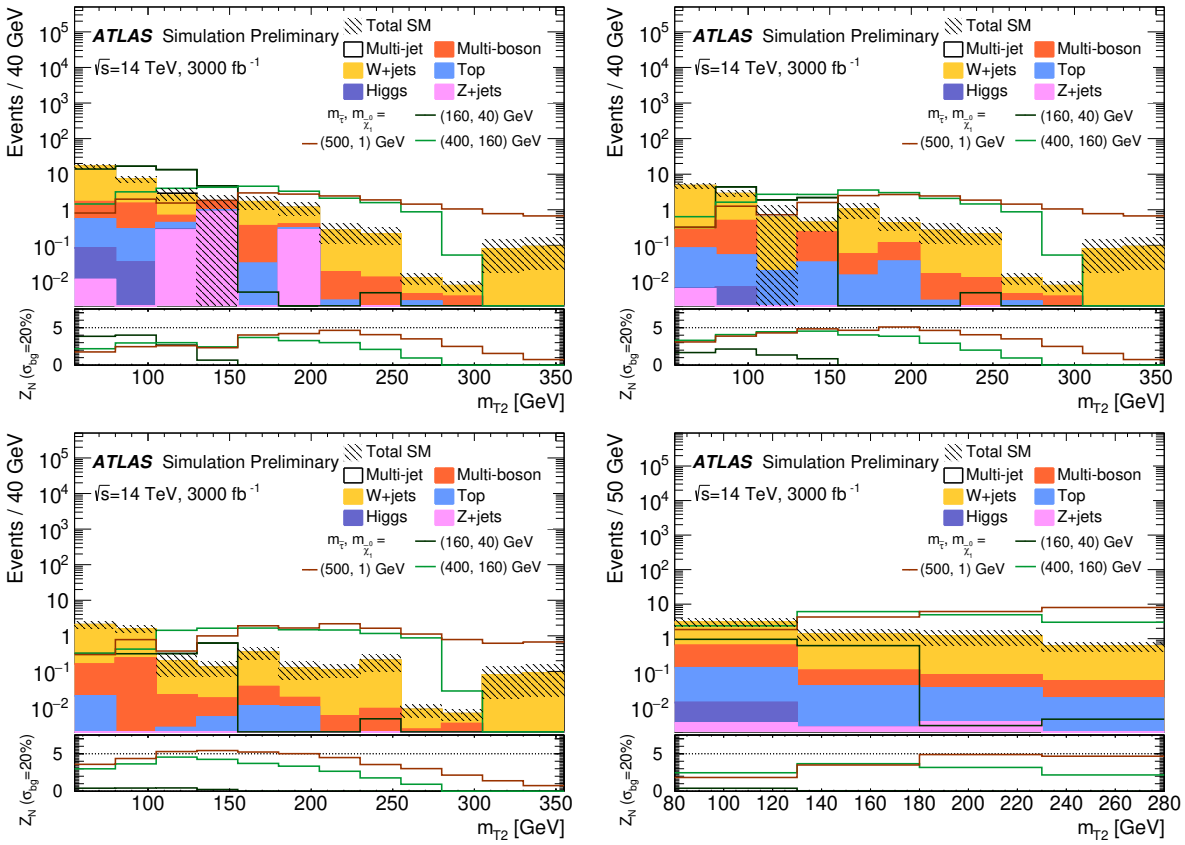

Fig. 2.3.2: Distributions of each m_{T2} variable in the SR-low, SR-med, SR-high and SR-exclHigh regions, applying all selections as Table 2.3.1 with the exception of m_{T2} itself. The stacked histograms show the expected SM backgrounds normalised to 3 ab^{-1}. The hatched bands represent the statistical uncertainties on the total SM background. For illustration, the distributions of the SUSY reference points are also shown as dashed lines. The lower pad in each plot shows the significance, Z_N using a background uncertainty of 20%, for the SUSY reference points. In the SR-exclHigh plot, the sensitivity distribution is the distribution for each m_{T2} bin.

independent discovery sensitivity targeting scenarios with low (SR-low), medium (SR-med) and high (SR-high) mass differences between the $\tilde{\tau}$ and $\tilde{\chi}_1^0$. A set of disjoint signal regions binned in m_{T2} are also defined to maximise model-dependent exclusion sensitivity based on the previous SR-high signal region with the jet veto threshold cut removed. Each SR is identified by the range of the m_{T2}. All signal regions are shown in Table 2.3.1.

Figure 2.3.2 shows the distributions of m_{T2} in these signal regions, applying all SR selections with the exception of m_{T2} itself.

The systematic uncertainties are evaluated based on the SR-high systematic uncertainty in Ref. [127]. A few of the experimental uncertainties are expected to be smaller at the HL-LHC compared to the 13 TeV studies. In particular, the tau energy scale in-situ uncertainty is scaled by a factor of 0.6 and the tau ID efficiency uncertainty is scaled by a factor of $0.45 - 0.9$. The multi-jet uncertainties scale with the increased integrated luminosity, and the background theoretical uncertainties are halved. The theoretical cross-section uncertainty for direct stau production is taken as 10%, while the MC/data related systematics are considered negligible. All other uncertainties are assumed to be the same as in the 13 TeV studies. In this assumption, the total background experimental uncertainty is $\sim 19\%$, with theoretical uncertainties on the Top, $Z/\gamma^* + \mathrm{jets}$ and Higgs backgrounds of 13%, theoretical uncertainties on the W+jets and multi-jet backgrounds of 10%, and uncertainties on the multi-boson background of 8%. This is referred to as the "Baseline uncertainty" scenario. The total uncertainty on the SUSY signal

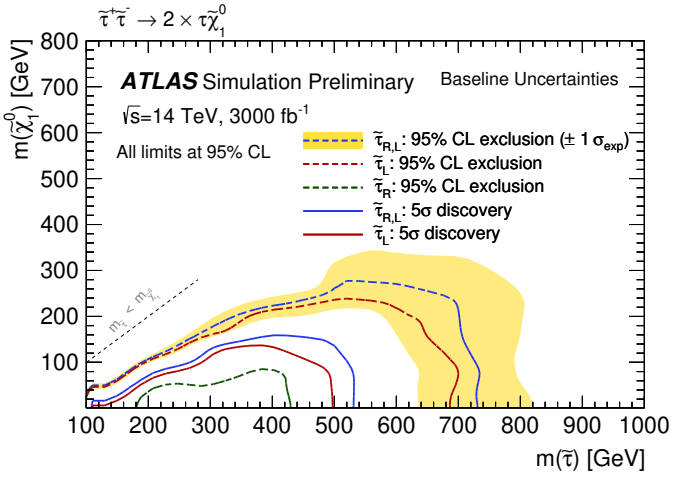

Fig. 2.3.3: 95% C.L. exclusion limits and 5σ discovery contours for 3 ab^{-1}luminosity on the pure $\tilde{\tau_L}\tilde{\tau_L}$ or $\tilde{\tau_R}\tilde{\tau_R}$ and combined $\tilde{\tau_L}\tilde{\tau_L}$, $\tilde{\tau_R}\tilde{\tau_R}$ production in HL-LHC under the baseline systematic uncertainty assumptions.

is $\sim 14\%$. Another scenario is also considered, where the expected uncertainties at the HL-LHC do not improve upon the 13 TeV studies for the SM background and signal. This results in a total background uncertainty of $\sim 38\%$ and a signal uncertainty of $\sim 21\%$ and is referred to as "Run-2 scenario".

To calculate the discovery potential, SR-low, SR-med and SR-High defined in Table 2.3.1 are used, while for the final exclusion limit, the best expected exclusion resulting from these and one additional region, SR-exclHigh, are used. The 95% C.L. exclusion limits and 5σ discovery contours on the combined $\tilde{\tau_L}\tilde{\tau_L}$ and $\tilde{\tau_R}\tilde{\tau_R}$ production, and separate $\tilde{\tau_L}\tilde{\tau_L}$ and $\tilde{\tau_R}\tilde{\tau_R}$ productions under baseline systematic uncertainty assumptions are shown in Fig. 2.3.3. The exclusion limit reaches 730 GeV in $\tilde{\tau}$ mass for the combined $\tilde{\tau_L}\tilde{\tau_L}$ and $\tilde{\tau_R}\tilde{\tau_R}$ production, and 690 GeV (430 GeV) for pure $\tilde{\tau_L}\tilde{\tau_L}$ (pure $\tilde{\tau_R}\tilde{\tau_R}$) production with a massless $\tilde{\chi}_1^0$. The discovery sensitivity reaches $110-530$ GeV ($110-500$ GeV) in $\tilde{\tau}$ mass for the combined $\tilde{\tau_L}\tilde{\tau_L}$ and $\tilde{\tau_R}\tilde{\tau_R}$ (pure $\tilde{\tau_L}\tilde{\tau_L}$) production with a massless $\tilde{\chi}_1^0$. No discovery sensitivity is found for pure $\tilde{\tau_R}\tilde{\tau_R}$ production as the production cross section is very small although a further reduction of the systematic uncertainties might open a window for discovery in the $100-200$ GeV mass range. In general, sensitivity is achieved for scenarios with large mass difference between the stau and neutralino, *i.e.* $\Delta m(\tilde{\tau}, \tilde{\chi}_1^0) > 100$ GeV.

Under the assumption where the expected uncertainties at the HL-LHC do not improve upon the 13 TeV (Run-2 scenario), the exclusion limit is reduced slightly, which down to 720 GeV in $\tilde{\tau}$ mass for the combined $\tilde{\tau_L}\tilde{\tau_L}$ and $\tilde{\tau_R}\tilde{\tau_R}$ production and 670 GeV (400 GeV) for pure $\tilde{\tau_L}\tilde{\tau_L}$ (pure $\tilde{\tau_R}\tilde{\tau_R}$) production with a massless $\tilde{\chi}_1^0$. The discovery sensitivity is also slightly reduced by about $20-50$ GeV.

2.3.2 *Searches for $\tilde{\tau}$ pair production in the $\tau_h\tau_h$ and $\tau_\ell\tau_h$ channels at CMS at the HL-LHC*

Contributors: I. Babounikau, A. Canepa, O. Colegrove, V. Dutta, I. Melzer-Pellmann, CMS

CMS investigates the expected reach for direct stau ($\tilde{\tau}$) pair production, where the $\tilde{\tau}$ decays to a τ and the lightest SUSY particle, the neutralino ($\tilde{\chi}_1^0$) [128]. Final states with either two hadronically decaying tau leptons (τ_h) or one τ_h and one electron or muon, referred to in the following as the $\tau\tau$ and $\ell\tau$ channels, respectively, are considered. In both cases we expect missing transverse momentum from the two LSPs.

The search assumes $\tilde{\tau}$ pair production in the mass-degenerate scenario. The cross-sections have been computed for $\sqrt{s} = 14$ TeV at NLO using the Prospino code [129]. Final values are calculated using the PDF4LHC recommendations for the two sets of cross sections following the prescriptions of the LHC SUSY Cross Section Working Group [61].

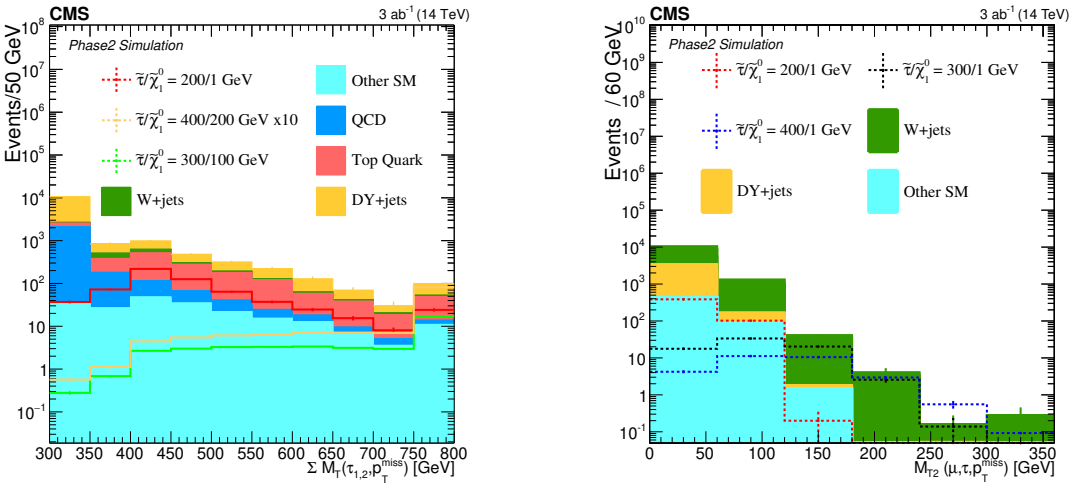

Fig. 2.3.4: Example plots for the main search variables: ΣM_T for the $\tau\tau$ analysis (left), and M_{T2} for the $\mu\tau$ analysis (right), both after the baseline selection.

The event selection for each final state requires the presence of exactly two reconstructed leptons with opposite charges, corresponding to the $\tau\tau$ or $\ell\tau$ final states. In order to pass the selection, electrons (muons) are required to have transverse momentum $p_T > 30$ GeV and pseudorapidity $|\eta| < 1.6(2.4)$ and a minimum azimuthal angle between each other of 1.5. Dedicated lepton identification criteria are applied, providing 50% to 90% efficiency for muons and 25% to 80% efficiency for electrons, depending on p_T and η. Both muons and electrons are required to be isolated.

The momentum of the τ_h candidates is required to be above 40 GeV in the $\ell\tau$ final state, while we require $p_T > 50$ GeV for the τ_h in the $\tau\tau$ final state. For both final states, the τ_h is required to be within $|\eta| < 2.3$. A tight working point is chosen for the τ_h identification in order to obtain a small rate of jets being misidentified as τ_h. The τ_h reconstruction efficiency for this working point is about 30%, with a fake rate of about 0.08% assuming an MVA optimisation. Overlaps between the two reconstructed leptons in the $\ell\tau$ final state are avoided by requiring them to have a minimum separation of $\Delta R > 0.3$.

In the $\ell\tau$ final state, all events with at least one jet are rejected. In the $\tau\tau$ channel, in order to suppress backgrounds with top quarks, we veto events containing any b-tagged jet with $p_T > 40$ GeV identified with the loose CSV working point in both final states, which corresponds to an identification efficiency of about $60 - 65\%$.

The main background for the $\tau\tau$ final state after this selection consists of quantum chromodynamics (QCD) multijet events, W+jets, DY+jets, and top quark events. Separating the background into prompt τ_h events, where both reconstructed taus are matched to a generator τ_h, and misidentified events, where one or more non-generator matched jets has been misidentified as prompt τ_h, we find that the misidentified background dominates our search regions.

In the $\ell\tau$ final state, all events with at least one jet are rejected. Due to kinematical constrains in the signal, we reduce the background from QCD multijet events by requiring a maximum separation of the two leptons in ΔR of 3.5.

In order to further improve discrimination against the SM background, we take advantage of the expected presence of two $\tilde{\chi}_1^0$ in the final state for signal events, which would lead to missing transverse momentum, $\vec{p_T}_{miss}$, defined as the projection onto the plane perpendicular to the beam axis of the negative vector sum of the momenta of all reconstructed objects in an event. Its magnitude, referred to as $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$, is an important discriminator between signal and SM background.

Events are then further selected using discriminating kinematic variables for each of the two final states to improve the sensitivity of the search to a range of sparticle masses, such as the trans-

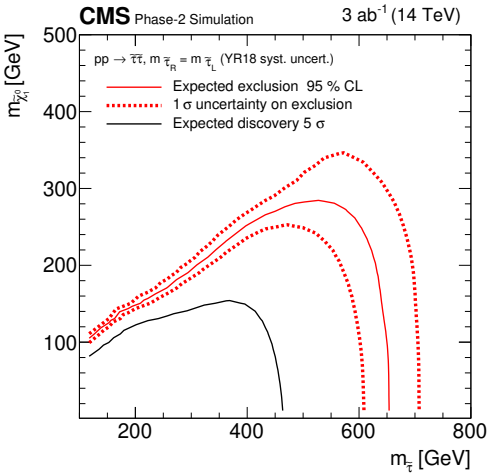

Fig. 2.3.5: Expected upper limits at the 95% C.L. (dashed line) and the 5σ discovery potential (full line) for the combination of the results of the $\tau\tau$ and $\ell\tau$ channels.

verse mass, $M_T(\ell, \vec{p_T}_m iss) \equiv \sqrt{2p_\ell \mathbf{p}_\mathrm{T}^\mathrm{miss}(1-\cos\Delta\phi(\vec{p}_\ell, \vec{p_T}_{miss}))}$, where ℓ represents the lepton. In addition, the scalar sum of the M_T calculated with the highest p_T (ℓ_1) and second highest p_T (ℓ_2) lepton and the missing transverse momentum is used to further reduce the background events: $\sum M_T = M_T(\ell_1, \vec{p_T}_{miss}) + M_T(\ell_2, \vec{p_T}_{miss})$. Finally the stransverse mass M_{T2} [130, 131] is used to discriminate the signal from the background.

The main variables that are used to define the search regions in the $\tau\tau$ final state are ΣM_T and M_{T2}, where the former is shown for the baseline selection in Fig. 2.3.4 (left). While we apply a stringent requirement of at least 400 GeV for ΣM_T, we require M_{T2} to be above 50 GeV. The $\tau\tau$ search regions are then binned in $M_{\mathrm{T2}}, \Sigma M_T$, and the number of jets n_{jet}.

In the $\ell\tau$ final state, we require $M_T(\mu, \vec{p_T}_{miss}) > 120$ GeV, which reduces the W+jets background significantly. To further suppress the SM background in the leptonic final states, $\mathbf{p}_\mathrm{T}^\mathrm{miss}$ has to be above 150 GeV, which mainly reduces QCD multijets and Drell Yan events. Additional binning in M_{T2} and the p_T of the τ_h is applied to define the search regions in the $\ell\tau$ selection. Figure 2.3.4 (right) shows the M_{T2} distribution after the baseline selection.

The dominant experimental uncertainties are those originating from jets being misidentified as τ_h (15%), τ_h identification efficiency (2.5%), the muon identification efficiency (0.5%), the electron identification efficiency (1%), the jet energy scale (1−3.5%) and resolution (3−5%), b-tagging efficiency (1%) and the integrated luminosity (1%). These systematic uncertainties are correlated between the signal and the irreducible background yields.

The expected upper limits and the discovery potential are given in Fig. 2.3.5. In mass-degenerate scenarios, degenerate production of τ sleptons are excluded up to 650 GeV with the discovery contour reaching up to 470 GeV for a massless neutralino. The $\tau\tau$ analysis has been found to drive the sensitivity, but adding the $\ell\tau$ channel enlarges the exclusion bounds by about $60 - 80$ GeV.

2.3.3 Remarks on stau pair production searches at HL-LHC

Prospects for stau pair production presented by ATLAS and CMS in the previous sections generally cover a similar region of the stau-neutralino mass plane. Stau masses up to 730 GeV are excluded by ATLAS for scenarios with large mass difference between stau and neutralino, *i.e.* $\Delta m(\tilde{\tau}, \tilde{\chi}_1^0) > 100$ GeV. CMS contours reach up to about 650 GeV covering a similar region in the parameter space. Differences in the reaches are small but noticeable, and are briefly highlighted in the following. The main difference between the ATLAS and CMS searches is the definition of the tau object. ATLAS has optimised the

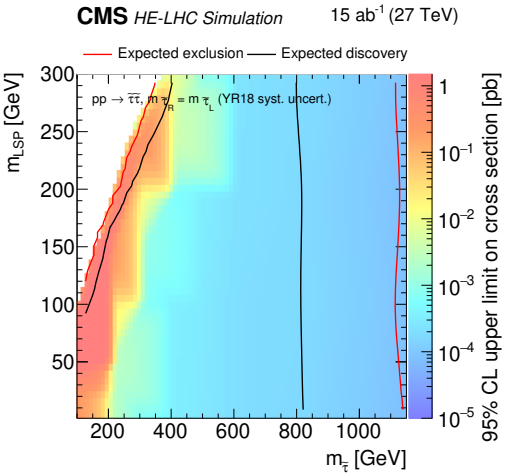

Fig. 2.3.6: Expected upper limits at the 95% C.L. (red line) and the 5σ discovery potential (black line) for the combination of the results of the $\tau\tau$ and $\ell\tau$ channels for HE-LHC.

so-called working point (WP), *i.e.* the combination of selection requirements leading to a certain level of identification efficiency and jet-rejection rate, and chosen a WP leading to 45% to 60% efficiency as a function of p_T and an average jet-rejection rate of 0.6% (0.02%) for 1-prong (3-prong) taus. The CMS analysis considers a tighter WP, resulting in an almost negligible level of misidentified taus but with lower efficiency ($\sim$ 30%). This leads to a small difference in terms of acceptance $\times$ efficiency which translates to 80 (50) GeV differences in the exclusion (discovery) contours.

Finally, we underline that the sensitivity to more compressed scenarios, as predicted in theoretically favoured co-annihilation scenarios, might be partially recovered exploiting the presence of a high p_T ISR jet, similarly to studies presented in Section 2.2.5. For this, identification of tau objects at low p_T will be crucial.

2.3.4 Searches for $\tilde{\tau}$ pair production in the $\tau_h\tau_h$ and $\tau_\ell\tau_h$ channels at CMS at HE-LHC

Contributors: I. Babounikau, A. Canepa, O. Colegrove, V. Dutta, I. Melzer-Pellmann, CMS

On top of the CMS HL-LHC analysis, we also study the influence of the increased cross section for 27 TeV and the increased luminosity of 15 ab^{-1} expected to be achieved in HE-LHC [128]. For this study the cross sections of all backgrounds and signal contributions are recalculated for $\sqrt{s} = 27$ TeV at NLO using PROSPINO. The signal region definition and kinematic distributions are the same as described in Section 2.3.2 for the HL-LHC study, but are scaled with the new cross sections and luminosity. The main gain in sensitivity comes from the increased luminosity, since the cross section increase for signal is the same order as that for background. The applied uncertainties are the same as for HL-LHC study described in Section 2.3.2.

The expected upper limits and the discovery potential are given in Fig. 2.3.6. In the mass-degenerate scenario, τ slepton production is excluded up to 1150 GeV with the discovery contour reaching up to 810 GeV for a massless neutralino. Signal events were generated up to neutralino mass of 300 GeV, at which point the discovery (exclusion) potential ranges from $400 - 800$ GeV ($350 - 1100$ GeV).

2.4 Other SUSY signatures and implications on SUSY models

Supersymmetry might manifest in different ways at hadron colliders. Simplified models help in setting the search strategy and illustrate the reach for individual processes, as shown in the prospects presented in previous sections. In this section, analyses of the discovery potential of HL- and HE-LHC are reported

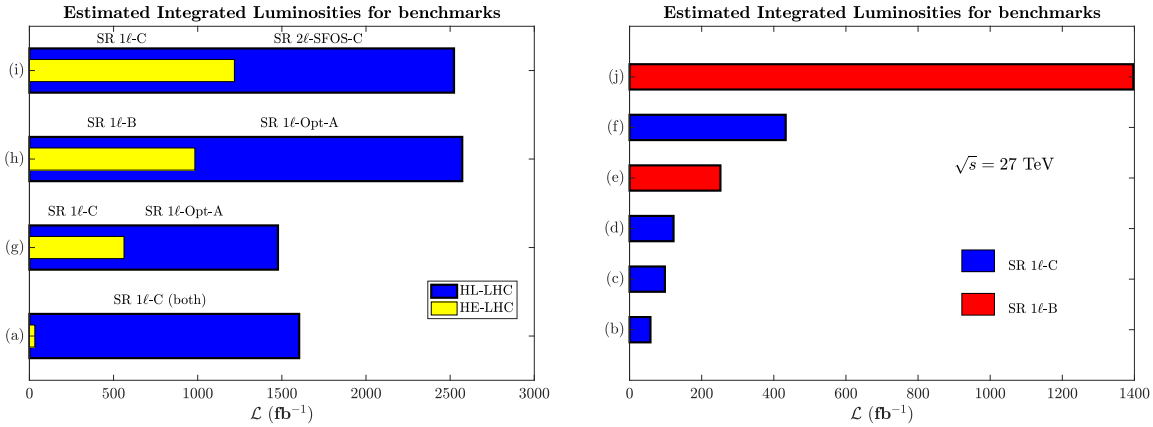

Fig. 2.4.1: Estimated integrated luminosities, $\mathcal{L}$, for a 5σ discovery of the benchmark points of Table 2.4.1. Left: comparison between $\mathcal{L}$ at HL-LHC and HE-LHC for points (a), (g), (h) and (i). Right: HE-LHC analysis for points (b), (c), (d), (e), (f) and (j). considering benchmark points in supergravity grand unified models, light higgsino scenarios, pMSSM and U(1)$'$-extended MSSM models.

2.4.1 SUSY discovery potential at HL- and HE-LHC

Contributors: A. Aboubrahim, P. Nath

We give an analysis of the discovery potential of HE-LHC with respect to the HL-LHC for supersymmetry, based on studies presented in Ref. [132]. Specifically, a set of benchmark points which are discoverable both at HE-LHC and HL-LHC are presented. In addition, we also report on a set of benchmarks which are beyond the reach of HL-LHC but are discoverable at HE-LHC. The models we consider are supergravity grand unified models [133–136] with non-universalities in the gaugino sector. Thus, the models are described by the set of parameters $m_0, m_1, m_2, m_3, A_0, \tan\beta, \mathrm{sgn}(\mu)$ where m_0 is the universal scalar mass (which can be large consistent with naturalness [137]), m_1, m_2, m_3 are the $U(1), SU(2)_L, SU(3)_C$ gaugino masses, A_0 is the universal trilinear coupling, and $\tan\beta = \langle H_2\rangle/\langle H_1\rangle$ is the ratio of the Higgs VEVS . The analysis is done under the constraints of Higgs boson mass and the relic density constraints which requires coannihilation [138–140]. The analysis uses signatures involving a single charged lepton and jets, two charged leptons and jets and three charged leptons and jets, resulting from the decay of a gluino pair (points (a)-(f) of Table 2.4.1) and the decay of $\tilde{\chi}_2^0\tilde{\chi}_1^\pm$ (points (g)-(j) of Table 2.4.1). It is found that most often the dominant signature is the single lepton and jets signature, indicated as SR-1ℓ-B or C in the figures, depending on the specific selections applied. Twelve different kinematic variables are used to discriminate the signal from the background. These consist of

$$N_{\rm jets},\ E_T^{\rm miss},\ H_T,\ m_{\rm eff},\ R,\ H_{20},\ p_T(j_n),\ m_T^\ell,\ m_T^{\rm min}(j_{1-2}, E_T^{\rm miss}) \tag{2.4.1}$$

where $N_{\rm jets}$ is the number of jets, $E_T^{\rm miss}$ is the missing transverse energy, H_T is the sum of the jets' transverse momenta, $m_{\rm eff}$ is the effective mass, $R = E_T^{\rm miss}/(E_T^{\rm miss} + p_T^\ell)$, H_{20} is the second Fox-Wolfram moment, $p_T(j_n)$ is the $n^{\rm th}$ jet transverse momentum, m_T^ℓ is the leading lepton transverse mass and $m_T^{\rm min}(j_{1-2}, E_T^{\rm miss})$ is the minimum of the transverse masses of the first and second leading jets. Finally, p_T^ℓ denotes the transverse momentum of the leading lepton.

The left panel of Fig. 2.4.1 exhibits four parameter points which are discoverable both at HE-LHC and at HL-LHC. Here one finds that the integrated luminosities needed for discovery at HL-LHC (blue bars) are 2-50 times larger than what is needed at HE-LHC (yellow bars). For these model points one finds that discovery would require an HL-LHC run between 5-8 years while the same parameter points can be discovered in a period of few weeks to ~ 1.5 yr at HE-LHC running at its optimal luminosity of

Model	h^0 [GeV]	μ [TeV]	$\tilde{\chi}_1^0$ [$\times 10^2$ GeV]	$\tilde{\chi}_1^\pm$ [$\times 10^2$ GeV]	$\tilde{t}$ [TeV]	$\tilde{g}$ [TeV]	$\Omega^{\rm th}_{\tilde{\chi}_1^0}h^2$
(a)	124	8.02	9.73	10.6	4.73	1.36	0.039
(b)	125	6.29	10.2	10.3	2.08	1.40	0.035

(j)	125	29.7	1.62	1.87	10.4	15.6	0.105

Table 2.4.1: The Higgs boson (h^0) mass, the μ parameter and some relevant sparticle masses, and the relic density for the benchmark points used in this analysis [132].

2.5×10^{35} cm^{-2}s^{-1}. The right panel of Fig. 2.4.1 gives a set of benchmarks which are not accessible at HL-LHC but will be visible at HE-LHC. We note that half of the benchmarks in the right panel of Fig. 2.4.1 can be discovered with less than 200 fb^{-1} of integrated luminosity at HE-LHC with few months of running at its optimal luminosity. Considering points that are just beyond the HL-LHC reach, point (j) requires a run of $\sim$ 1.6 yr while point (b) $\sim$ 3.5 weeks for discovery at the HE-LHC. In summary, the analysis above indicates that a transition from HL-LHC to HE-LHC can aid in the discovery of supersymmetry for part of the parameter space accessible to both. Further to that, HE-LHC can explore significantly beyond the realm of the parameter space accessible to HL-LHC.

2.4.2 Natural SUSY at HL- and HE-LHC

Contributors: H. Baer, V. Barger, J. Gainer, H. Serce, D. Sengupta, X. Tata

We present HL- and HE-LHC reach calculations for supersymmetry in models with light higgsinos. The light higgsino scenario is inspired by the requirement of naturalness in that if the superpotential (higgsino) mass parameter μ is much beyond the weak scale, then the weak scale soft term $m_{H_u}^2$ will have to be fine-tuned in order to maintain $m_{W,Z,h}$ at their measured mass values.

HL/HE-LHC reach for gluino pair production

In Ref. [141] we evaluated the reach of the HL-LHC for gluino pair production, assuming that $\tilde{g} \to t\tilde{t}_1$ and $\tilde{t}_1 \to b\tilde{\chi}_1^+$ or $t\tilde{\chi}_{1,2}^0$ and that the decay products of the higgsinos $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ are essentially invisible.In Ref. [142] we computed the reach of HE-LHC for both gluinos and top squarks in the light higgsino scenario (with $\sqrt{s} = 33$ TeV). These results have been updated for HE-LHC with $\sqrt{s} = 27$ TeV and 15 ab^{-1}of integrated luminosity in Ref. [143] where more details can be found. We use MADGRAPH [67] to generate gluino pair production events and SM backgrounds. We interface MADGRAPH with PYTHIA [68] for initial/final state showering, hadronisation and underlying event simulation. The DELPHES detector simulation [33] is used with specifications as listed in Ref. [142]. SM backgrounds include $t\bar{t}$, $t\bar{t}b\bar{b}$, $t\bar{t}t\bar{t}$, $t\bar{t}Z$, $t\bar{t}h$, $b\bar{b}Z$ and single top production. We require at least four high p_T jets, with two or more identified as b-jets, no isolated leptons and large $E_{\rm T}^{\rm miss}$ selections.

Results are shown in the left panel of Fig. 2.4.2 where we report the gluino pair production signal versus $m_{\tilde{g}}$ for a natural NUHM2 model line with parameter choice $m_0 = 5m_{1/2}$, $A_0 = -1.6m_0$, $m_A = m_{1/2}$, $\tan\beta = 10$ and $\mu = 150$ GeV with varying $m_{1/2}$. The results are not expected to be sensitive to this precise choice of parameters as long as first generation squarks are much heavier than

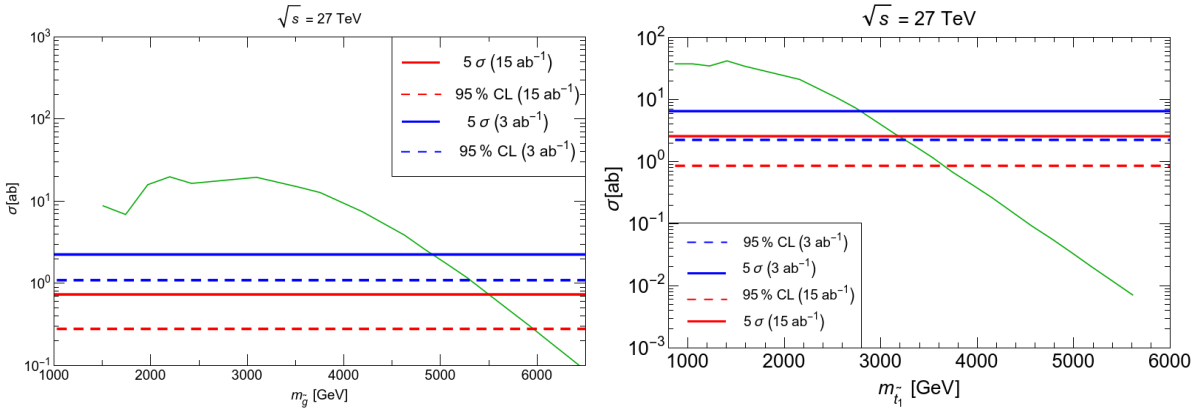

Fig. 2.4.2: Left: gluino pair production cross section vs. $m_{\tilde{g}}$ after selections at HE-LHC with $\sqrt{s} = 27$ TeV (green curve). Right: top-squark pair production cross section vs. $m_{\tilde{t}_1}$ after selections at HE-LHC with $\sqrt{s} = 27$ TeV (green curve). Both panels also show the 5σ reach and 95% C.L. exclusion lines assuming 3 and 15 ab^{-1} of integrated luminosity.

gluinos. From the figure, we see that the 5σ discovery reach of HE-LHC extends to $m_{\tilde{g}} = 4.9$ TeV for 3 ab^{-1} and to $m_{\tilde{g}} = 5.5$ TeV for 15 $\text{ab}^{-1}$of integrated luminosity. The corresponding 95% C.L. exclusion reaches extend to $m_{\tilde{g}} = 5.3$ TeV for 3 ab^{-1} and to $m_{\tilde{g}} = 5.9$ TeV for 15 $\text{ab}^{-1}$of integrated luminosity. The impact of the theoretical uncertainties related to the total production rate of gluinos is not taken into account. For comparison, the 5σ discovery reach of LHC14 is (2.4) 2.8 TeV for an integrated luminosity of (300 fb^{-1}) 3 ab^{-1} [141].

Top-squark pair production

In Ref. [142], the reach of a 33 TeV LHC upgrade for top-squark pair production was investigated. Here, we repeat the analysis but for updated LHC energy upgrade $\sqrt{s} = 27$ TeV. We use MADGRAPH [67] to generate top-squark pair production events within a simplified model where $\tilde{t}_1 \to b\widetilde{\chi}_1^{\pm}$ at 50%, and $\tilde{t}_1 \to t\widetilde{\chi}_{1,2}^0$ each at 25% branching fraction, which are typical of most SUSY models [144] with light higgsinos. The higgsino-like electroweakino masses are $m_{\widetilde{\chi}_{1,2}^0,\widetilde{\chi}_1^{\pm}} \simeq 150$ GeV. We also used MADGRAPH-PYTHIA-DELPHES for the same SM background processes as listed above for the gluino pair production case. We required at least two high p_T b-jets, no isolated leptons and large $E_{\text{T}}^{\text{miss}}$, see Ref. [143] for details.

Using these background rates for LHC at $\sqrt{s} = 27$ TeV, we compute the 5σ reach and 95% C.L. exclusion of HE-LHC for 3 and 15 ab^{-1} of integrated luminosity using Poisson statistics. Our results are shown in the right panel of Fig. 2.4.2 along with the top-squark pair production cross section after cuts versus $m_{\tilde{t}_1}$. From the figure, we see the 5σ discovery reach of HE-LHC extends to $m_{\tilde{t}_1} = 2.8$ TeV for 3 ab^{-1} and to 3.16 TeV for 15 ab^{-1}. The 95% C.L. exclusion limits extend to $m_{\tilde{t}_1} = 3.25$ TeV for 3 ab^{-1} and to $m_{\tilde{t}_1} = 3.65$ TeV for 15 ab^{-1}. We checked that S/B exceeds 0.8 whenever we deem the signal to be observable [143]. For comparison, the Atlas projected 95% C.L. LHC14 reach [145] for 3 ab^{-1} extends to $m_{\tilde{t}_1} \simeq 1.7$ TeV (see Section 2.1 for details) assuming $\tilde{t}_1 \to t\widetilde{\chi}_1^0$ decays.

Combined reach for stops and gluinos

In Fig. 2.4.3 we exhibit the gluino and top-squark reach values in the $m_{\tilde{t}_1}$ vs. $m_{\tilde{g}}$ plane. We compare the reach of HL- and HE-LHC to values of gluino and stop masses (shown by the dots) in a variety of natural SUSY models defined to have $\Delta_{\text{EW}} < 30$ [146,147], [1] including the two- and three-extra parameter non-universal Higgs models [149] (nNUHM2 and nNUHM3), natural generalised mirage mediation [150]

[1] The onset of fine-tuning for larger values of Δ_{EW} is visually displayed in Ref. [148].

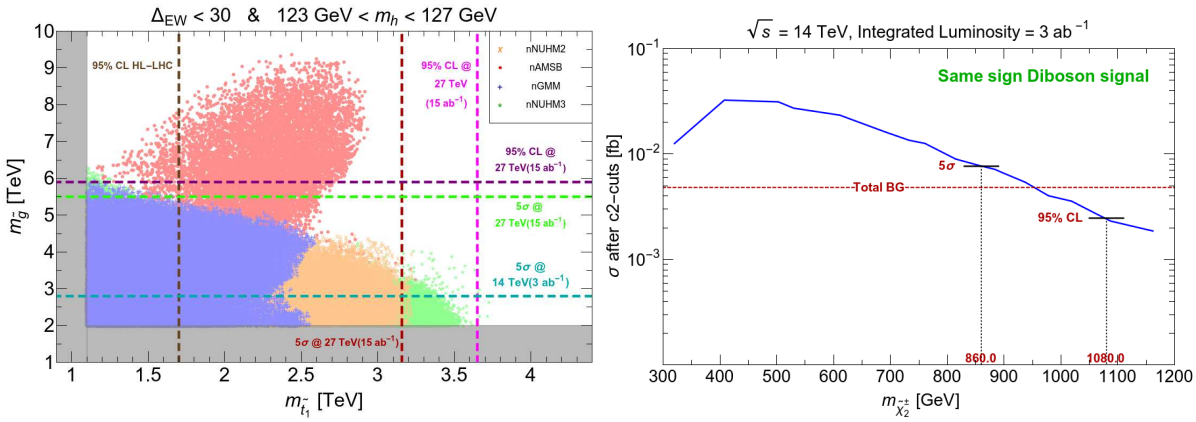

Fig. 2.4.3: Left: points in the $m_{\tilde{t}_1}$ vs. $m_{\tilde{g}}$ plane from a scan over nNUHM2, nNUHM3, nGMM and nAMSB model parameter space. We compare to recent search limits from the ATLAS/CMS experiments (shaded regions) and show the projected reach of HL- and HE-LHC. Right: cross section for SSdB production after cuts versus wino mass at the LHC with $\sqrt{s} = 14$ TeV. We show the 5σ and 95% C.L. reach assuming a HL-LHC integrated luminosity of 3 ab^{-1}.

(nGMM) and natural anomaly-mediation [151] (nAMSB). These models all allow for input of the SUSY μ parameter at values $\mu \sim 100 - 350$ GeV which is a necessary (though not sufficient) condition for naturalness in the MSSM.

The highlight of this figure is that at least one of the gluino or the stop should be discoverable at the HE-LHC. We also see that in natural SUSY models (with the exception of nAMSB), the highest values of $m_{\tilde{g}}$ coincide with the lowest values of $m_{\tilde{t}_1}$ while the highest top squark masses occur at the lowest gluino masses. Thus, a marginal signal in one channel (due to the sparticle mass being near their upper limit) should be accompanied by a robust signal in the other channel. Over most of the parameter range of weak scale natural SUSY there should be a 5σ signal in *both* the top-squark and gluino pair production channels at HE-LHC.

Same-sign diboson signature from wino pair production

The wino pair production reaction $pp \to \tilde{\chi}_2^\pm \tilde{\chi}_4^0$ can occur at observable rates for SUSY models with light higgsinos. The decays $\tilde{\chi}_2^\pm \to W^\pm \tilde{\chi}_{1,2}^0$ and $\tilde{\chi}_4^0 \to W^\pm \tilde{\chi}_1^\mp$ lead to final state dibosons which half the time give a relatively jet-free same-sign diboson signature (SSdB). This has only tiny SM backgrounds [89, 97, 152] and excellent prospects for discovery.

We have computed the reach of HL-LHC for the SSdB signature in Fig. 2.4.3 including $t\bar{t}$, WZ, $t\bar{t}W$, $t\bar{t}Z$, $t\bar{t}t\bar{t}$, WWW and $WWjj$ backgrounds. For LHC14 with 3 ab^{-1} of integrated luminosity, the 5σ reach extends to $m(\text{wino}) \sim 860$ GeV while the 95% C.L. exclusion extends to $m(\text{wino}) \sim 1080$ GeV. In models with unified gaugino masses, these would correspond to a reach in terms of $m_{\tilde{g}}$ of 2.4 (3) TeV, respectively. These values are comparable to what LHC14 can achieve via gluino pair searches with 3 ab^{-1}. The SSdB signature is distinctive for the case of SUSY models with light higgsinos.

While Fig. 2.4.3 presents the HL-LHC reach for SUSY in the SSdB channel, the corresponding reach of HE-LHC has not yet been computed. The SSdB signal arises via EW production, and the signal rates are expected to rise by a factor of a few by moving from $\sqrt{s} = 14$ TeV to $\sqrt{s} = 27$ TeV. In contrast, some of the strongly-produced SM backgrounds like $t\bar{t}$ production will rise by much larger factors. Thus, it is not yet clear whether the reach for SUSY in the SSdB channel will be increased by moving from HL-LHC to HE-LHC. We note though that other signals channels from wino decays to higgsinos plus a W, Z and Higgs boson may offer further SUSY detection possibilities.

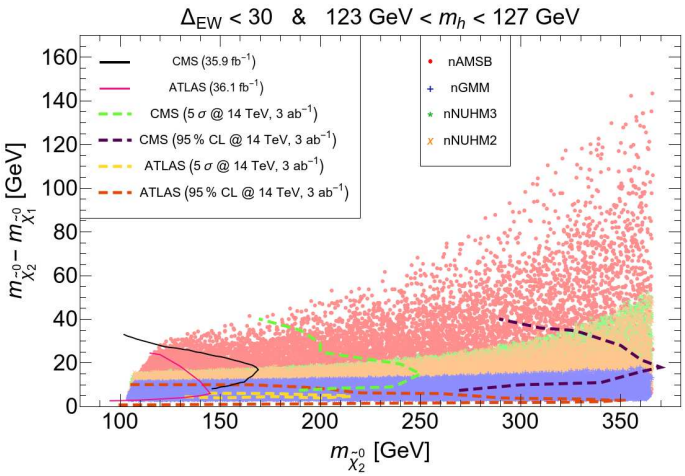

Fig. 2.4.4: Points in the $m_{\tilde{\chi}_2^0}$ vs. $m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}$ plane from a scan over nNUHM2, nNUHM3, nGMM and nAMSB model parameter space. We compare to recent search limits from the ATLAS/CMS experiments and to future reach contours for HL-LHC.

Higgsino pair production at LHC upgrades

The four higgsino-like charginos $\tilde{\chi}_1^{\pm}$ and neutralinos $\tilde{\chi}_{1,2}^0$ are the only SUSY particles required by naturalness to lie near to the weak scale at $m_{weak} \sim 100$ GeV. In spite of their lightness, they are very challenging to detect at LHC. The lightest neutralino evidently comprises just a portion of dark matter [153], and if produced at LHC via $pp \to \tilde{\chi}_1^0\tilde{\chi}_1^0$, $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\mp}$ and $\tilde{\chi}_1^{\pm}\tilde{\chi}_{1,2}^0$ could escape detection. This is because the decay products of $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^{\pm}$ are expected to be very soft, causing the signal to be well below SM processes like WW and $t\bar{t}$ production. The monojet signal arising from initial state radiation (ISR) $pp \to \tilde{\chi}_1^0\tilde{\chi}_1^0 j$, $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\mp} j$ and $\tilde{\chi}_1^{\pm}\tilde{\chi}_{1,2}^0 j$ has been evaluated in Ref. [154] and was found to have similar shape distributions to the dominant $pp \to Zj$ background but with background levels about 100 times larger than signal. However, at HE-LHC harder monojet-like selections may be possible [155], and generic prospects studies are presented in Section 3.1 of this report.

A way forward has been proposed via the $pp \to \tilde{\chi}_1^0\tilde{\chi}_2^0 j$ channel where $\tilde{\chi}_2^0 \to \ell^+\ell^-\tilde{\chi}_1^0$: a soft opposite-sign dilepton pair recoils against a hard initial state jet radiation which serves as a trigger [156]. Experimental prospect searches presented in Section 2.2.5 by ATLAS and CMS exploit this kind of signature. The projected reach for 5σ and 95% C.L. reach at the HL-LHC with 3 ab^{-1} in $\ell^+\ell^- E_{\rm T}^{\rm miss}$ final state events are shown in the $m_{\tilde{\chi}_2^0}$ vs. $m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}$ plane in Fig. 2.4.4. The ATLAS and CMS experiments contours are shown as the yellow, green, purple and red dashed contours. We see that these contours can probe considerably more parameter space although some of natural SUSY parameter space (shown by dots for the same set of models as in Fig. 2.4.3) might lie beyond these projected reaches. So far, reach contours for HE-LHC in this search channel have not been computed but it is again anticipated that HE-LHC will not be greatly beneficial here since $pp \to \tilde{\chi}_1^0\tilde{\chi}_2^0$ is an EW production process so the signal cross section will increase only marginally while SM background processes like $t\bar{t}$ production will increase substantially.

It is imperative that future search channels try to squeeze their reach to the lowest $m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}$ mass gaps which are favoured to lie in the $3-5$ GeV region for string landscape projections [157] of SUSY mass spectra. The Atlas red-dashed contour appears to go a long way in this regard, though the corresponding 5σ reach is considerably smaller.

Summary

We have delineated the reach of the HE-LHC and compared it to the corresponding reach of the HL-LHC for SUSY models with light higgsinos, expected in a variety of natural SUSY models. While the HL-

LHC increases the SUSY search range, it appears that the HE-LHC will definitively probe natural SUSY models with $\Delta_{\rm EW} < 30$ via a 5σ discovery of at least one of the top squark or the gluino (likely even both), possibly also with signals in other channels.

2.4.3 The pMSSM at HL- and HE-LHC

Contributors: A. Arbey, M. Battaglia, F. Mahmoudi

The phenomenological MSSM (pMSSM) [158], contains 20 free parameters, and is the most general CP and R-parity conserving MSSM scenario with minimal flavour violation. It was introduced in order to reduce the theoretical prejudices of the constrained MSSM scenarios. In the following, we consider the case where the lightest neutralino is the LSP and can constitute part or all of the dark matter. Technical details concerning the pMSSM scans and software required for the presented analyses can be found in Ref. [159, 160].

SUSY and Higgs searches:

The direct SUSY searches at the LHC are extremely powerful in probing the strongly interacting sector of the MSSM. Nevertheless, scenarios with compressed spectra or with long decay chains can escape the current searches and remain challenging. In the pMSSM, such cases are not rare, and thus the complementary information from other sectors can be of interest. In particular the Higgs sector, namely the measurement of the couplings of the lightest Higgs boson as well as searches for heavier states can unveil additional MSSM phase space [32], especially during HL and HE runs of the LHC.

In the extended Higgs sector of the MSSM, the couplings of the lightest Higgs boson to up- and down-type quarks are modified by terms inversely proportional to the CP-odd A boson mass as $2M_Z^2/M_A^2 \tan^2\beta$ and $2M_Z^2/M_A^2$ respectively, providing an indirect sensitivity to the scale of M_A, if deviations in the branching fractions to up- and down-type quarks are detected, or a lower bound on M_A, if the coupling properties agree with the SM predictions. At present, the direct sensitivity to the A (and H) boson at the LHC comes mostly from the $pp \to A/H \to \tau^+\tau^-$ process. On the other hand, the bbH associate production and gluon fusion processes decrease the total cross section with $\tan\beta$ up to the point where the b-quark loops take over and the cross section increases. For $\tan\beta < 10$, the decay branching fraction is proportional to $\tan\beta$. Thus, the bounds from the $\tau\tau$ final state become particularly strong for large values of $\tan\beta$ but quite unconstrained for $\tan\beta \simeq 10$.

The modification of the Higgs couplings to fermions induced by loops of strongly interacting SUSY particles, namely the Δ_b correction in the Higgs coupling to $b\bar{b}$ is of special importance, as the SUSY contribution scales with $\mu \tan\beta M_{\tilde{g}}/M^2_{\tilde{g},\tilde{b},\tilde{t}}$. Since the value of $\mu\tan\beta$ can be much larger than the mass of the SUSY particles in the denominator, the SUSY strongly interacting sector does not decouple. Therefore, the study of the Higgs branching fractions, or the Higgs signal strengths, can unravel SUSY scenarios with strongly interacting particles at masses well beyond the kinematic reach of the LHC [161].

The sensitivity to SUSY mass scales is summarised in Fig. 2.4.5, which gives a comparison of the direct and indirect sensitivity to M_A with the mass of the gluino and squarks of the third generation, as a function of the different energies and integrated luminosities of the LHC. Direct searches are accounted for by implementing LHC Run-1 searches in jets + $E_{\rm T}^{\rm miss}$ [162, 163], jets + leptons + $E_{\rm T}^{\rm miss}$ [164–166], leptons + $E_{\rm T}^{\rm miss}$ [85, 167] and monojets [168, 169]. Signal selection cuts corresponding to each of the analyses are applied to these simulated signal events. The number of SM background events in the signal regions are taken from the estimates reported by the experiments. Results are projected to 14 TeV for 300 $\rm fb^{-1}$ and 3 $\rm ab^{-1}$ of integrated luminosity, by generating events at 14 TeV and rescaling the 8 TeV backgrounds by the corresponding increase in cross section and signal cut acceptance at the higher energy [170]. The use of 7 + 8 TeV analyses at the higher energy ensures a constant scaling for the various energy and integrated luminosity conditions considered here. In addition, the constraints from the Higgs signal strengths for the $\gamma\gamma$, WW, ZZ, $\tau\tau$ and $b\bar{b}$ channels have been added. Here we

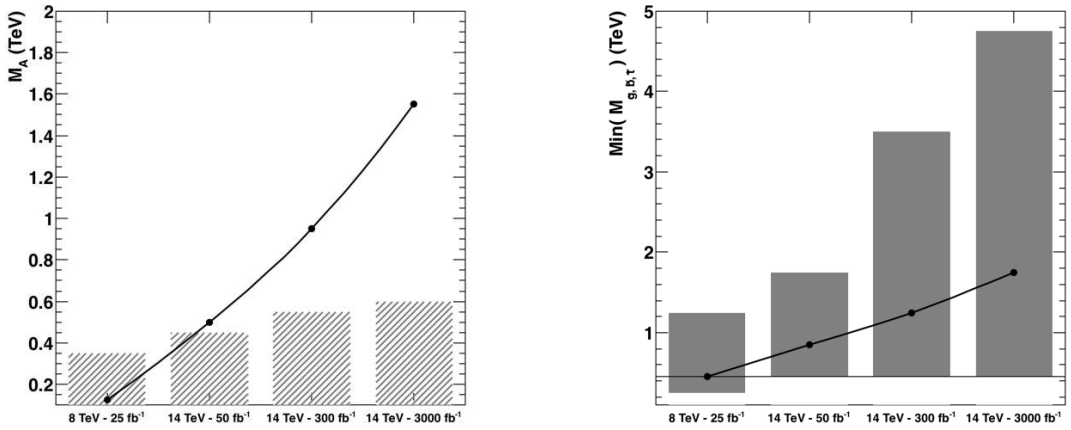

Fig. 2.4.5: Sensitivity to the mass of the CP-odd A boson (left) and the lightest state among $\tilde{g}$, $\tilde{b}$ and $\tilde{t}$ (right) as a function of the energy and luminosity of the LHC, in the pMSSM. The 95% C.L. exclusion range, when the MSSM parameters are varied, are given for the direct search by the continuous line and for the indirect constraints from the h decay properties by the filled bars (from Ref. [161]).

Table 2.4.2: Fractions of pMSSM points excluded by the combination of LHC MET searches, and the LHC Higgs data.

assume SM-like central values and evolve the statistical uncertainties according to the increase of signal events with energy and integrated luminosity [171] following the same procedures as in Ref. [161]. Table 2.4.2 summarises the fraction of pMSSM points with SUSY masses up to 5 TeV excluded by the LHC searches based on $E_{\mathrm{T}}^{\mathrm{miss}}$+jets signatures, and by the addition of the Higgs data.

Monojets

Monojet searches remain a powerful tool for discovery at pp colliders of increasing energy and luminosity and specific prospects for WIMP searches using this signature are presented in this report (Section 3). Beyond those scenarios, the monojet signature can be sensitive to specific MSSM scenarios such as decays with two gluinos or scalar tops and an ISR hard jet, when the scalar top decays are soft enough for the event to be classified as monojet-like. Expanding on the work of [172], we consider here these monojet-like signatures at $\sqrt{s}$ energies of 8, 13, 14 and 27 TeV for two different pMSSM scenarios featuring a light gluino and a light bino neutralino with a mass splitting of 10 GeV, and a light stop and bino-wino neutralino and chargino with a mass splitting slightly smaller than the top quark mass so that the stop decays into three soft jets and the lightest neutralino.

The mass splittings have been chosen to maximise the number of monojet events, and also to ensure the consistency with the dark matter relic density constraint which requires small mass splittings for co-annihilations. It is instructive to consider the scaling of the product of the monojet production cross section times efficiency with respect to the neutralino mass and the collider energy. The acceptance is defined by $\sqrt{s}$-dependent lower cuts on the jet p_T and missing energy ($E_{\mathrm{T}}^{\mathrm{miss}}$), scaled from early LHC monojet and monojet-like analyses [168,169] as discussed in details in Ref. [172]. The results are shown in Fig. 2.4.6. Although the change in cross section times efficiency from 8 to 14 TeV as a function of the mass has been relatively small, the increase in mass coverage afforded by 14 TeV is very significant. This motivates a possible further increase of the energy up to 27 TeV, and beyond.

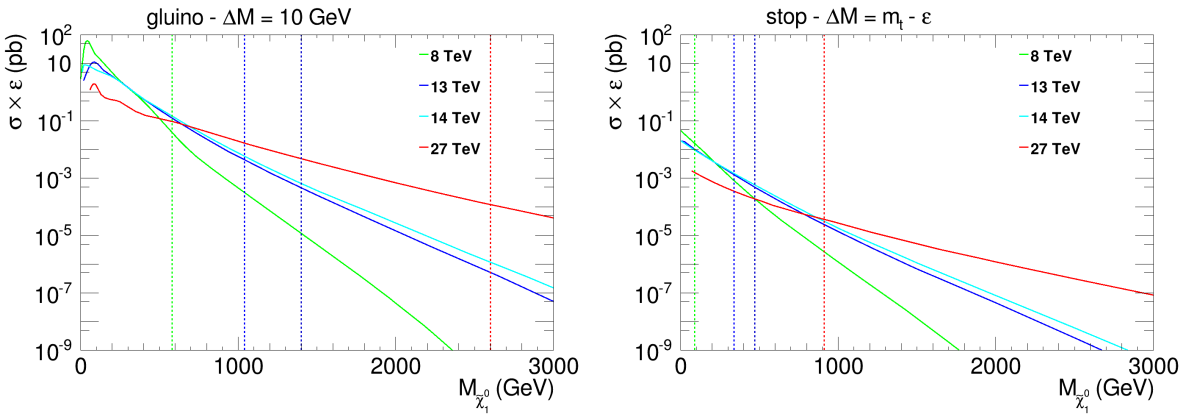

Fig. 2.4.6: Monojet production cross section times acceptance and efficiency as a function of the neutralino mass, for scenarios with a gluino (left) and a stop (right) with small mass splittings with the neutralino LSP. The different curves correspond to $\sqrt{s} = 8$, 13, 14 and 27 TeV LHC c.o.m. energies. The green vertical dashed line corresponds to an indicative exclusion limit by the LHC Run-1, the light (dark) blue line to a prospective limit for the LHC 14 TeV run with 300 fb^{-1} (3 ab^{-1}) of data, and the red line to a potential limit at 27 TeV with 15 $\text{ab}^{-1}$of data.

2.4.4 Z' bosons in supersymmetric and leptophobic scenarios at HL- and HE-LHC

Contributors: J. Y. Araz, G. Corcella, M. Frank, B. Fuks

Searching for heavy neutral vector bosons Z' is one of the challenging objectives of the LHC. Such heavy bosons are predicted by $U(1)'$ models inspired by Grand Unification Theories (GUT) as well as by the Sequential Standard Model (SSM), one of the simplest extensions of the SM wherein Z' and possible W' bosons have the same couplings as the SM Z and W. The LHC experiments have searched for Z' signals by exploring high-mass dilepton and dijet systems and have set exclusion limits of a few TeV on the Z' mass. For studies of Z'-bosons at HL/HE-LHC see Section 6.

While such analyses have assumed that the Z'-boson can only decay into SM channels, recent investigations (see, *e.g.*, Ref. [173, 174]) have considered the possibility that the Z'-boson could decay according to modes BSM, like for instance in supersymmetric final states in the so-called UMSSM framework. From the MSSM viewpoint, extending it via a $U(1)'$ group has the advantage that the extra symmetry forbids a too quick proton decay and allows to stabilise all particle masses with respect to quantum corrections. Regarding the searches, assuming BSM decays lowers the rates into lepton and quark pairs, and therefore milder exclusion limits are to be expected.

Unlike direct sparticle production in pp collisions, the Z' mass sets one further kinematic constrain on the invariant masses of the produced supersymmetric particles. Furthermore, as will be discussed in the following, there are realisations of the $U(1)'$ symmetry wherein, due to the kinetic mixing with the SM $U(1)$ group, the Z' is leptophobic. Leptonic final states can therefore occur, in the UMSSM, only through supersymmetric cascades. Such scenarios avoid the present dilepton bounds and may well be worth to be investigated, especially in the high-luminosity LHC phase.

In what follows we shall review the theoretical framework of our exploration, present some phenomenological results at the HL-LHC and then some final remarks will be given.

Grand-unified theories are based on a rank-6 group E_6, where the symmetry-breaking scheme proceeds via multiple steps:

$$E_6 \to SO(10)\otimes U(1)_\psi \to SU(5)\otimes U(1)_\chi \otimes U(1)_\psi \to SU(3)_C \otimes SU(2)_L \otimes U(1)_Y \otimes U(1)' \,. \quad (2.4.2)$$

The $U(1)'$ symmetry surviving at the EW scale can be expressed as a combination of $U(1)_\chi$ and $U(1)_\psi$, $U(1)' = U(1)_\psi \cos\theta - U(1)_\chi \sin\theta$, where θ is the E_6 mixing angle. The neutral vector bosons associated with $U(1)_\psi$ and $U(1)_\chi$ are called Z'_ψ and Z'_χ, while a generic Z' is given by their mixing.

Parameter	θ	$\tan\beta$	$\mu_{\rm eff}$ [GeV]	$M_{Z'}$ [TeV]	M_0 [TeV]	M_1 [GeV]
BM I	$-0.79\,\pi$	9.11	218.9	2.5	2.6	106.5
BM II	$0.2\,\pi$	16.08	345.3	2.5	1.9	186.7

Parameter	M_2 [GeV]	M_3 [TeV]	M_1' [GeV]	A_0 [TeV]	A_λ [TeV]	$\sin\chi$
BM I	230.0	3.6	198.9	2	5.9	-0.35
BM II	545.5	5.5	551.7	1.5	5.1	0.33

Table 2.4.3: UMSSM parameters for the reference points **BM I** and **BM II**.

We investigate possible Z' supersymmetric decays in the UMSSM. As for the particle content of the UMSSM after EWSB, one is left in the Higgs sector with two charged $H^\pm$ and four neutral scalar bosons, namely one pseudoscalar A and three neutral scalars h, H and H', where h and H are MSSM-like, with h roughly corresponding to the SM Higgs, and H' is a new singlet-like Higgs boson related to the extra $U(1)'$. In the gaugino sector, one has two extra neutralinos with respect to the MSSM, related to the supersymmetric partners of Z' and H', for a total of six $\tilde{\chi}_1^0, \ldots, \tilde{\chi}_6^0$ neutralinos. The chargino sector is unchanged, since the Z' is electrically neutral.

It was found in Ref. [175] that the very inclusion of supersymmetric modes lowers the exclusion limits on $M_{Z'}$ obtained from the analysis of the dilepton channels by about $200 - 300$ GeV, depending on the $U(1)'$ model, while searches relying on the dijet mode, which already exhibit milder limits, are basically unconstraining once BSM channels are accounted for.

In the present investigation, the mixing between the new $U(1)'$ and the SM groups plays a crucial role. First, there could be some mass mixing between the Z and Z' eigenstates parametrised by a mixing angle $\alpha_{ZZ'}$, which is nevertheless constrained by the EW precision tests (EWPT) to be very small [176]. Then, the Z and Z' can kinematically mix through an angle χ, which modifies the interaction term between the Z' and the fermions. In detail, after accounting for the kinetic mixing, the interaction of the Z' with a fermion ψ_i having charges Y_i and Q_i' under $U(1)_Y$ and $U(1)'$ is given by the Lagrangian

$$\mathcal{L}_{\rm int} = -g' \bar{\psi}_i \gamma^\mu \bar{Q}_i Z'_\mu \psi_i \,, \tag{2.4.3}$$

where $\bar{Q}_i = \frac{Q_i'}{\cos\chi} - \frac{g_1}{g'} Y_i \tan\chi$ is the modified fermion $U(1)'$ charge after kinetic mixing and g' is the $U(1)'$ coupling constant. Leptophobic scenarios can hence be obtained by requiring $\bar{Q}_i = 0$ for both left- and right-handed leptons, *i.e.*, $\bar{Q}_L = \bar{Q}_E = 0$ [177]. As discussed in Ref. [175], the leptophobic condition can be naturally achieved for the model labelled as $U(1)'_\eta$, corresponding to an E_6 mixing angle $\theta = \arccos\sqrt{5/8}$. Furthermore, using the typical GUT-inspired proportionality relation between the coupling constants of $U(1)$ and $U(1)'$ $g' = \sqrt{\frac{5}{3}}\, g_1$, the leptophobic condition is realised for $\sin\chi \approx -0.3$. As pointed out in Ref. [175], this relation can be defined either at the Z' mass scale, *i.e.* O(TeV), or at the GUT scale. Imposing unification at the Z' scale clearly yields a higher value of g' and hence a larger Z' production cross section at the LHC. In the following, we assume unification at the TeV scale.

Following [175], two UMSSM benchmark points are considered for this study, denoted by **BM I** and **BM II**, consistent with the current experimental data and featuring a leptophobic Z'. In both cases the Z' mass is set to $M_{Z'} = 2.5$ TeV. In Table 2.4.3, the relevant parameters for these reference points are reported: the particle mass spectrum can be calculated by using the SARAH code [116] and its interface with SPHENO [178]. The particle masses and the decay tables of **BMI** and **BMII** have been given in Ref. [175] and we do not quote them here for the sake of brevity. The Z' BRs into BSM final states are of about 12% for **BM I** and 15% for **BM II**. In particular, the BR of the Z' into chargino pairs

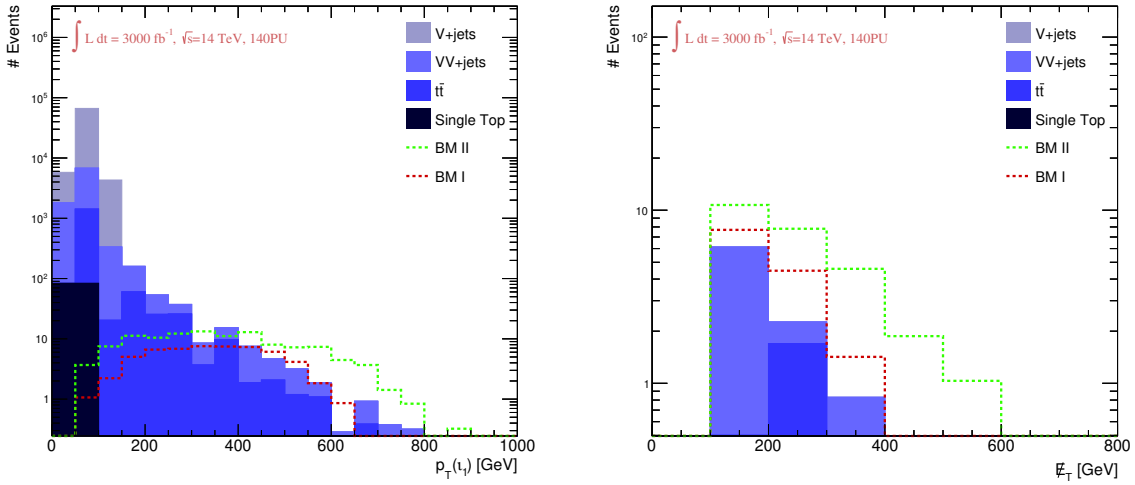

Fig. 2.4.7: Transverse momentum distribution of the leading muon l_1 after applying the first 6 cuts (left) and missing transverse-energy spectrum after all cuts (right) for both leptophobic UMSSM benchmark signals and backgrounds.

$\tilde{\chi}_1^+\tilde{\chi}_1^-$ is about 2% in **BM I** and 6% in **BM II**.

Since in **BM I** and **BM II** the mass splitting between the lightest charginos and neutralinos is larger than the W mass ($M_{\tilde{\chi}_1^\pm} \simeq 177$ GeV and $M_{\tilde{\chi}_1^0} \simeq 95$ GeV in **BM I**, $M_{\tilde{\chi}_1^\pm} \simeq 344$ GeV and $M_{\tilde{\chi}_1^0} \simeq 178$ GeV in **BM II**), then $\tilde{\chi}_1^\pm$ can undergo the transition $\tilde{\chi}^\pm \to W^\pm\tilde{\chi}_1^0$ with real W-bosons. As a case study of a leptophobic Z' in the UMSSM at the HL-LHC, we then explore the decay chain

$$pp \to Z' \to \tilde{\chi}_1^+\tilde{\chi}_1^- \to l^+l^-\not{E}_T, \tag{2.4.4}$$

where we have assumed that both W-bosons decay leptonically and $\not{E}_T$ is the missing transverse energy carried away by final-state neutrinos and neutralinos. The amplitudes of the process (2.4.4) have been computed at the NLO accuracy by means of MADGRAPH5_aMC@NLO [67], yielding a cross section of about $\sigma(pp \to Z') \simeq 120$ pb. In our phenomenological study, parton showers and hadronisation are provided by PYTHIA 8 [68], with the response of a typical LHC detector modelled according to the DELPHES 3 package [33] (version 3.3.2), the detector parameterisation being the one provided by Snowmass [179, 180]. While the default mean number of pile-up events is in this case of 140 and thus a bit low, our analysis essentially relies on very hard isolated leptons (with transverse momenta larger than 200 GeV) and a large amount of missing energy (greater than 100 GeV) which are expected to only be slightly affected by the differences. Jets are clustered following the anti-k_T algorithm [34] with a radius parameter $R = 0.6$, as implemented in the FASTJETprogram (version 3.1.3) [35].

As backgrounds to our signal, we consider single vector-boson (V) and vector-boson pair (VV) production, possibly accompanied by jets, top-quark pairs and single-top events. Our results concern pp collisions at 14 TeV and an integrated luminosity of $\mathcal{L} = 3\,\text{ab}^{-1}$, which corresponds to the HL-LHC. We require two charged muons in the final state at an invariant opening angle ΔR larger than 2.5 and take into account only isolated muons, with an activity of at most 15% of the muon transverse momentum lying in a cone of radius 0.4 centred on the muon; also, we set cuts of 300 GeV and 200 GeV on the hardest and next-to-hardest lepton and force the missing transverse momentum to be above 100 GeV. Setting such cuts, we are able to separate the signal from the background with significances s and Z_A, defined by

$$s = \frac{S}{\sqrt{B+\sigma_B^2}}, \quad Z_A = \sqrt{2\left((S+B)\ln\left[\frac{(S+B)(S+\sigma_B^2)}{B^2+(S+B)\sigma_B^2}\right] - \frac{B^2}{\sigma_B^2}\ln\left[1+\frac{\sigma_B^2 S}{B(B+\sigma_B^2)}\right]\right)}, \tag{2.4.5}$$

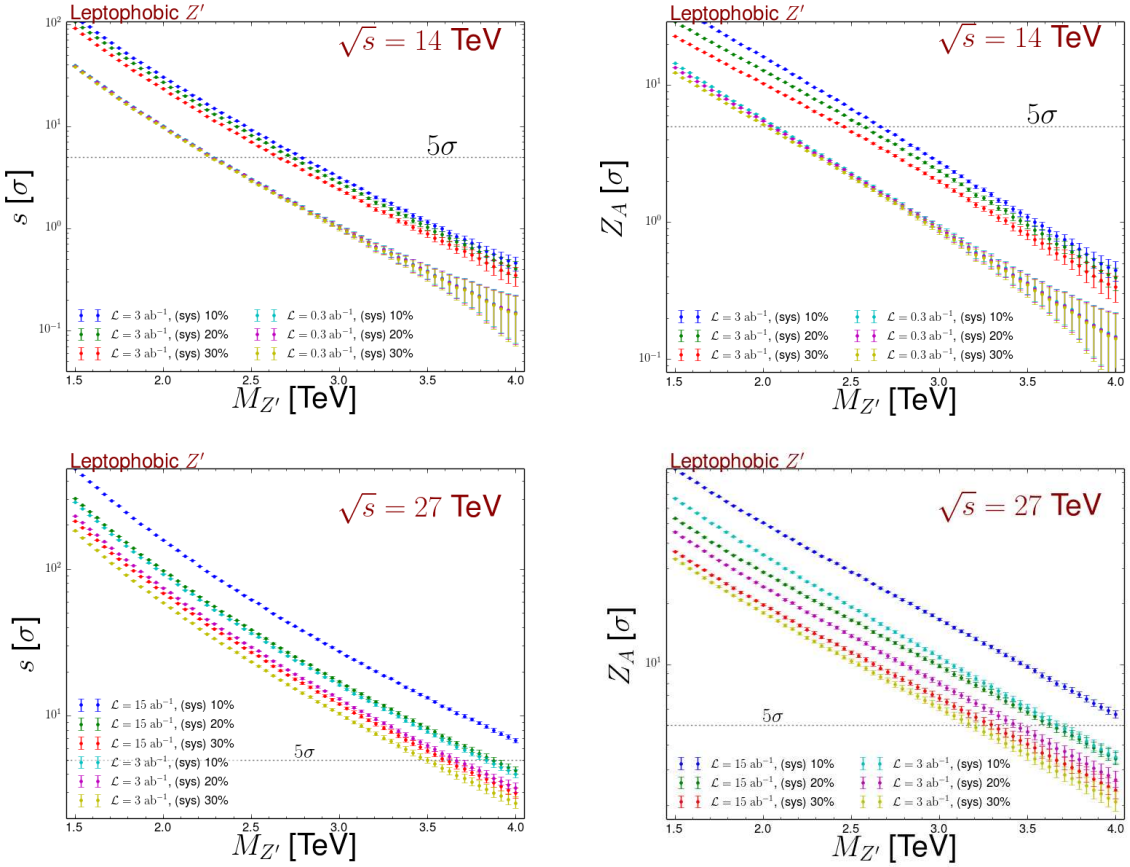

Fig. 2.4.8: Significances s (right) and Z_A (left) to discover a leptophobic Z' boson decaying into charginos as a function of its mass $M_{Z'}$, for a few values of luminosity and systematic error on the SM background. All results are obtained for a c.o.m. energy $\sqrt{s} = 14$ TeV (top) and $\sqrt{s} = 27$ TeV (bottom).

varying between 3σ and 7σ. Besides the total number of events, one can explore differential distributions, such as the leading-lepton transverse momentum or the missing transverse energy presented in Fig. 2.4.7. As for the $p_T(l_1)$ spectrum (left), all four considered backgrounds contribute at small p_T, while above 100 GeV only VV and $t\bar{t}$ events survive. The signal spectra are broad and below the backgrounds at low transverse momentum, whereas, for $p_T(l_1) > 300$ GeV, both **BM I** and **BM II** signals are competitive with the background. For even larger p_T, say $p_T(l_1) > 500$ GeV, muons coming from supersymmetric decays of a leptophobic Z' become dominant, especially for the reference point **BM II**. In Fig. 2.4.7 (right) we present the missing transverse energy, due to the lightest neutralinos $\tilde{\chi}_1^0$ in the signal and to neutrinos in the backgrounds, after all cuts are imposed. Our $\not{E}_T$ signal spectra are well above the backgrounds due to VV and $t\bar{t}$ production. The **BM II** scenario, in particular, is capable of yielding a few events up to $\not{E}_T \simeq 600$ GeV, while all backgrounds are negligible for $\not{E}_T > 400$ GeV.

We present projections for proton-proton collisions at 14 TeV and 27 TeV as functions of the luminosity, $M_{Z'}$ and different assumptions for the systematic uncertainties on the background. We consider a leptophobic Z' decaying into charginos and refer to the BM II reference point as it turns out to be the more promising setup for a possible discovery of a Z' boson in supersymmetric and leptophobic scenarios. In Fig. 2.4.8 we show the significances s (left) and Z_A (right) at 14 TeV (up) and 27 TeV (down), for a Z' mass in the 1.5 TeV $< M_{Z'} <$ 4 TeV mass window. In each figure, we consider two luminosity options chosen to be 300 fb^{-1} and 3 ab^{-1} for a collisions at a c.o.m. energy of 14 TeV, and 3 $\mathrm{ab}^{-1}$and 15 $\mathrm{ab}^{-1}$for 27 TeV collisions. We moreover allow the systematics σ_B on the SM background to vary from 10% to 30% of the background itself.

It turns out that with $300\,\mathrm{fb}^{-1}$ of 14 TeV collisions, leptophobic $Z'$with masses ranging up to 2.3 TeV could be discovered (*i.e.* $s \geq 5\sigma$) regardless of the assumption on the systematic errors (Fig. 2.4.8, top left). In the high-luminosity phase of the LHC, with a luminosity of $3\,\mathrm{ab}^{-1}$, the lower bound on the Z' mass increases to 2.6 TeV (for $\sigma_B = 0.3B$) or 2.8 TeV (for more optimistic systematics of $\sigma_B = 0.1B$). In terms of Z_A, the discovery reach is reduced to $M_{Z'} = 2$ TeV for $300\,\mathrm{fb}^{-1}$, again independently of any assumption on the background systematics σ_B, and to $2.5\,\mathrm{TeV} < M_{Z'} < 2.7\,\mathrm{TeV}$ for $3\,\mathrm{ab}^{-1}$ (Fig. 2.4.8, top right).

In the high-energy phase of the LHC at 27 TeV (Fig. 2.4.8 bottom), a visible Z'signal can be obviously obtained even for much higher masses. In detail, a significance of $s = 5\sigma$ can be reached for Z' masses ranging up to $3.8 - 4$ TeV at 27 TeV and for a luminosity of $15\,\mathrm{ab}^{-1}$. The limits are slightly worse for a reduced luminosity of $3\,\mathrm{ab}^{-1}$and then reach $3.5 - 3.7$ TeV. Using in contrast a more conservative definition of the significance Z_A, we obtain a reach of $3.7 - 4$ TeV for $15\,\mathrm{ab}^{-1}$and only of $3.2 - 3.5$ TeV for a luminosity of $3\,\mathrm{ab}^{-1}$.

We explored possible loop-holes in GUT-inspired Z' searches at the LHC by investigating supersymmetric and leptophobic models, finding that the inclusion of BSM decay modes lowers the exclusion limits on $M_{Z'}$ in dilepton final states by a few hundred GeV and that the limits from dijets can be evaded as well. In leptophobic models, only supersymmetric Z' decay chains can give rise to charged leptons. As a case study, we considered the decay of a leptophobic Z' with mass $M_{Z'} = 2.5$ TeV into charginos, leading to final states with leptons and missing energy. We chose two benchmark points in the UMSSM parameter space and found that both yield a substantial signal at LHC, which one can separate from the background with a sensitivity between 3σ and 7σ at 14 TeV and $3\,\mathrm{ab}^{-1}$. We finally investigated the reach of the high-luminosity and high-energy LHC runs in terms of the Z' mass and systematic uncertainty on the background. We found that at 14 TeV and $3\,\mathrm{ab}^{-1}$a leptophobic Z' can be discovered with a significance about 5σ for a mass $M_{Z'} < 2.8$ TeV, while at 27 TeV and $15\,\mathrm{ab}^{-1}$one can explore leptophobic and supersymmetric Z' models up to about $M_{Z'} \simeq 4$ TeV. These result make therefore the investigation of such scenarios both feasible and worthwhile at HL- and HE-LHC.

3 Dark Matter and Dark Sectors Searches

There is now overwhelming evidence for the existence of a new matter component of the universe, dark matter (DM). Precision measurements of the cosmic microwave background and gravitational lensing measurements confirm the presence of this non-luminous matter. Through its gravitational interactions we know that dark matter makes up $\sim 26\%$ of the matter-energy budget of the universe, and that the stars of the Milky Way move inside a far larger, approximately spherical, dark matter halo. However, the nature and properties of DM remain largely unknown. Searches for DM particles are performed using multiple, complementary, approaches: the measurement of elastic scattering of DM with nuclei and electrons in a detector (direct detection) [181], the detection of SM particles produced in the annihilations or decays of DM in the universe (indirect detection) [182–186], the study of the effect of DM self interactions on astrophysical systems [187], and the production of DM particles at colliders [188, 189]. The latter process is the focus of this section.

These various approaches are very complementary in nature. For instance, the first three techniques all require relic DM to interact and thus suffer from uncertainties related to our knowledge of DM's distribution whereas the production of DM at colliders does not, but is instead limited by the kinematic reach of the machine. By combining the results of all search techniques we gain a deeper understanding of the nature of dark matter.

Dark Matter production by itself does not lead to an observable signal at hadronic machines, where the total c.o.m. energy of the collision is not known. Instead if the DM system recoils against visible activity it can be searched for as missing transverse energy and momentum. We catalogue the search strategies for DM composed of a by what this visible activity is, and report on prospective DM studies in Section 3.1 to Section 3.3, while Section 3.4 is focused on searches for light vector bosons associated with forces in the dark sector. In particular, if this dark sector force is abelian then the associated "dark photon" can kinetically mix with the $U(1)$ in the SM, leading to lepton pairs, possibly with displacement, or missing energy signals.

DM production in association with a high p_T jet is presented in Section 3.1, with sensitivities depending on the careful assessment of systematics. This channel is a useful probe of DM production through the exchange of a neutral mediator that couples to the SM. It may also be produced in the decay of an exotic coloured state. Furthermore, compressed SUSY scenarios, such as higgsino or wino DM, can be probed through the monojet signature.

DM production in association with heavy flavour quarks is presented in Section 3.2. The HL-LHC will improve the sensitivity to mediator masses by a factor of 3-8 relative to the Run-2 searches with $36\ \mathrm{fb}^{-1}$, while HE-LHC will extend the coverage to otherwise inaccessible regions of the parameter space. The case of 2HDMa models is complemented by 4-top final states at HL-LHC, searched in events with two same-charge leptons, or with at least three leptons. While searches using $36\ \mathrm{fb}^{-1}$ Run-2 data have limited sensitivity considering the most favourable signal scenarios (*e.g.* $\tan\beta = 0.5$), HL-LHC will probe possible evidence of a signal with $\tan\beta = 1$, $m_H = 600$ GeV and mixing angle of $\sin\theta = 0.35$, assuming m_a masses between 400 GeV and 1 TeV, and will allow exclusion for all $200\ \mathrm{GeV} < \mathrm{m_a} < 1\ \mathrm{TeV}$.

Prospect studies where DM is produced in association with, or through interactions with, EW gauge bosons are reported in Section 3.3. Compressed SUSY scenarios, as well as other DM models, can be targeted using signatures such as mono-photon and vector-boson-fusion (VBF) production, in addition to the classic monojet channel. We show that mono-photon and VBF events allow targeting an EW fermionic triplet (minimal DM), equivalent to a wino-like signature in SUSY, for which there is no sensitivity in Run-2 searches with $36\ \mathrm{fb}^{-1}$. Masses of the $\tilde{\chi}_1^0$ up to 310 GeV (130 GeV) can be excluded by the mono-photon (VBF) channel, with improvements being possible, reducing the theoretical uncertainties. Projections for searches for a mono-Z signature with $Z \to \ell^+\ell^-$ recoiling against missing E_T, have been interpreted in terms of models with a spin-1 mediator and 2HDMa models. The exclusion is

expected for mediator masses up to 1.5 TeV, and for DM and pseudoscalar masses up to 600 GeV, a factor of ~ 3 better than the 36 fb^{-1} Run-2 constraints. The potential to target Higgs portal models and prospects for the HL- and HE-LHC to probe viable multi-TeV dark matter are also presented.

Simple DM models consist of a DM particle and a mediator that couples it to the SM. The DM may, however, sit in a larger *hidden* (or *dark*) sector with additional new states and new interactions. If these interactions include a light $U(1)$ gauge boson, A', this dark photon may mix, through the kinetic-mixing portal, with the SM photon leading to interesting collider signatures. In Section 3.4, searches for dark photons under various hypotheses of dark sectors are presented. Prospects for an inclusive search for dark photons decaying into muon or electron pairs indicate that the HL-LHC could cover a large fraction of the theoretically favoured $\epsilon - m_{A'}$ space, where ϵ is the size of the kinetic mixing between the photon and the dark photon.

3.1 Dark Matter and Jets

If DM is produced in association with QCD activity it is typically searched for in the monojet channel. The DM may be produced through a SM neutral mediator, see Section 3.1.1, or it may be produced as the decay product of a new heavy coloured state, see Section 3.1.2. Monojet-like signatures can be exploited to search for higgsinos and winos in SUSY, see Section 3.1.3. If the parent state that decays to DM is charged and relatively long lived it is more efficient to search in the disappearing track topology. Additional discussion of disappearing track analyses, in the context of long lived particle searches, can be found in Section 4.1.

3.1.1 Studies on the sensitivity to Dark Matter of the monojet channel at HL-LHC

Contributors: G. Frattari, V. Ippolito, G. Gustavino, J. Stupak, ATLAS

The goal of this study, detailed in [190], is to evaluate the impact of different assumed systematic uncertainty scenarios on the expected sensitivity to WIMP Dark Matter in the jet+$E_{\text{T}}^{\text{miss}}$ channel, based on the extrapolation to higher luminosity of the limits published by the ATLAS Collaboration with 36. fb^{-1} of pp collisions at a c.o.m. energy $\sqrt{s} = 13$ TeV [191]. The WIMPs escape the detector giving rise to large $E_{\text{T}}^{\text{miss}}$ arising if they recoil against a jet from initial state radiation (ISR) off the colliding partons, leading to the so-called monojet topology. The $E_{\text{T}}^{\text{miss}}$ in this study is calculated treating electrons and muons as invisible particles. The strategy pursued takes signal and background $E_{\text{T}}^{\text{miss}}$ distributions from the Run-2 ATLAS data analysis and scales them to 300 $\text{fb}^{-1}$and 3 ab^{-1}, exploring various scenarios for the scaling of the systematic uncertainties.

The dominant backgrounds for the 13 TeV data analysis come from W/Z+jets processes. These backgrounds are estimated using MC samples generated with SHERPA 2.2.1. MC samples are reweighted to account for higher-order QCD and EW corrections following the procedure described in Ref. [192] and are normalised in dedicated control regions (CR) described below. Sub-leading backgrounds consist of $t\bar{t}$ and single-top production, which are generated via POWHEG-BOX v2 and showered with PYTHIA 8, and diboson processes, which are taken from SHERPA. The benchmark signal process is generated for WIMP masses in the range 1 GeV $-$ 1 TeV and mediator masses in the range 10 GeV $-$ 10 TeV using POWHEG-BOX v2 with the DMV model [193], assuming mediator couplings to the quark and WIMP of $g_q = 0.25$ and $g_\chi = 1$, respectively. The small multijet and non-collision backgrounds, which are estimated from data in the 13 TeV analysis, are neglected.

The event selection follows that applied in the 13 TeV analysis and selects events with $E_{\text{T}}^{\text{miss}} > 250$ GeV in association with at least one high-p_T jet. Up to three additional jets are allowed and all jets are required to be well separated from the missing transverse momentum direction in azimuth. The signal region is required to contain no reconstructed electron or muon. Four additional CRs to isolate the dominant backgrounds are defined based on the number and type of leptons. Events with exactly one muon, no other leptons, and transverse mass in the 30–100 GeV range form the W+jets

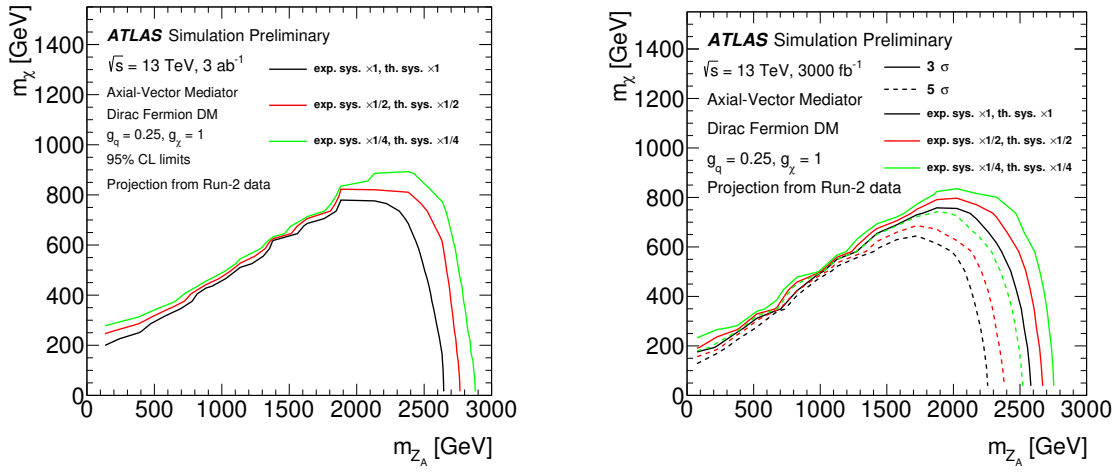

Fig. 3.1.1: Left: expected 95% C.L. excluded regions in the (m_χ, m_{Z_A}) mass plane for the axial-vector simplified model with couplings $g_q = 0.25$ and $g_\chi = 1$, for a luminosity of 3 ab^{-1}. Three contours are shown in each plot, corresponding to the three different systematic uncertainty scenarios: standard (black), reduced by a factor 2 (red) and 4 (green). Right: 3σ and 5σ discovery contours corresponding to the three different systematic uncertainty scenarios: standard (black), reduced by a factor 2 (red) and 4 (green).

($t\bar{t}$) CR if they have zero (at least one) b-tagged jet. A second W+jets CR is built by requiring exactly one electron, no other leptons, and the same transverse mass requirement. Finally, events with 2 muons with an invariant mass consistent with the Z boson form the Z+jets CR. A simultaneous, binned likelihood fit of a signal plus background model to the simulated $E_{\mathrm{T}}^{\mathrm{miss}}$ distributions of the analysis regions is performed. The signal normalisation and two additional normalisation factors, one which rescales the prediction for processes containing Z and W bosons produced in association with jets, and one for $t\bar{t}$ and single-top production, are free parameters of the fit. Nuisance parameters with Gaussian constraints are used to describe the effect of systematic uncertainties on the signal and background $E_{\mathrm{T}}^{\mathrm{miss}}$ distributions. Correlations of systematic uncertainties across $E_{\mathrm{T}}^{\mathrm{miss}}$ bins are taken into account.

The projection for high luminosity proceeds as follows:

- The $E_{\mathrm{T}}^{\mathrm{miss}}$ distributions for signal and the main backgrounds from the 13 TeV data analysis in Run-2 are scaled from 36.1 fb^{-1} to 3 ab^{-1}. The increased statistics achieved by the higher luminosity allows the discriminant to be binned more finely, increasing the number of $E_{\mathrm{T}}^{\mathrm{miss}}$ bins from 10 in the recent data analysis to 17 for the high-luminosity projection. The lower end of the last $E_{\mathrm{T}}^{\mathrm{miss}}$ bin, 1.6 TeV, is chosen in order to keep a similar level of uncertainty on signal and control region as for the Run-2 search. This turns into an improvement of about 100 GeV in the projected mediator mass reach.
- The background distributions are further scaled up by a factor of 1.27 (1.06) for Z/W+jets ($t\bar{t}$ and single top) in order to reflect the observation in the CRs of the Run-2 data analysis.
- No correction is made for the increase in the c.o.m. energy to 14 TeV at the HL-LHC since the dedicated NLO QCD and EW corrections for the main W/Z+jets background are not available. Given the signal cross-section would be expected to increase by $20-40\%$, while the dominant W/Z+jets background cross section will increase by $10-15\%$, this leads to a conservative estimate of the potential and the actual sensitivity will be slightly better than estimated here.

In Ref. [191], the main background experimental uncertainties for $E_{\mathrm{T}}^{\mathrm{miss}} > 250$ GeV (> 1 TeV) are related to the leptons (jet and $E_{\mathrm{T}}^{\mathrm{miss}}$ scales and resolution), amounting up to 1.7% (5.3%), while the main background theoretical uncertainties are related to the W/Z parton shower modelling and PDF (W/Z QCD and EW corrections), amounting to 0.8% (2%). The signal predictions are mainly affected

by jet and $E_{\mathrm{T}}^{\mathrm{miss}}$ scale and resolution uncertainties on the experimental side, and on the theory side by initial/final-state radiation and PDF uncertainties. In the high-luminosity projection, three different systematic uncertainty scenarios are tested to reflect the possible improvements in detector performance and in the theoretical modelling of signal and background processes, which could be achieved in the next years thanks to the foreseen detector upgrades and to progress in QCD and EW calculations:

- standard: same uncertainties as in Ref. [191];
- reduced by factor 2: all pre-fit signal and background uncertainties are reduced by a factor two;
- reduced by factor 4: all pre-fit signal and background uncertainties are reduced by a factor four;

The projected exclusion limits with a luminosity of 3 $\mathrm{ab}^{-1}$for these three scenarios are plotted in the (m_χ, m_{Z_A}) mass plane in Fig. 3.1.1 (left), where χ is the WIMP DM candidate and Z_A the axial-vector mediator. The 95% C.L. exclusion contour for $m_\chi = 1$ GeVcan be up to $m_{Z_A} = 2.65$ TeV, assuming the same uncertainties as in Ref. [191]. The excluded region that can be obtained by reducing by a factor two (four) all systematic uncertainties reaches, for low m_χ, mediator masses of about 2.77 (2.88) TeV. Small differences between systematic uncertainty scenarios are observed when approaching the region where the decay of the mediator in two WIMPs is off-shell ($m_{Z_A} < 2m_\chi$), due to the decrease of the signal cross-section. The discovery contours at 3 and 5σ are shown in Fig. 3.1.1 (right): for $m_\chi = 1$ GeV, a background incompatibility greater than 5σ would be reached for $m_{Z_A} = 2.25$ TeV, 2.38 TeV and 2.52 TeV assuming the same uncertainties as in Ref. [191], the scenario obtained by reducing by a factor two, and by a factor four all the systematic uncertainties, respectively. The increase in sensitivity of the scenarios with lowered systematic uncertainties was checked to be mainly driven by the reduction in the theoretical uncertainties. Among these, V+jets and diboson uncertainties, as well as theoretical uncertainties on signal processes, are similar in size and give the leading contributions.

3.1.2 Monojet Signatures from Heavy Coloured Particles at HL- and HE-LHC

Contributors: A. Chakraborty, S. Kuttimalai, S. H. Lim, M. M. Nojiri, and R. Ruiz

Search strategies for hypothetical coloured particles $\mathcal{Q}$ that can decay to dark matter candidates usually involve jets and leptons produced in association with large missing transverse energy $E_{\mathrm{T}}^{\mathrm{miss}}$. In compressed mass spectrum scenarios the visible decay products in the $\mathcal{Q} \to$DM+SM process do not have sufficient momenta to be readily distinguished from SM backgrounds and monojet-like topologies arise.

Were evidence for a new particle $\mathcal{Q}$ established at the LHC, or a successor experiment such as the HE-LHC, it would be crucial to determine the properties of $\mathcal{Q}$, especially its mass, spin, and colour representation, in order to help understand the nature of DM. Such a program would typically include investigating various collider observables that can discriminate against possible candidates for $\mathcal{Q}$, and hence requires that observables are known to sufficiently high precision. It is the case though that leading order (LO) calculations are poor approximations for QCD processes, even when using sensible scale choices. The situation, however, is more hopeful with the advent of general-purpose precision Monte Carlo event generators HERWIG [194], MADGRAPH5_AMC@NLO+PYTHIA 8 [67,68], and SHERPA [195]. With automated event generation up to NLO in QCD with parton shower (PS) matching and multijet merging, even for BSM processes [196], one can now systematically investigate the impact of crucial $\mathcal{O}(\alpha_s)$ corrections on the inclusive monojet process.

We now summarise the key findings of a recent [197] investigation into the prospect for determining the properties of a hypothetical heavy resonance $\mathcal{Q}$ associated with DM via the the monojet signature. This includes systematically quantifying theory uncertainties associated with the renormalisation, factorisation, and parton shower scales as well as those originating from distribution functions and and multijet merging using state-of-the-art technology. One finds that in aggregate, the total uncertainties are comparable to differences observed when varying $\mathcal{Q}$ itself. However, the precision achievable with

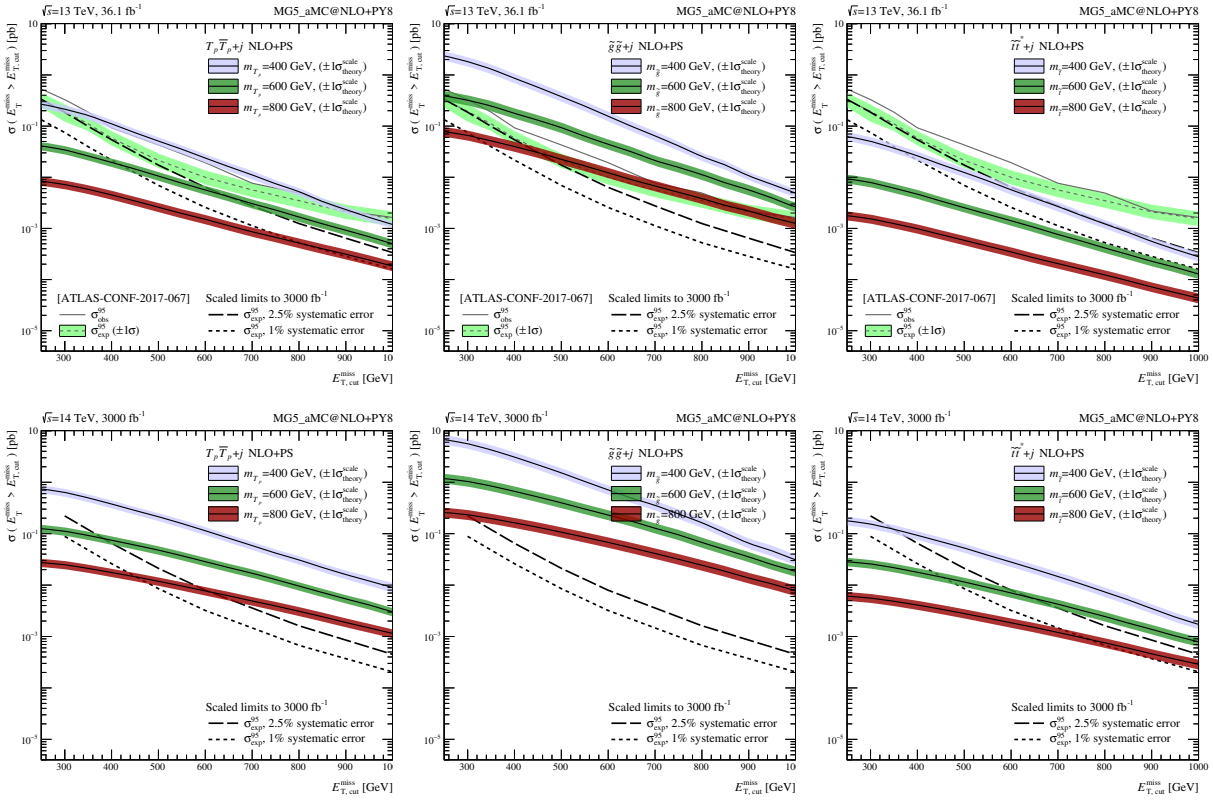

Fig. 3.1.2: Top: $pp \to \mathcal{Q}\overline{\mathcal{Q}} + j$ cross section as a function of minimum $E_{\mathrm{T}}^{\mathrm{miss}}$ after the experimental selection criteria at 13 TeV, for $\mathcal{Q} = T_p$, $\tilde{g}$, and $\tilde{t}$, with current 95% C.L. limits after $\mathcal{L} = 36.1\ \mathrm{fb}^{-1}$ of data at the 13 TeV LHC. Bottom: same plots for 14 TeV LHC. We also shown the estimated sensitivity with $\mathcal{L} = 3\ \mathrm{ab}^{-1}$, assuming $\delta_{\mathrm{Syst.}} = 2.5\%$ and 1% systematical errors.

next-to-next-to-leading order (NNLO) calculations, where available, can resolve this dilemma. In light of this, we further emphasise that the HL- and HE-LHC runs possibly resolve different candidates for the new coloured particle. For additional details beyond what is provided here, see Ref. [197].
The ATLAS and CMS collaborations have studied $\mathcal{L} = 36.1\ \mathrm{fb}^{-1}$ of $\sqrt{s} = 13$ TeV collision data using signatures with significant transverse momentum imbalance and at least one energetic jet [198, 199]. The non-observation of significant deviations from SM predictions leads to model-independent 95% C.L. upper limits on the production cross section of new particles. In Fig. 3.1.2, we show these experimental limits along with NLO+PS-accurate cross section, and associated scale uncertainty, for the $\mathcal{Q}\overline{\mathcal{Q}} + j$ process, where we include a hard jet at the matrix-element level, and for $\mathcal{Q} \in \{\tilde{t}, T_p, \tilde{g}\}$, as listed in Table 3.1.1.

We find that the lower limits on $\mathcal{Q}$ masses stand at around $m_{T_p} = 400$ GeV for the fermionic top partner and $m_{\tilde{g}} = 600$ GeV for the gluino, while no constraint on stop masses is found within the mass range under consideration. It has been observed that for high-p_T bins both the systematic and

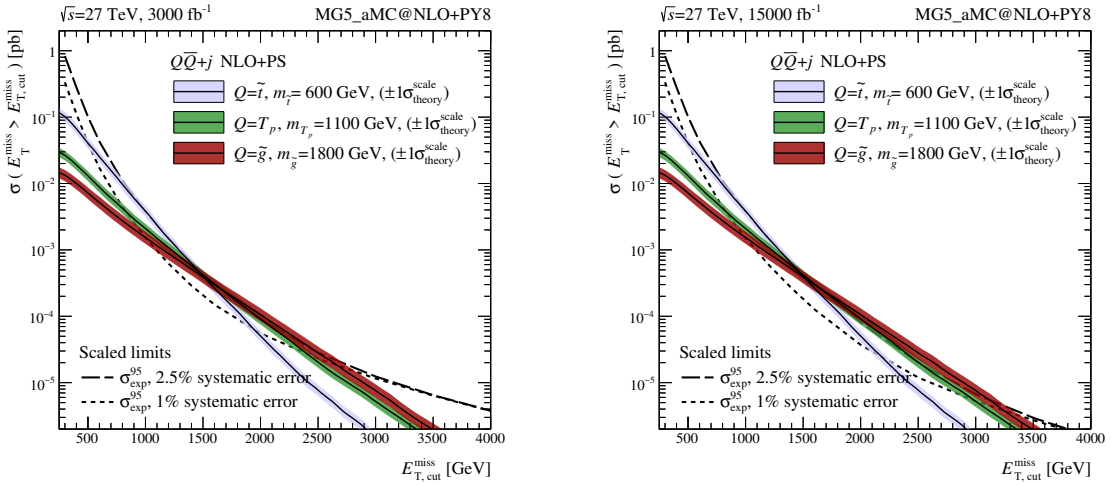

Fig. 3.1.3: Same as Fig. 3.1.2 but scaled for $\sqrt{s} = 27$ TeV assuming $\mathcal{L} = 3$ ab^{-1} (left) and 15 ab^{-1} (right).

statistical experimental uncertainties play a crucial role. Sensitivity is expected to improve at the HL-LHC due to a much larger dataset with better control on uncertainties. We calculate the expected upper limits at HL-LHC with $\mathcal{L} = 3$ ab^{-1} and $\sqrt{s} = 13$ TeV by rescaling the numbers at 13 TeV with two values of total systematic uncertainty, namely $\delta_{\text{Sys.}} = 2.5\%$ and 1%. From the scaled limits, we find that fermionic top partners with masses $m_{T_p} \lesssim 800$ GeV, gluinos with $m_{\tilde{g}} \lesssim 1000$ GeV, and stops with masses $m_{\tilde{t}} \lesssim 600$ GeV can be excluded at 13 TeV with $\mathcal{L} = 3$ ab^{-1}, using the inclusive monojet signature for a compressed mass spectrum.

Another possibility that can significantly improve the sensitivity to heavy coloured particles is increasing the beam energy of the LHC to the proposed $\sqrt{s} = 27$ TeV HE-LHC [203]. Here, we assume that the SM background is still dominated by $Z+j$ process and then scale the model-independent 95% C.L. upper limit at $\sqrt{s} = 13$ TeV according to the production cross section ratio. In Fig. 3.1.3, we estimate the expected reach at the 27 TeV LHC for $pp \to \mathcal{Q}\overline{\mathcal{Q}} + j$ process. Note, here also we assume that the detector acceptance and efficiencies are the same at 13 and 27 TeV. For comparison, we consider systematic uncertainties of 2.5% and 1%, the same considered before. We observe that with $\mathcal{L} = 3 - 15$ ab^{-1}, one can probe the compressed spectra featuring fermionic top partners with masses $m_{T_p} \lesssim 1100$ GeV, gluinos with masses $m_{\tilde{g}} \lesssim 1800$ GeV, and stops with masses $m_{\tilde{t}} \lesssim 600$ GeV.

Theoretical uncertainties associated with the monojet signal process are estimated by employing the state-of-the-art MC suites MADGRAPH5_AMC@NLO and SHERPA. A single measurement of signal cross section does not constrain the nature of $\mathcal{Q}$ uniquely as different spin and colour hypotheses can lead to identical cross sections if the mass is tuned accordingly. For example, a stop of mass 400 GeV, a fermionic top partner of mass 600 GeV, and a gluino of mass 800 GeV have practically the same $pp \to \mathcal{Q}\overline{\mathcal{Q}} + j$ cross section for $p_{T,\text{cut}}^{j_1}$ around 500 GeV at $\sqrt{s} = 14$ TeV, see Fig. 3.1.4 (left). The degeneracy, however, can be resolved through additional cross section measurements with larger $p_{T,\text{cut}}^{j_1}$. Cross section measurements at a higher c.o.m. energy can also lift this degeneracy, see Fig. 3.1.4 (right). To distinguish different new physics candidates, one, however, needs theoretical uncertainties smaller than $\mathcal{O}(30\%)$ and $\mathcal{O}(5\%/100$ GeV), respectively, on the total cross section normalisations and on the change of the cross section for $\sigma(pp \to \mathcal{Q}\overline{\mathcal{Q}} + j)$ as a function of $p_{T,\text{cut}}^{j_1}$. Alternatively, one can also consider ratios of cross sections measured at two different $p_{T,\text{cut}}^{j_1}$ and two different energies $\sqrt{s} = 14$ and 27 TeV.

We find that the monojet signal process under consideration exhibits a residual (factorisation, renormalisation, and shower) scale uncertainty around 40% at LO and 20% at NLO, and is about twice as large as the the inclusive $pp \to T_p\bar{T}_p$ cross section due to the presence of additional α_s factors. Based

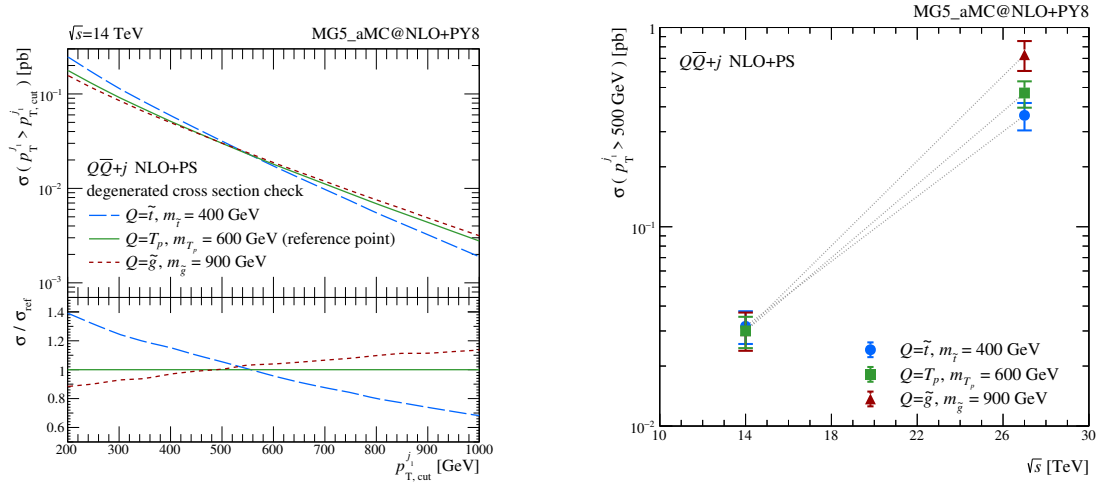

Fig. 3.1.4: Left: $pp \to \mathcal{Q}\overline{\mathcal{Q}} + j$ cross section at $\sqrt{s} = 14$ TeV as a function of jet p_T selection criterion ($p^{j_1}_{T,\mathrm{cut}}$), for representative $(\mathcal{Q}, m_{\mathcal{Q}})$ combinations. Right: $pp \to \mathcal{Q}\overline{\mathcal{Q}} + j$ cross section at $\sqrt{s} = 14$ and 27 TeV, with $p^{j_1}_{T,\mathrm{cut}} = 500$ GeV. The error bar reflects the renormalisation and factorisation scale variation.

on available NNLO calculations [204, 205], we anticipate such uncertainties can be reduced to the 10% level at NNLO. As the corrections beyond NLO mainly impact the overall normalisation, cross sections at different $p^{j_1}_{T,\mathrm{cut}}$ possess correlated uncertainties. Hence, constructing ratios and double-ratios of cross sections at different $p^{j_1}_{T,\mathrm{cut}}$, can partially cancel uncertainties and help with the identification of $\mathcal{Q}$.

3.1.3 Searching for Electroweakinos in monojet final states at HL- and HE-LHC

Contributors: T. Han, S. Mukhopadhyay, X. Wang

Among the multitude of possibilities for WIMP dark matter, particles that belong to a multiplet of the SM weak interactions are one of the best representatives. We focus on two representative scenarios for EW DM, namely a wino-like $SU(2)_L$ triplet and a Higgsino-like $SU(2)_L$ doublet. Such models are often challenging to probe in direct detection experiments due to loop-suppressed scattering cross-sections. Searches at hadron colliders are thus crucial for testing such a scenario, and depending upon the gauge representation, can be complementary to indirect detection probes in different mass windows. Moreover, since the relic abundance of EW DM is uniquely determined by its mass value, 3 TeV for wino-like triplet [206–208] and 1 TeV for Higgsino-like doublet [209], they represent a well-defined target in the collider search for DM in general. Without large additional corrections from higher-dimensional operators, the mass splitting between the charged and neutral components of the DM $\mathrm{SU(2)_L}$ multiplets is only of the order of a few hundred MeV [210, 211]. This nearly degenerate spectrum motivates two major search channels at hadron colliders for the EW DM sector, namely, the monojet with missing transverse momentum search and the disappearing charged track search. The first one is reported in this section, the second in Section 4.1.3.

We present our results [155] on the future reach of three different scenarios of collider energy and integrated luminosity: HL-LHC, HE-LHC, and FCC-hh/SppC (100 TeV, 30 ab^{-1}). We adopt as a definition of significance $S/\sqrt{B + (\Delta_B B)^2 + (\Delta_S S)^2}$ where S and B are the total number of signal and background events, and Δ_S, Δ_B refer to the corresponding percentage systematic uncertainties, respectively.

The classic monojet and missing transverse momentum search for pair production of a DM particle in association with a hadronic jet originating from initial state radiation is considered. Pair production of both the charged state $\chi^{\pm}$ and the neutral state χ^0 would contribute to the signal in the monojet search channel, since the charged pions from the charged state $\chi^{\pm}$ decay are too soft to detect at hadron

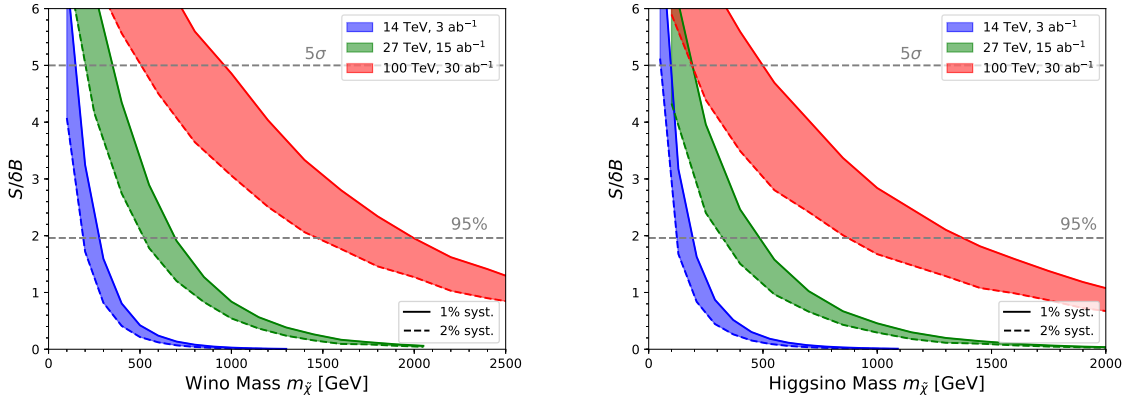

Fig. 3.1.5: Comparative reach of the HL-LHC, HE-LHC and FCC-hh/SppC options in the monojet channel for wino-like (left) and Higgsino-like (right) DM search. The solid and dashed lines correspond to optimistic values of the systematic uncertainties on the background estimate of 1% and 2% respectively, which might be achievable using data-driven methods with the accumulation of large statistics.

95% C.L.	Wino	Higgsino
14 TeV	280 GeV	200 GeV
27 TeV	700 GeV	490 GeV
100 TeV	2 TeV	1.4 TeV

Table 3.1.2: Summary of DM mass reach at 95% C.L. for an EW triplet (wino-like) and a doublet (Higgsino-like) representation, at the HL-LHC, HE-LHC and the FCC-hh/SppC colliders, in optimistic scenarios for the background systematics.

colliders. Systematic uncertainties $\Delta_B = 1-2\%$ and $\Delta_S = 10\%$ are assumed. In Fig. 3.1.5 we compare the reach of the HL-LHC, HE-LHC and FCC-hh/SppC options in the monojet channel for wino-like (left) and Higgsino-like (right) DM search. The solid and dashed lines correspond to systematic uncertainties on the background estimate of 1% and 2% respectively. Results are summarised in Table 3.1.2. In an optimistic scenario, wino-like DM mass of up to 280, 700 and 2000 GeVis expected to be probed at the 95% C.L., at the 14, 27 and 100 TeV colliders respectively. For the Higgsino-like scenario, these numbers decrease to 200, 490 and 1370 GeV, primarily due to the reduced production cross-section. Clearly, a 27 TeV collider can substantially improve the reach by a factor of two or more compared to the HL-LHC, while improvement of another factor of three can be further achieved at the 100 TeV collider.

3.2 Dark Matter and Heavy Flavour

When the mediator between the dark sector and the SM is a scalar or pseudoscalar one expects the couplings to the SM to scale with the SM fermion mass. Thus, a natural place to look for DM production is in association with pairs of top or bottom quarks, see Section 3.2.1 and Section 3.2.2. Alternatively, a neutral vector mediator with flavour-changing interactions can produce DM in association with a single top, see Section 3.2.3. Finally, scalar mediators may be searched for directly in four top final states, as shown in Section 3.2.4.

3.2.1 Associated production of dark matter and heavy flavour quarks at HL-LHC

Contributors: M. Rimoldi, E. McDonald, F. Meloni, P. Pani, F. Ungaro, ATLAS

The prospects of a search for dark matter produced in association with heavy flavour (bottom

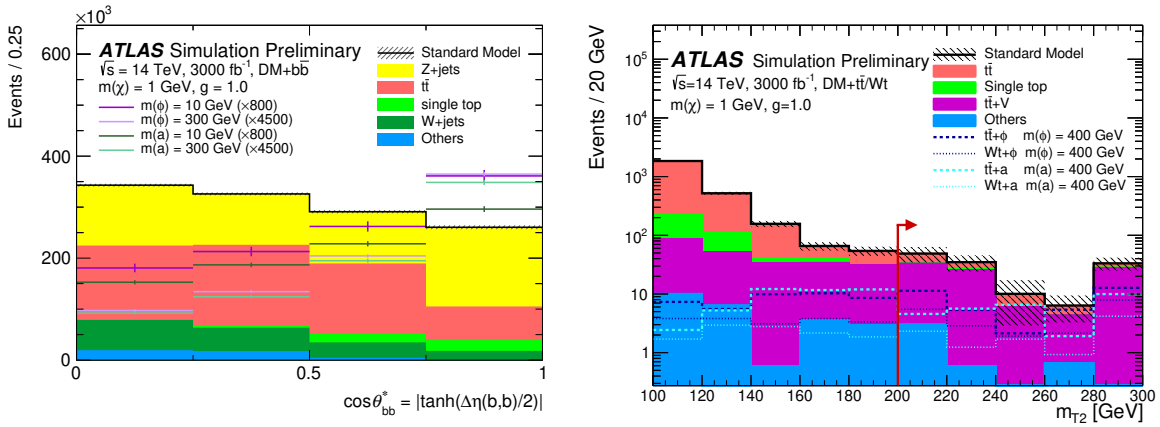

Fig. 3.2.1: Distributions of the main discriminants used for the $DM + b\bar{b}$ and $DM + t\bar{t}$ searches: $\cos\theta^*_{bb}$ (left) and m_{T2} (right). For the $\cos\theta^*_{bb}$ distribution events are required to have $E_{\mathrm{T}}^{\mathrm{miss}} > 210$ GeV, no leptons, 2 or 3 jets, and at least two b-jets. For the m_{T2} distribution events must satisfy the corresponding signal region criteria except for that on the variable shown.

or top) quarks at the HL-LHC are presented in this section [212]. The study therefore focuses on two simplified models, defined by either a scalar, ϕ, or pseudoscalar, a, mediator. In both cases, the mediating particle is taken to be colour-neutral and the dark matter candidate is assumed to be a weakly interacting Dirac fermion, χ, uncharged under the SM.

The $\chi\bar{\chi}$ production in association with top-quarks is expected to dominate at the HL-LHC. Two signatures featuring top quarks in the final state are therefore considered. The first signature, denoted $DM + t\bar{t}$, is characterised by two tops decaying di-leptonically. The second signature, $DM + W\bar{t}$, involves a single top produced in tandem with a W-boson, both of which decay leptonically. Dark matter production in association with b-quarks is also considered in this study, as it is relevant if the coupling to up-type quarks is suppressed. The $DM + b\bar{b}$ final state is equivalently well motivated as an avenue for probing the parameter space of two-Higgs doublet models. In the 2HDM+a model for example, the rate for $pp \to b\bar{b} + a$ is enhanced by the ratio of the Higgs doublet vacuum expectation values, $\tan\beta$, if a Yukawa sector of type-II is realised. A straightforward recasting of exclusion limits on the simplified pseudoscalar mediator model can then be used to extract constraints on $\tan\beta$.

A search targeting the DM+$b\bar{b}$ and DM+$t\bar{t}$ signatures was performed at the LHC using 36.1 fb^{-1} of data collected in 2015 and 2016 at a centre of mass energy of 13 TeV. This study presents the prospects for further constraining these models with HL-LHC data and is divided into two independent analyses.

Signatures with b-quarks and $E_{\mathrm{T}}^{\mathrm{miss}}$ To isolate the event topology of the $DM + b\bar{b}$ final state, events are required to have at least two b-tagged jets. The contribution from SM background processes is suppressed via the application of selection criteria based on that of the 13 TeV analysis and updated to align with HL-LHC design considerations. To reduce the contribution from leptonic and semi-leptonic $t\bar{t}$ decays and from leptonic decays of W and Z bosons, events containing at least one baseline lepton are vetoed. A further requirement of no more than 2 or 3 jets is imposed in order to control the large background from hadronic $t\bar{t}$ decays. The main background from $Z(\to \nu\bar{\nu})$+jets events is reduced by cutting on variables which exploit the difference in spin between the scalar and pseudoscalar particles and the Z boson. These variables make use of the pseudorapidity and azimuthal separations between jets, b-jets, and the missing transverse momentum. Among them, the hyperbolic tangent of the pseudo-rapidity separation between the leading and sub-leading b-jet, $\Delta\eta(b,b) = \eta(b_1) - \eta(b_2)$, is used. This variable, referred to as $\cos\theta^*_{bb}$, is expected to yield a reasonably flat distribution for b-jets produced in association with vector particles. For b-jets accompanying the production of a heavy scalar or pseudoscalar mediator however, $\cos\theta^*_{bb}$ is expected to peak around 1. Owing to this shape difference, the $\cos\theta^*_{bb}$ variable provides the best discrimination between signal and background events in the $DM + b\bar{b}$

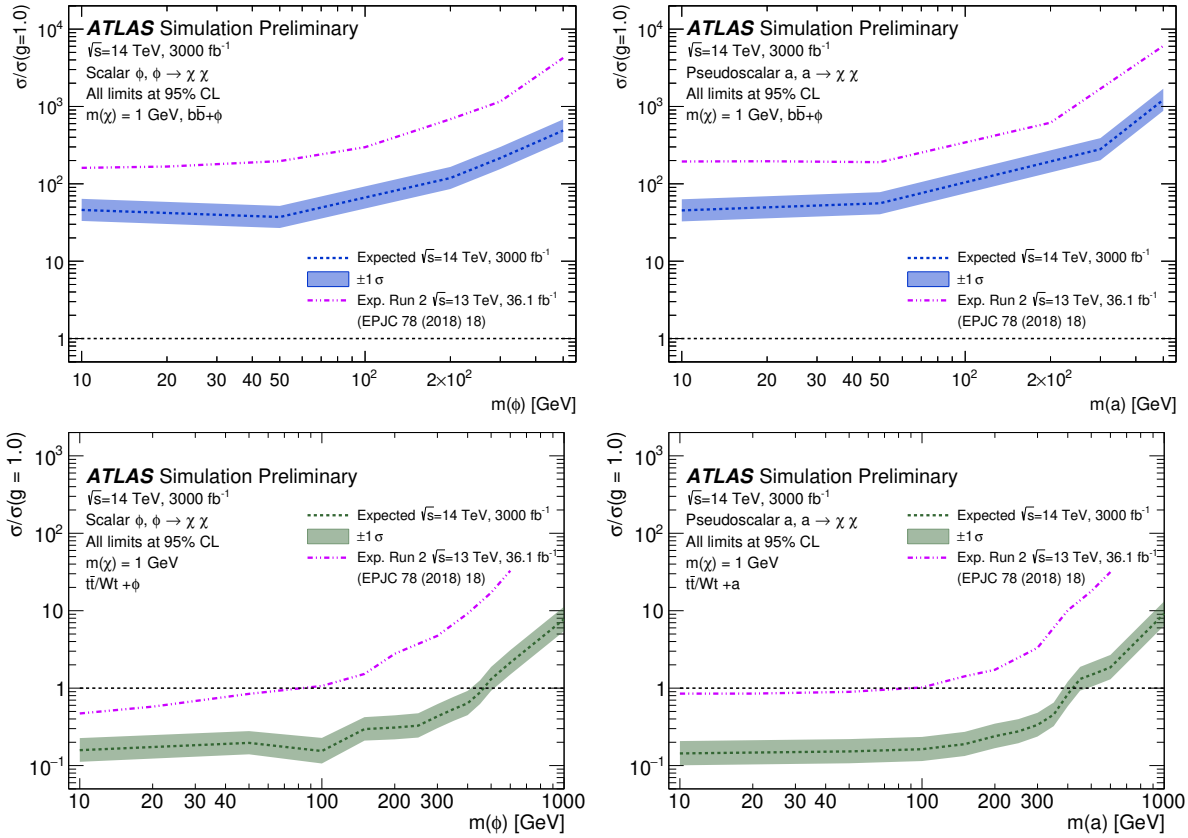

Fig. 3.2.2: Exclusion limits for the production of a colour-neutral mediator in association with bottom quarks (top) or with top quarks (bottom) in case of scalar (left) and pseudoscalar (right) mediator decaying to a pair of dark matter particles with mass 1 GeV. Also shown for comparison is the expected limit from the current analysis [213].

channel. The signal region for this search is therefore defined by four equal-width exclusive bins in $\cos\theta^*_{bb}$ as shown in Fig. 3.2.1, reflecting the configuration used in Run-2. Separate selections are derived for $m(\phi/a) < 100$ GeV and $m(\phi/a) \geq 100$ GeV to further enhance the difference in shape, which can depend strongly on the mass of the mediating particle. The resulting signal regions are denoted by $SR_{b,\text{low}}$ and $SR_{b,\text{high}}$ respectively. For more details, see Ref. [212].

Signatures with top quarks and $\boldsymbol{E}_{\mathbf{T}}^{\mathbf{miss}}$ A single signal region, denoted $SR_{2\ell}$, is used for the search targeting DM production in association with one or two top quarks. Events are required to have exactly two leptons (electrons or muons), possessing the same or different flavour and opposite electric charge. To reduce the $t\bar{t}$ background, the lepton pair must have an invariant mass larger than 100 GeV. Furthermore, candidate signal events are required to have at least one identified b-jet.

Different discriminators and kinematic variables are used to further separate the $t\bar{t} + \phi/a$ and $Wt + \phi/a$ signal from the SM background. These variables include the lepton-based transverse mass m_{T2}, the distribution for which is shown in Fig. 3.2.1 for events passing all of the SR requirements except that on m_{T2}. For the calculation of exclusion limits, the m_{T2} distribution is divided into five equal-width (20 GeV) exclusive bins.

Results For both $SR_{b,\text{low}}$ and $SR_{b,\text{high}}$, the main background consists of Z+jets events followed by hadronic decays of $t\bar{t}$. A significant contribution also comes from single top quark processes and events featuring a W-boson produced in association with jets. In $SR_{2\ell}$, the dominant background consists of di-leptonic decays of $t\bar{t}$ and $t\bar{t}Z$ with $Z \to \nu\nu$. Systematic uncertainties include theory modelling and experimental uncertainties related to, for example, the Jet Energy Scale and b-jet mis-identification. The

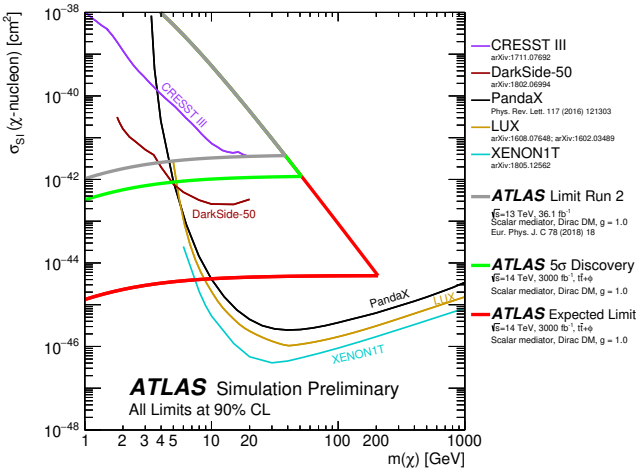

Fig. 3.2.3: Comparison of the 90% C.L. limits on the spin-independent DM-nucleon cross-section as a function of DM mass between these results and the direct-detection experiments, in the context of the colour-neutral simplified model with scalar mediator. The green contour indicates the 5σ discovery potential at HL–LHC. The lower horizontal line of the DM–nucleon scattering cross-section for the red (green) contour corresponds to value of the cross section for $m(\phi) = 430$ GeV ($m(\phi) = 105$ GeV). The grey contour indicates the exclusion derived from the observed limits for Run-2 taken from Ref. [213]. The results are compared with limits from direct detection experiments.

total systematic uncertainty on the SM background is 14% for $SR_{b,\text{low}}$/$SR_{b,\text{high}}$ and 13% for $SR_{2\ell}$.

Exclusion limits are derived at 95% C.L. for mediator masses in the range $10-500$ GeV assuming a DM mass of 1 GeV and a coupling (g) of 1.0. The limits are shown in Fig. 3.2.2 for $\phi/a \rightarrow \chi\bar{\chi}$ production in association with either bottom quarks or top quarks for $\mathcal{L} = 3$ ab^{-1} at $\sqrt{s} = 14$ TeV. Also shown for comparison are the corresponding limits at 13 TeV with 36.1 fb^{-1} taken from the previous Run-2 analysis.

For $\phi/a + b\bar{b}$, the exclusion potential at the HL-LHC is found to improve by a factor of $\sim 3-8.7$ with respect to Run-2. In the context of the 2HDM+a model with $m(A) \gg m(a)$, $\sin\theta = 0.35$ and $y_\chi = 1$, the HL-LHC limits translate to an approximate upper bound on $\tan\beta$ ranging from ~ 19 for $m(a) = 10$ GeV to ~ 100 for $m(a) = 500$ GeV, significantly extending the current phase space coverage. In final states with one or two leptonically-decaying top quarks, the mass range for which a colour-neutral scalar mediator is excluded extends from 80 GeV to 405 GeV. Similarly, exclusion of pseudoscalar masses up to 385 GeV is expected. In the case of the scalar mediator model, this represents a factor of 5 improvement with respect to the 36 fb^{-1} 13 TeV results in the same channel. An additional improvement of approximately 3 is possible when considering a statistical combination of all relevant top decay channels [214], which is not explored for the HL-LHC in this work.

For each DM and mediator mass pair, the exclusion limit on the cross-section for producing colour-neutral scalar mediator particles can be converted into a limit on the cross-section for spin-independent DM-nucleon scattering with the procedure described in Ref. [215]. Limits on the $t\bar{t} + \phi$ model at 90% C.L., corresponding to exclusion of mediator masses up to $m(\phi) = 430$ GeV, are used for this purpose. Fig. 3.2.3 shows the resulting constraints in the plane defined by the DM mass and the scattering cross-section. The maximum value of the DM-nucleon scattering cross-section depicted in the plot corresponds to the value of the cross section for a mediator mass of 10 GeV. The exclusion limits at 90% C.L. are shown in red and the 5σ discovery potential is illustrated in green. The lower horizontal line in the green (red) contour corresponds to the value of the cross section for $m(\phi) = 105$ GeV ($m(\phi) = 430$ GeV). Overlaid for comparison are the most stringent limits to date from several DM direct detection experiments.

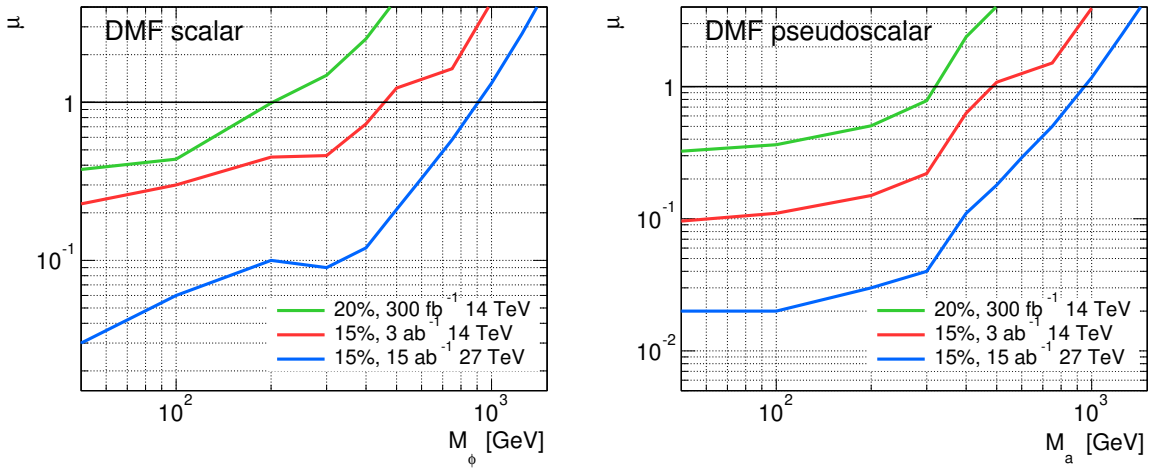

Fig. 3.2.4: Values of the signal strength μ that can be excluded at 95% C.L. as a function of the mass for DMF scalar (left) and pseudoscalar (right) mediators. The reach with 300 fb^{-1} (LHC Run-3) and 3 ab^{-1} (HL-LHC) of $\sqrt{s} = 14$ TeV data is given for a 5-bin shape fit with 20% (green curves) and 15% (red curves) errors. A hypothetical shape-fit scenario based on 15 ab^{-1} of $\sqrt{s} = 27$ TeV of data (HE-LHC) and 15% systematics is also shown (blue curves).

3.2.2 Production of dark matter in association with top quarks at HL- and HE-LHC

Contributors: U. Haisch, P. Pani, and G. Polesello

The prospects of the HL-LHC and the HE-LHC to search for DM production in association with top-quark pairs ($t\bar{t} + E_T^{\text{miss}}$) and in single-top quark events ($tX + E_T^{\text{miss}}$) are investigated. Our sensitivity studies are based on the analysis strategies presented in Ref. [216–218]. In the case of the $t\bar{t} + E_T^{\text{miss}}$ signal, the two-lepton final state is considered. Since the selections employed in Ref. [216] turn out to lead to the best performance also at the HL-LHC and the HE-LHC, the selections in our $t\bar{t} + E_T^{\text{miss}}$ sensitivity study were not changed with respect to that used in the earlier analysis. In the case of the $tX + E_T^{\text{miss}}$ signature, both the two-lepton and one-lepton final state is studied. Since modifying the selections did not notably increase the sensitivity, the selections of the dilepton search were kept identical to the ones used in Ref. [217]. The single-lepton final state selections employed in Ref. [218] were instead reoptimised in our sensitivity study to take full advantage of the increased data set expected at future high-luminosity and high-energy LHC runs.

Sensitivity study of the $t\bar{t} + E_T^{\text{miss}}$ signature: Given the presence of a sizeable irreducible background surviving all the selections, the experimental sensitivity of future $t\bar{t} + E_T^{\text{miss}}$ searches will be largely determined by the systematic uncertainty on the estimate of the SM backgrounds. This uncertainty has two main sources: first, uncertainties on the parameters of the detector performance such as the energy scale for hadronic jets and the identification efficiency for leptons, and second, uncertainties plaguing the modelling of SM processes. Depending on the process and on the kinematic selection, the total uncertainty can vary between a few percent and a few tens of percent. The present analysis does not select extreme kinematic configurations for the dominant $t\bar{t}Z$ background, and it thus should be possible to control the experimental systematics at the 10% to 30% level. In the following, we will assume a systematic error of either 20% or 15% on both background and signal, fully correlated between the two and across kinematic bins. We have checked that in the absence of an external measurement (*e.g.* a background control region) which profiles uncertainties, the use of correlated uncertainties provides the most conservative results. In addition, we consider a 5% uncertainty on the signal only to account for the theoretical uncertainty on the $t\bar{t} + E_T^{\text{miss}}$ signal.

In Fig. 3.2.4 we present sensitivity estimates at LHC Run-3, the HL-LHC and the HE-LHC for scalar (left panel) and pseudoscalar (right panel) simplified DM model mediators. The shown results

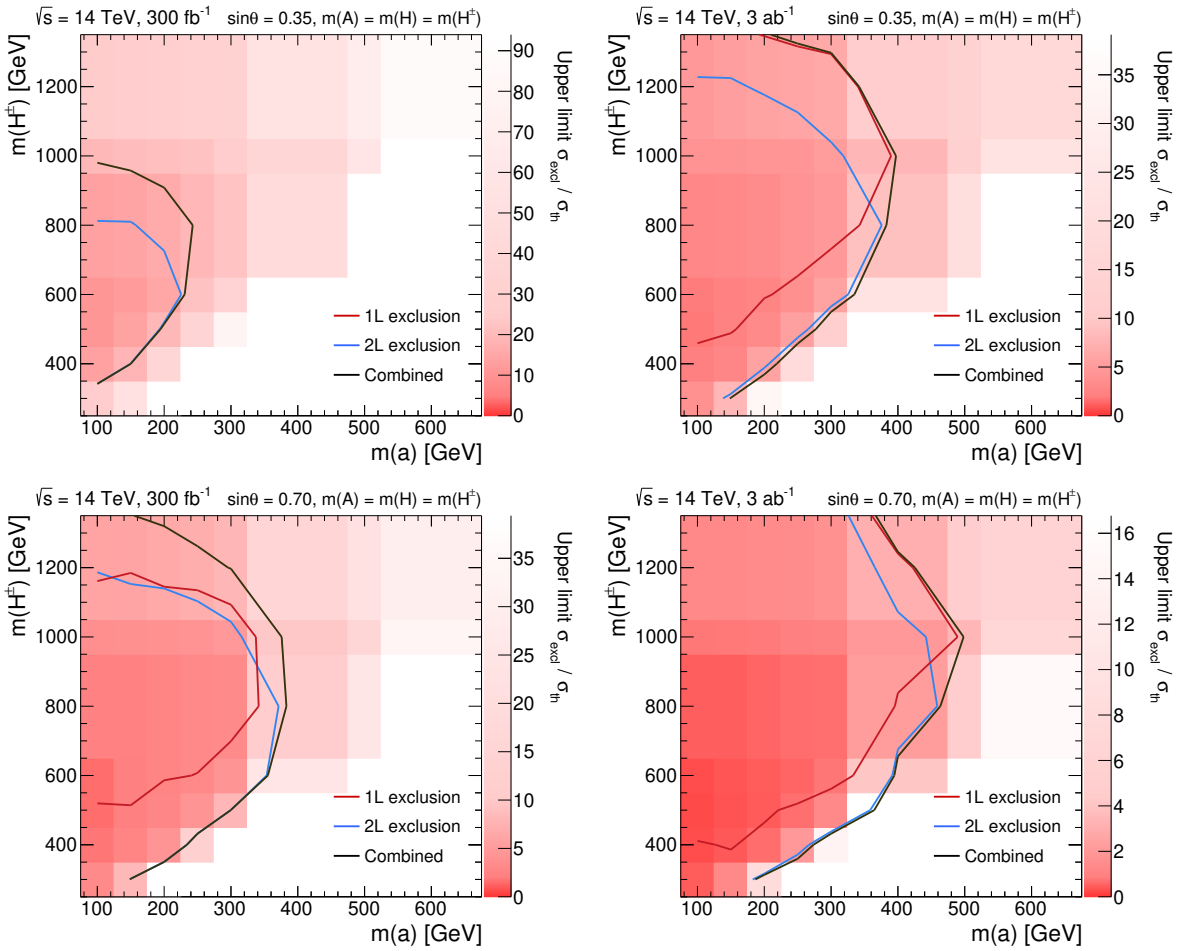

Fig. 3.2.5: 95% C.L. exclusion limits in the $m(a) - m(H^{\pm})$ plane following from our one-lepton (1L) and two-lepton (2L) analysis shown as red and blue lines. The black curves indicate the bounds obtained by a combination of the two search strategies. The used 2HDM+a parameters are indicated. The left (right) panels correspond to 300 fb^{-1} (3 ab^{-1}) of $\sqrt{s} = 14$ TeV data. Systematic uncertainties of 20% (5%) on the SM background (signal) are assumed.

correspond to a DM mass of $m_{\chi} = 1$ GeV and the coupling choices $g_q = g_{\chi} = 1$, as recommended by the ATLAS/CMS DM Forum (DMF) [219] and the LHC DM Working Group [215]. The estimated 95% C.L. exclusion limits are obtained from a 5-bin likelihood fit to the $|\cos\theta_{\ell\ell}| = \tanh(\Delta\eta_{\ell\ell}/2)$ distribution. The inclusion of shape information is motivated by the observation that the distributions of events as a function of the pseudorapidity difference $\Delta\eta_{\ell\ell}$ of the dilepton pair is different for signal and background [216]. At LHC Run-3 it should be possible to exclude DMF scalar (pseudoscalar) models that predict a signal strength of $\mu = 1$ for mediator masses up to around 200 GeV (300 GeV) using the 5-bin likelihood fit employed in our study. It should be possible to improve the maximal mass reach by roughly a factor of 2 when going from LHC Run-3 to the HL-LHC and from the HL-LHC to the HE-LHC. The corresponding 95% C.L. exclusion limits on DMF scalar (pseudoscalar) mediators are thus expected to be around 450 GeV (500 GeV) and 900 GeV (950 GeV) at the HL-LHC and the HE-LHC, respectively. Another conclusion that can be drawn from our sensitivity study is that the reach of future LHC runs depends strongly on the systematic background uncertainty, and as a result a good experimental understanding of $t\bar{t}Z$ production within the SM will be a key ingredient to a possible discovery of DM in the $t\bar{t} + E_T^{\text{miss}}$ channel.

Using the recasting procedure described in Ref. [220], the sensitivity estimates presented in Fig. 3.2.4 for the DMF spin-0 models can be translated into exclusion limits on next-generation spin-

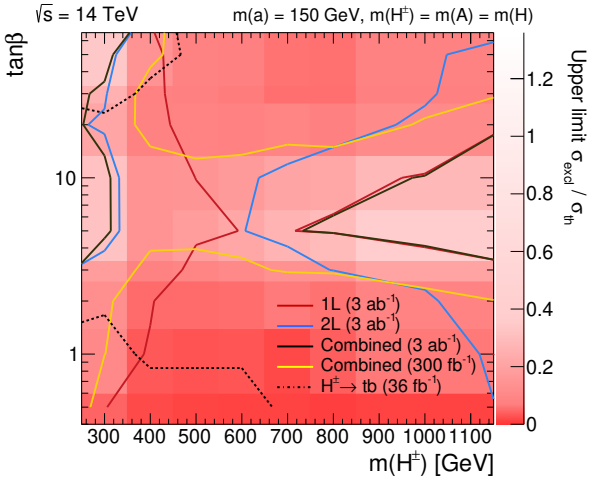

Fig. 3.2.6: Regions in the $m(H^\pm) - \tan\beta$ which can be excluded at 95% C.L. through the one-lepton (1L), two-lepton (2L) searches and their combination. The used 2HDM+a parameters are shown in the headline of the figure. The projections assume 300 fb^{-1} or 3 ab^{-1} of $\sqrt{s} = 14$ TeV data and a systematic uncertainty of 20% (5%) on the SM background (signal). The shown $H^\pm \to tb$ limits have been obtained by recasting the experimental results presented in Ref. [226].

0 DM models. In the case of the 2HDM+a model [221–225] for instance and adopting the benchmark (4.5) and (4.6) introduced in Ref. [220], one finds for $\tan\beta = 1$ the 95% C.L. bounds $m(a) \lesssim 150$ GeV (HL-LHC) and $m(a) \lesssim 350$ GeV (HE-LHC) on the mass of the 2HDM+a pseudoscalar mediator a. These numbers show again that a HE-LHC is expected to be able to significantly improve upon the HL-LHC reach, in particular for spin-0 DM model realisations that predict small $t\bar{t} + E_T^{\text{miss}}$ signal cross sections.

Sensitivity study of the $tX + E_T^{\text{miss}}$ signature: Following the analyses [217,218], we interpret our $tX + E_T^{\text{miss}}$ results in the context of the 2HDM+a model. The total background in the two-lepton selection is approximately 100 events, dominantly composed of the $t\bar{t}Z/W$ and tWZ background processes. For charged Higgs masses $m(H^\pm)$ between 300 GeV and 700 GeV, the acceptance for signal events containing at least two leptons is in the range $[0.1, 0.7]$% for $m(a) = 150$ GeV and $\tan\beta = 1$. The total background in the one-lepton selection is approximately 30 events for the leptonic-$H^\pm$ signal selection and 45 events for the hadronic-$H^\pm$ one. More than 70% of the SM background arises from $t\bar{t}Z/W$ and tZ processes in both selections and the rest is in equal parts due to the contributions of top pairs (dileptonic decays) and the single-top tW channel for the hadronic-$H^\pm$ selection, while in the case of the leptonic-$H^\pm$ selection the remaining 30% are dominated by single-top processes. For $m(H^\pm)$ in the range of 600 GeV and 1 TeV, the acceptance for signal events containing at least one lepton amounts to approximately $[0.2, 0.5]$% for $m(a) = 150$ GeV and $\tan\beta = 1$.

In Fig. 3.2.5 we present the results of our $tX + E_T^{\text{miss}}$ sensitivity study in the $m(a) - m(H^\pm)$ plane of the 2HDM+a model employing a DM mass of $m_\chi = 1$ GeV. As indicated by the headlines of the individual panels, two different values for the mixing angle in the pseudoscalar sector ($\sin\theta$) are employed. The parameters not explicitly specified have been set to the benchmark choices (4.5) made in Ref. [220]. One observes that at LHC Run-3 a combination of the one-lepton and two-lepton search should allow one to exclude masses $m(a)$ up to around 250 GeV (375 GeV) for $\sin\theta = 0.35$ ($\sin\theta = 0.7$). The corresponding HL-LHC limits instead read 400 GeV (500 GeV), implying that collecting ten times more luminosity is expected to lead to an improvement in the LHC reach by a factor of around 1.5 in the case at hand. Also notice that the one-lepton and two-lepton analyses are complementary because they have different sensitivities on $m(H^\pm)$.

One can also compare the HL-LHC reach in the $m(H^\pm) - \tan\beta$ plane to that derived in Ref. [217]

for LHC Run-3. Such a comparison is presented in Fig. 3.2.6. Numerically, we find that all values of $\tan\beta$ can be excluded for a charged Higgs mass between 300 GeV and 700 GeV, improving the LHC Run-3 forecast, which showed a coverage in $\tan\beta$ up to 3 and above 15 for the same mass range. For $m(H^{\pm}) = 1$ TeV instead, the upper limit in $\tan\beta$ is extended from 2 to 3 and the lower limit is extended from around 30 to 20. Compared to LHC Run-3 the HL-LHC is thus expected to have a significantly improved coverage in $\tan\beta$, in particular for not too heavy 2HDM spin-0 states. Limits on $m(H^{\pm})$ and $\tan\beta$ also derive from $H^{\pm}$ production followed by the decay of the charged Higgs into SM final states such as $\tau\nu$ or tb. As indicated in Fig. 3.2.6, in the 2HDM+a model the searches for $H^{\pm} \to tb$ cover an area largely complementary to the results of the $tX + E_T^{\text{miss}}$ searches.

3.2.3 Dark matter production in single-top events at HL-LHC

Contributors: L. Barranco, F. Castillo, M. J. Costa, C. Escobar, J. García-Navarro, D. Madaffari, J. Navarro, ATLAS

The expected sensitivity of a search for the non-resonant production of an exotic state decaying into a pair of invisible DM particle candidates in association with a right-handed top quark is presented [227]. Such final-state events, commonly referred to as "monotop" events, are expected to have a reasonably small background contribution from SM processes. In this analysis only the topologies where the W boson from the top quark decays into a lepton and a neutrino are considered.

The non-resonant monotop is produced via a flavour-changing neutral interaction where a top quark, a light-flavour up-type quark and an exotic massive vector-like particle V can be parametrised through a general Lagrangian [219, 228]:

$$\mathcal{L}_{\text{int}} = aV_{\mu}\bar{u}\gamma^{\mu}P_{\text{R}}t + g_{\chi}V_{\mu}\bar{\chi}\gamma^{\mu}\chi + \text{h.c.}\,, \tag{3.2.1}$$

where V is coupled to a pair of DM particles (represented by Dirac fermions $\chi\bar{\chi}$) whose strength can be controlled through a parameter g_{χ} and where P_{R} represents the right-handed chirality projector. The parameter a stands for the coupling constant between the massive invisible vector boson V, and the t- and u-quarks, and γ^{μ} are the Dirac matrices.

The experimental signature of the non-resonant monotop events with W boson decaying leptonically is one lepton from the W-boson decay, large $E_{\text{T}}^{\text{miss}}$, and one jet identified as likely to be originated from a b-quark. The signal event candidates are selected by requiring exactly one lepton with $p_{\text{T}} > 30$ GeV, exactly one jet with $p_T > 30$ GeVidentified as a b-jet and $E_{\text{T}}^{\text{miss}} > 100$ GeV. Since the considered monotop process favours final states with positive leptons, events with negative lepton charge are rejected. These criteria define the base selection.

In order to maximise the sensitivity of the study, in addition to the base selection further discrimination is achieved by applying additional criteria according to the kinematic properties of the signal while rejecting background. The transverse mass of the lepton–$E_{\text{T}}^{\text{miss}}$ system, $m_{\text{T}}(\ell, E_{\text{T}}^{\text{miss}})$, is required to be larger than 100 GeV in order to reduce the background contribution. In background events the spectrum of this quantity decreases rapidly for values higher than the W-boson mass. In signal events instead, the spectrum has a tail at higher mass values. When originating from the decay of a top quark, the lepton and the b-jet are close to each other. Therefore, events are required to have an azimuthal difference between the lepton momentum and the b-jet momentum directions ($\Delta\phi(\ell,\text{b}-jet)$) of less than 2.0, which disfavours the W+jets and diboson backgrounds.

Further selection is performed via a BDT algorithm provided by the Toolkit for Multivariate Analysis [229]. The BDT is trained to discriminate the monotop signal from the dominant $t\bar{t}$ background. For the training, since no significant difference is observed for the different mass values, the sample with $m_V = 2.5$ TeV is used. Half of the events of both signal and background samples are selected randomly and used to train the BDT. The other half is used to probe the BDT behaviour in order to avoid the presence of overtraining. The variables entering the BDT are selected from a pool of fundamental quantities,

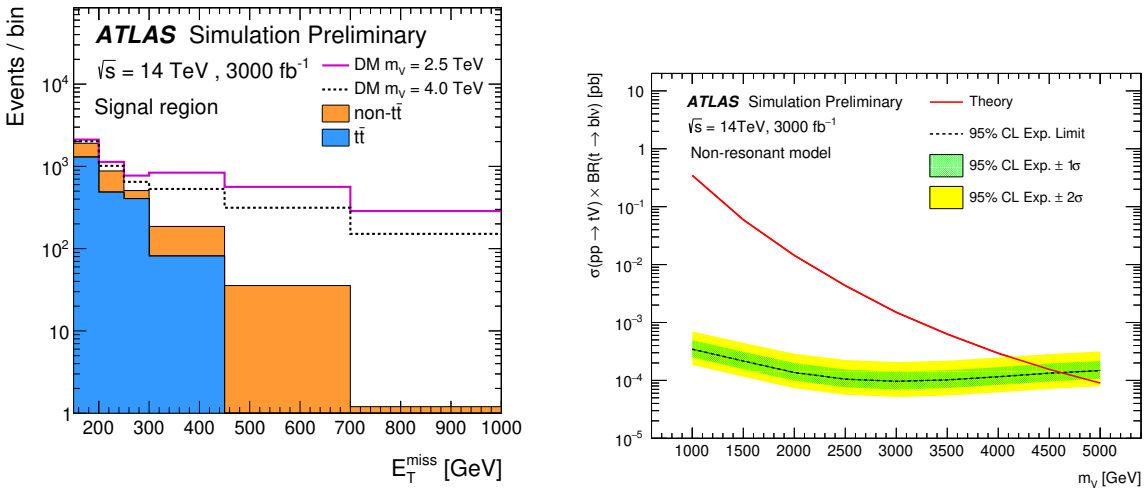

Fig. 3.2.7: Left: expected post-fit $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution in the signal region. The stack distribution shows the $t\bar{t}$ and non-$t\bar{t}$ background predictions. Solid and dashed lines represent the signal corresponding to a mediator mass of 2.5 and 4.0 TeV, respectively. The signal event samples are normalised to the number of background events. The binning is the same as the optimised, non-equidistant binning used in the fit. Last bin includes overflow events. Right: expected 95% C.L. upper limits on the signal cross-section as a function of the mass of the mediator for the non-resonant model assuming $m_{\chi} = 1$ GeV, $a = 0.5$ and $g_{\chi} = 1$ using a BDT analysis. The MC statistical uncertainty is not considered but the full set of systematics, extrapolated from the 13 TeV analysis, is used.

like p_T of jets and b-jets, and angular distances. The variables selected are the ones showing the best discriminating power. In particular, $\Delta\phi(\ell, E_{\mathrm{T}}^{\mathrm{miss}})$ and $m_{\mathrm{T}}(\ell, E_{\mathrm{T}}^{\mathrm{miss}})$ are found to be the most effective variables. Only events with BDT response > 0.9 and $E_{\mathrm{T}}^{\mathrm{miss}} > 150$ GeVenter in the signal region and are used in the extraction of the result. The shape of the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution is used in the statistical analysis, as it is expected to be the most sensitive variable to the presence of new physics. The binning of this distribution is optimised for the sensitivity of the analysis in the signal region while ensuring the stability of the fit. This results in a non-equidistant binning which exhibits wider bins in regions with a large signal contribution, while preserving a sufficiently large number of background events in each bin.

Figure 3.2.7 (left) shows the post-fit $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution in the signal region. The result does not include MC statistical uncertainties but incorporates effects of systematic uncertainties. The theoretical modelling of signal and background has the largest prior, 15%. The second largest source of uncertainty is the one relative to the $E_{\mathrm{T}}^{\mathrm{miss}}$ reconstruction, with 6% prior. Jet energy scale (JES) and jet energy resolution (JER) contribute with a total of 5%. The uncertainty on the requirements for pile-up jets rejection is 5%, whilst uncertainties on lepton identification, b-tagging efficiencies and luminosity are 1.2%, 2.5% and 1%, respectively.

Figure 3.2.7 (right) shows the expected 95% C.L. upper limits as a function of the mediator mass for the non-resonant model assuming $m_{\chi} = 1$ GeV, $a = 0.5$ and $g_{\chi} = 1$. After the fit, the largest impact on the result is coming from the uncertainty on the $E_{\mathrm{T}}^{\mathrm{miss}}$ reconstruction. This is expected since the $E_{\mathrm{T}}^{\mathrm{miss}}$ is the final discriminant in the analysis. The second largest contribution is coming from background and signal modelling. The other contributions are, in order of importance: pile-up jet rejection requirements, JES and JER, lepton reconstruction efficiency and b-tagging efficiency. The uncertainty on the expected luminosity is found to have the smallest effect. The expected mass limit at 95% C.L. is 4.6 TeV while the discovery reach (based on 5σ significance) is 4.0 TeV. For the current analysis the effect of possible improvements in the systematic uncertainties is estimated by reducing by half the uncertainties. This has the effect of increasing the exclusion limit (discovery reach) by 80 (50) GeV. The expectation for the equivalent of Run-3 integrated luminosity (300 fb^{-1}) is checked, obtaining an exclusion limit (discovery reach) of 3.7 TeV (3.2 TeV).

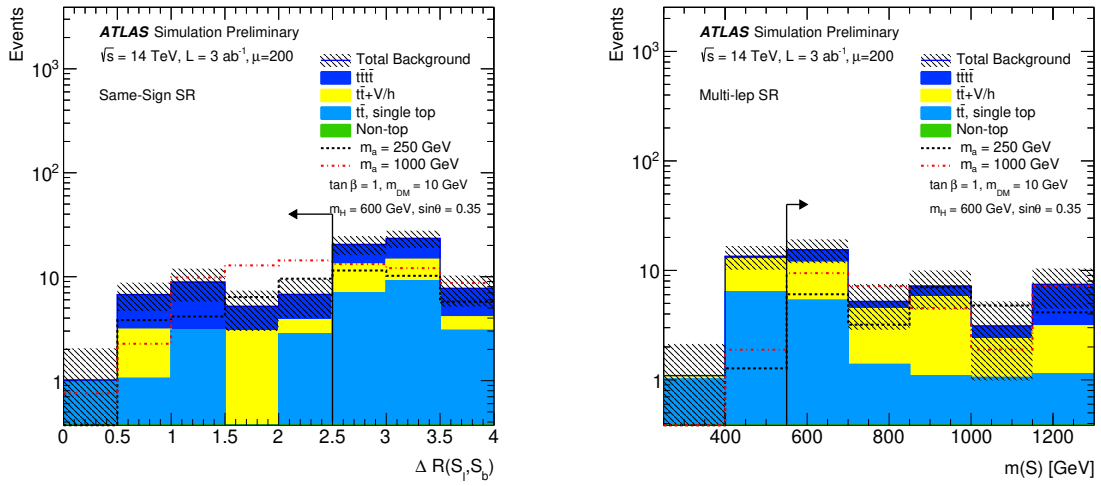

Fig. 3.2.8: Key distributions for events passing all Same-Sign (left) or Multi-lep (right) selection requirements except that on the distribution itself. The contributions from all SM backgrounds are shown, and the hashed band represents the statistical uncertainty on the total SM background prediction. The expected distributions for signal models with $m_a = 250$ GeV and $m_a = 1000$ GeV, assuming $m_H = 600$ GeV, $\sin\theta = 0.35$ are also shown as dashed lines for comparison.

3.2.4 Four-top signatures at the HL-LHC

Contributors: P. Pani, F. Meloni, ATLAS

A class of simplified models for dark matter searches at the LHC involving a two-Higgs-doublet extended sector together with an additional pseudoscalar mediator to DM, the 2HDM+a, are considered in this study [230]. The additional pseudoscalar mediator of the model, a, couples the DM particles to the SM and mixes with the pseudoscalar partner of the SM Higgs boson, A. This model is characterised by a rich phenomenology and can produce very different final states according to the production and decay modes for the various bosons composing the Higgs sector, which can decay both into dark matter or SM particles. The four-top signature is interesting if at least some of the neutral Higgs partners masses are kept above the $t\bar{t}$ threshold, since, when kinematically allowed, all four neutral bosons can contribute to this final state. The total four top-quark production cross-section is dominated by the light pseudoscalar and the heavy scalar bosons. In order to highlight this interplay, four benchmark models will be considered, assuming different choices for the mass of the light CP-odd and heavy CP-even bosons and the mixing angle between the two CP-odd weak eigenstates ($\sin\theta$).

Scenario 1 m_a sensitivity scan assuming:

a) $m_H = 600$ GeV , $\sin\theta = 0.35$.
b) $m_H = 1$ TeV , $\sin\theta = 0.7$.

Scenario 2 $\sin\theta$ sensitivity scan assuming:

a) $m_H = 600$ GeV , $m_a = 200$ GeV.
b) $m_H = 1$ TeV , $m_a = 350$ GeV.

This prospect study considers four top-quarks final states involving at least two leptons with the same electric charge or at least three or more leptons. Final states with high jet multiplicity and one lepton are also very powerful to constrain these signatures, but are not considered here. Complementary studies of the potential for the measurement of standard model production of the four top final state at CMS [231] and ATLAS [232] are also discussed in working group chapter 1 [30].

Events are accepted if they contain at least two electrons, two muons or one electron and one muon with the same electric charge or at least three leptons ($p_T > 25$ GeV). Furthermore, events are required

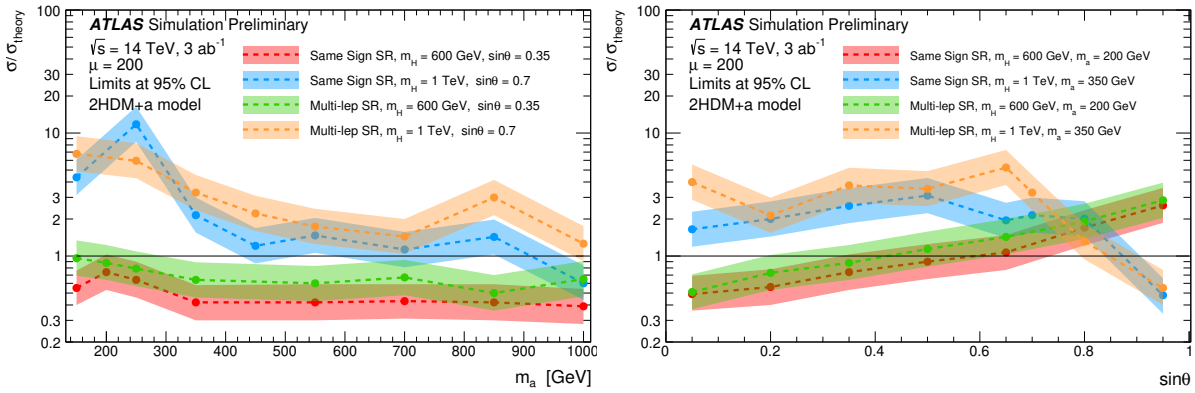

Fig. 3.2.9: Exclusion limits at 95% C.L. for Same-Sign and Multi-lep SRs in terms of excluded cross-section (σ) over the cross-section predicted by the model (σ_{theory}). Limits are derived from the analysis of 3 $\mathrm{ab}^{-1}$of 14 TeV proton-proton collision data as a function of m_a (left) or as a function of $\sin\theta$ (right) for each parameter assumptions described and indicated in the legend. The 1σ variation of the total uncertainty on the limit is indicated as a band around each exclusion line.

to contain at least three b-jets. The up to four leading leptons and up to four leading b-jets in the event are grouped respectively in two systems, called $\mathcal{S}_\ell$ and $\mathcal{S}_b$. A signal system $\mathcal{S}$ is defined by $\mathcal{S} = \mathcal{S}_\ell \cup \mathcal{S}_b$. Different discriminators and kinematic variables are used in the analysis to separate the signal from the SM background.

- $p_T(\mathcal{S}_\ell)$: the vector sum of the lepton four momenta in $\mathcal{S}_\ell$;
- $\Delta R(\mathcal{S}_\ell, \mathcal{S}_b)$: the ΔR between the vectorial sum of the leptons in $\mathcal{S}_\ell$ and the vectorial sum of the b-jets in $\mathcal{S}_b$;
- m($\mathcal{S}$): the invariant mass of the signal system $\mathcal{S}$;

A common selection is applied to all events, before further categorisations. Events are required to have at least two jets with a $p_T > 50$ GeV. In events with exactly two (anti-)electrons, the contribution of SM processes including an on-shell Z boson decaying leptonically with a lepton charge misidentification is reduced by vetoing events with 81.2 GeV $<$ m$_{\ell\ell}$ $<$ 101.2 GeV. Furthermore, low mass resonances are vetoed by requiring $m_{\ell\ell} > 15$ GeV. Two signal regions (SRs) are defined selecting events with exactly two charged leptons with the same electric charge (denoted Same-Sign) or three or more charged leptons (denoted Multi-lep). Figure 3.2.8 shows two key distributions ($\Delta R(\mathcal{S}_\ell, \mathcal{S}_b)$ and $m(\mathcal{S})$) for events passing one set of SRs requirements except for the requirement on the shown variable itself. The main backgrounds that survive the selections are the irreducible $t\bar{t}t\bar{t}$ and $t\bar{t}$+V/h channels. The dominant uncertainties are expected to be due to theoretical modelling of the irreducible backgrounds and, to a lesser extent, to the jet energy scale and resolution, and the b-tagging efficiency. Owing to the reduced statistical uncertainty and a better understanding of the physics models, it is expected that JES, JER, b-tagging efficiency and irreducible background modelling uncertainties will all be reduced. This leads to an estimate of the total background uncertainty of about 20%. The resulting experimental uncertainty is assumed to be fully correlated between the background and the signal when setting 95% C.L. exclusion limits. Furthermore, an additional systematic of 5% is considered for the signal, in order to account for the theoretical systematic uncertainty on the model.

Scans of expected exclusion limits at 95% C.L. are shown in Figures 3.2.9 as a function of m_a, for fixed m_H and $\sin\theta$ and as a function of $\sin\theta$ for fixed m_a and m_H. In all benchmarks, it is assumed that $\tan\beta = 1$ and $m_\chi = 10$ GeV. For light pseudoscalar masses above the $t\bar{t}$ decay threshold, a significance of about 3σ is expected if $m_H = 600$ GeV and $\sin\theta = 0.35$. The same benchmark is expected to be excluded for all light-pseudoscalar masses and for $\sin\theta < 0.35$ if $m_a = 200$ GeV. Mixing angles such that $\sin\theta > 0.95$ are also expected to be excluded for $m_a = 350$ GeV, $m_H = 1$ TeV and, under the

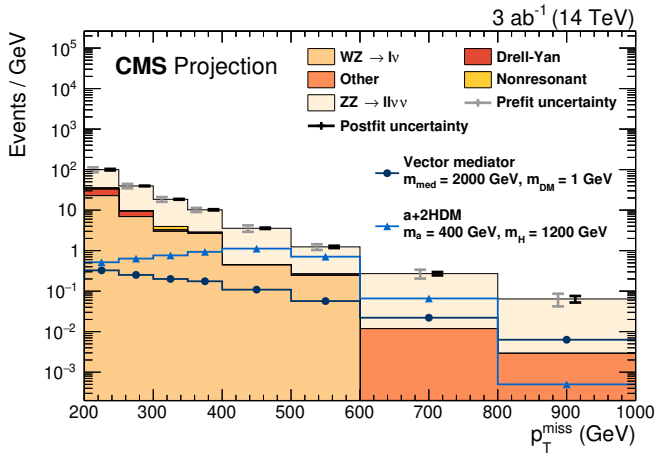

Fig. 3.3.1: Spectrum of $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ in the signal region. Uncertainty bands for the background prediction are shown before and after applying a background-only maximum-likelihood fit to the Asimov dataset in signal and control regions.

same assumptions, an upper limit of about two times the theoretical cross section is set for $\sin\theta < 0.8$. Finally, $\sin\theta < 0.4$ is excluded for $m_H = 600$ GeV, $m_a = 200$ GeV. In almost all cases the Same-Sign SR yields the strongest constraints on the parameter space considered in this work. However, the Multi-lep SR offers a complementary channel whose sensitivity is of the same order of magnitude. Possibly, exploiting dedicated techniques developed to suppress or better estimate the $t\bar{t} + V$ background that affects the Multi-lep SR, this signature can achieve sensitivity comparable to the Same-Sign selection.

3.3 Dark Matter and Electroweak Bosons

DM can be produced in association with, or through interactions with, EW gauge bosons. The DM may recoil against a (leptonically decaying) Z boson that was produced as ISR or in the decay of a heavy mediator to a lighter mediator and a Z, see Section 3.3.1. It may recoil against a photon or be produced through its couplings to W, Z in VBF, as in Section 3.3.2. A standard way to couple to the dark sector is through SM "portals". UV completing the Higgs portal leads to signals only involving the mediators and not the DM, such as diHiggs or di-mediator production. Prospects are presented in Section 3.3.3. Alternatively, heavier dark sector states with couplings to the Z boson can produce DM in their decays, as shown in Section 3.3.4.

3.3.1 Dark matter produced in association with a Z boson at HL-LHC

Contributors: A. Albert, K. Hoepfner, CMS

Collider searches for DM production critically rely on a visible particle being produced in association with the sought-after invisible DM candidate. One possible choice of an accompanying SM signature is a Z boson reconstructed from an e^+e^- or $\mu^+\mu^-$ pair. In the hadronic environment of the LHC, this leptonic signature is well reconstructible and the resonant behaviour of the dilepton mass allows for efficient rejection of non-Z background processes. The presence of a signal is determined from a maximum-likelihood fit of the $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ spectrum of selected events, which would be hardened by the presence of a DM signal relative to the SM backgrounds.

This study from CMS is a projection based on the results of Ref. [233]. Event-by-event weights are applied to simulated samples to account for the difference in c.o.m. energy and $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ resolution between the Run-2 and HL-LHC scenarios [234]. The $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ spectrum in the signal region is shown in Fig. 3.3.1.

The results are interpreted in two simplified models of DM production. In the first model, a

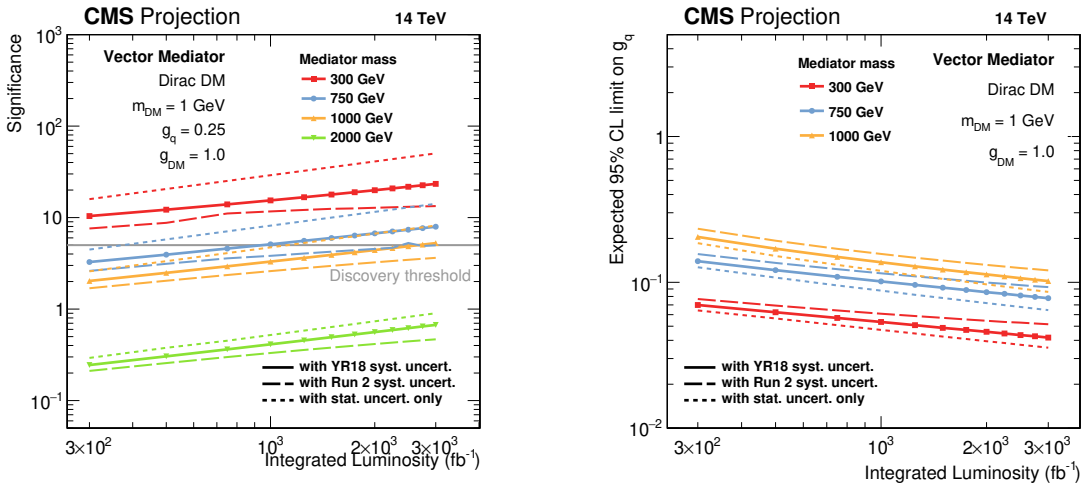

Fig. 3.3.2: Expected significance of a vector mediator signal with unity signal strength (left) and 95% C.L. exclusion limits on the coupling g_q (right). Both quantities are shown as a function of integrated luminosity for multiple choices of the mediator mass m_{med}.

minimal scenario is assumed where there is one new mediator boson and one new DM Dirac fermion χ [219]. The mediator is assumed to have vector couplings g_q and g_{DM} to quarks and DM, respectively. In the second model, referred to as "a+2HDM", the SM is extended by a second Higgs doublet as well as a light pseudoscalar DM mediator, a [224]. By allowing for the light pseudoscalar to mix with the heavier pseudoscalar state from the second Higgs doublet, the mediation mechanism can be realised without violating any of the various existing direct and indirect constraints on the scalar sector [220,224]. Importantly, this second model allows for the production of the pseudoscalar mediator and Z boson through the decay of a new heavy scalar H. This production mode provides excellent sensitivity for the $Z + \mathbf{p}_{\text{T}}^{\text{miss}}$ search compared to other searches such as jets+$\mathbf{p}_{\text{T}}^{\text{miss}}$ [220].

For the vector mediator scenario, the expected signal significance and expected exclusion limits on g_q are shown in Fig. 3.3.2. A signal with a mediator of mass $m_{\text{med}} = 750$ GeV could be discovered with $\mathcal{L}_{\text{int}} \approx 1\,\text{ab}^{-1}$, while a heavier mediator with $m_{\text{med}} = 1$ TeV would require $\mathcal{L}_{\text{int}} \approx 3\,\text{ab}^{-1}$. Especially the latter case highlights the effect of the systematic uncertainty scenarios. Improved handling of systematic uncertainties could reduce the integrated luminosity required for a discovery by a factor three, and thus advance the discovery by years. Framed as an exclusion on the mediator-quark coupling g_q, values down to 0.04 will be probed for a lighter mediator with $m_{\text{med}} = 300$ GeV, and $g_q \approx 0.1$ will be testable for $m_{\text{med}} = 1$ TeV. A heavier mediator of mass $m_{\text{med}} = 2$ TeV will remain out of reach even with the final HL-LHC dataset of $3\,\text{ab}^{-1}$. The two-dimensional exclusion as a function of the relevant particle masses for both models is shown in Fig. 3.3.3. In the case of the vector mediator, mediator masses up to ~ 1.5 TeV will be probed, assuming $m_{\text{med}}/2 > m_{\text{DM}}$. Depending on the choice of systematic uncertainty scenario, the mediator mass exclusion varies by ≈ 100 GeV. In the a+2HDM model, light pseudoscalar masses up to 600 GeV and heavy boson masses up to 1.9 TeV will be probed. Again, the choice of systematic uncertainty scenarios may influence these values by ≈ 100 GeV (m_{a}) and $100 - 150$ GeV (m_{H}). These mass exclusion ranges show an improvement of a factor ~ 2.5 in the mediator masses and up to ~ 3 for the pseudoscalar mass compared to the Run-2 result with $\mathcal{L}_{\text{int}} = 36\,\text{fb}^{-1}$ [233,235].

3.3.2 Dark matter searches in mono-photon and VBF+$E_{\text{T}}^{\text{miss}}$ final states at HL-LHC

Contributors: L. Carminati, D. Cavalli, M. Cirelli, C. Guyot, A. Demela, I. Lim, B. Nachman, M. M. Perego, S. Resconi, F. Sala, ATLAS

A prospect study for DM searches with the ATLAS detector is presented in a scenario where the

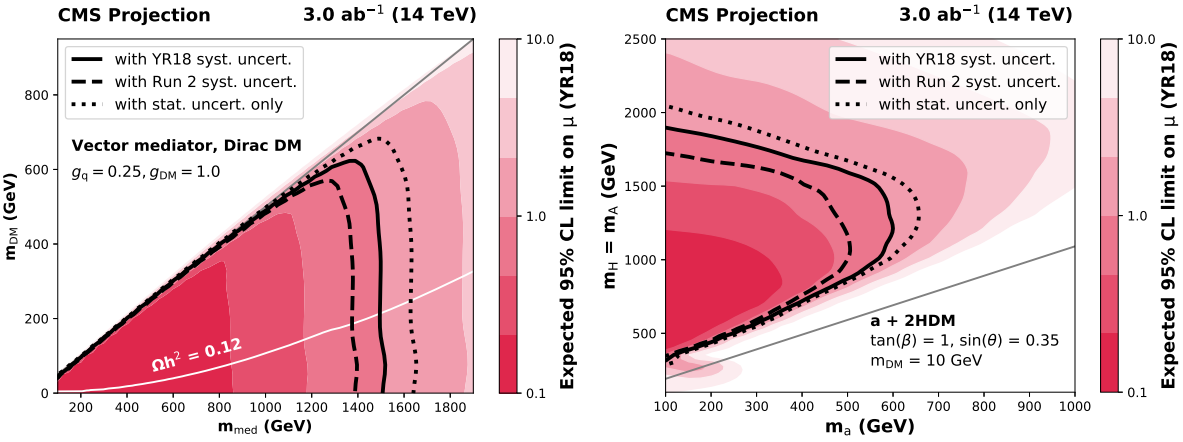

Fig. 3.3.3: Expected 95% C.L. exclusion limits on the signal strength in the vector mediator (left) and a+2HDM scenarios (right). In the vector mediator case, the exclusion is presented in the plane of the mediator and dark matter masses, while the result is shown in the plane of the pseudoscalar mediator mass m_a and the heavy boson masses $m_H = m_A$. The grey lines indicate the relevant kinematic boundaries that limit the sensitive regions: $m_{med}/2 = m_{DM}$ in the vector mediator case, and $m_H = m_a + m_Z$ in the a+2HDM case. For the vector mediator scenario, the white line indicates the parameter combinations that reproduce the observed DM relic density in the universe [236, 237].

SM is extended by the addition of an EW fermionic triplet with null hypercharge [238]. The lightest mass state of the triplet constitutes a weakly interacting massive particle DM candidate. This model is inspired by SUSY with anomaly-mediated SUSY breaking [239–241] and by models of Minimal Dark Matter (MDM) [242–244], and provides a benchmark in the spirit of simplified models [219] where the mediator is a SM particle. Projections for an integrated luminosity of 3 ab^{-1}are presented for the DM searches in the mono-photon [245] and VBF+$E_{\mathrm{T}}^{\mathrm{miss}}$ [246] final states, based on the Run-2 analyses strategy. To illustrate the experimental challenges associated to a high pile-up environment due to the high luminosity, the effect of the pile-up on the VBF invisibly decaying Higgs boson is studied as a benchmark process.

EW fermionic WIMP Dark Matter triplet

A fermionic triplet χ of the $SU(2)_L$ group with null hypercharge (Y): $\chi = \begin{pmatrix} \chi^+ \\ \chi_0 \\ \chi^- \end{pmatrix}$ is added to the SM with a Lagrangian:

$$\begin{aligned}\mathcal{L}_{MDM} &= \frac{1}{2}\bar{\chi}(i\not{D} + M)\chi \\ &= \frac{1}{2}\bar{\chi_0}(i\not{\partial} - M_{\chi^0})\chi_0 + \bar{\chi^+}(i\not{\partial} - M_{\chi^+})\chi^+ \\ &+ g(\bar{\chi^+}\gamma_\mu\chi^+(\sin\theta_W A_\mu + \cos\theta_W Z_\mu)) + \bar{\chi^+}\gamma_\mu\chi_0 W_\mu^- + \bar{\chi_0}\gamma_\mu\chi^+ W_\mu^+\end{aligned}$$

where g is the $SU(2)$ gauge coupling; M is the tree-level mass of the particle; $\sin\theta_W$ and $\cos\theta_W$ are the sine and cosine of the Weinberg angle; A_μ, Z_μ, W_μ are the SM boson fields. The lightest component of the triplet is stable if some extra symmetry is imposed, like lepton number, baryon minus lepton number or a new symmetry under which χ is charged (*e.g.* R-parity in SUSY).

At tree level all the χ components have the same mass, but a mass splitting is induced by the EW corrections given by loops of SM gauge bosons between the charged and neutral components of χ. These corrections make the charged components heavier than the neutral one (χ_0). Its mass differs by $\simeq$ 165 MeV [210] from the one of the charged components. Being neutral and stable, χ_0 constitutes a

potential DM candidate. If the thermal relic abundance is assumed, the mass of χ_0 is $M_{\chi_0} \simeq 3$ TeV. However, if χ is not the only particle composing dark matter or if it is not thermally produced [241], its mass can be $M_{\chi_0} < 3$ TeV.

This model provides a benchmark of a typical WIMP DM candidate and its phenomenology recreates the one of supersymmetric models where the Wino is the lightest SUSY particle (LSP), for this reason this triplet is referred to as *Wino-like*. As studied in Ref. [247], treating M as a free parameter, this triplet can be probed at the LHC in different ways. Once produced, the charged components of the triplet decay into the lightest neutral component χ_0 plus very soft charged pions. χ_0 is identified as $E_{\mathrm{T}}^{\mathrm{miss}}$ in the detector while the pions, because of the small mass splitting between the neutral and charged components, are so soft that they are lost and not reconstructed. Therefore, the production of χ can be searched for by in mono-X events, such as mono-jet [248] and mono-photon; in VBF +$E_{\mathrm{T}}^{\mathrm{miss}}$ events as χ can also be produced via VBF [249]; and also in events characterised by high p_T tracks (caused by $\chi^{\pm}$) which end inside the detector once they have decayed into χ_0 and soft pions, disappearing tracks [250]. The VBF production mode and the mono-photon final state, studied in this contribution, constitute a necessary complement to the mono-jet, discussed in Sections 3.1.1 and 3.1.3, and disappearing track searches, see Section 4.1.3, because of the very different dependencies on the model parameters like the EW representation and the value of the mass splitting. LEP limits exclude masses below ~ 90 GeV [99, 251, 252], therefore the focus here is on $M_{\chi_0} \geq 90$ GeV.

Signal events with a pair of χ produced in the framework of this model [247] have been generated in the $\gamma+E_{\mathrm{T}}^{\mathrm{miss}}$ and VBF+$E_{\mathrm{T}}^{\mathrm{miss}}$ final state and simulated for different values of χ_0 mass with the official ATLASFAST-II simulation of the current detector [253] at $\sqrt{s} = 13$ TeV. For the VBF+$E_{\mathrm{T}}^{\mathrm{miss}}$ analysis, diagrams not properly originating from two vector bosons (in contrast to pure VBF processes) also contribute to the signal as they produce a jets+$E_{\mathrm{T}}^{\mathrm{miss}}$ signature where the jets have large pseudorapidity separation. To consider the realistic conditions at the HL-LHC, VBF H (H$\rightarrow ZZ^* \rightarrow \nu\bar{\nu}\nu\bar{\nu}$) events have been fully simulated, using GEANT 4 [54, 254], in the upgraded ATLAS detector including the upgraded inner tracker (ITk) [255, 256], with $\langle\mu\rangle = 200$ and at $\sqrt{s} = 14$ TeV.

Mono-Photon final state

The mono-photon analysis is characterised by a relatively clean final state, containing a photon with a high transverse energy and large $E_{\mathrm{T}}^{\mathrm{miss}}$, which can be mimicked by few SM processes. The search for new phenomena performed in mono-photon events in pp collisions at $\sqrt{s} = 13$ TeV at the LHC, using data collected by the ATLAS experiment in Run-2 corresponding to an integrated luminosity of 36.1 fb^{-1} [245], has shown no deviations from the SM expectations. The Run-2 mono-photon search is reinterpreted in the context of the WIMP triplet model at HL by keeping the same strategy for background estimates and event selection to exploit the full complexity of the analysis. The dominant backgrounds consist in processes with a Z or W boson produced in association with a photon, mainly Z($\rightarrow \nu\nu$) + γ. They are estimated by rescaling the MC prediction for those backgrounds with factors obtained from a simultaneous fitting technique, based on control regions (CRs) built by reverting one or more cuts of the signal region such that one type of process becomes dominant in that region. Other backgrounds, like W/Z + jet, top and diboson, in which electrons or jets can fake photons are estimated with data-driven techniques.

Events passing the lowest unprescaled single photon trigger are selected requiring $E_{\mathrm{T}}^{\mathrm{miss}} > 150$ GeV. The leading photon has to satisfy the "tight" identification criteria and is required to have $p_{\mathrm{T}}^{\gamma} > 150$ GeV, $|\eta| < 2.37$ and to be isolated. The photon and $E_{\mathrm{T}}^{\mathrm{miss}}$ are required to be well separated, with $\Delta\phi(\gamma,\ E_{\mathrm{T}}^{\mathrm{miss}}) > 0.4$. Finally, events are required to have no electrons or muons and no more than one jet with $\Delta\phi(\mathrm{jet},\ E_{\mathrm{T}}^{\mathrm{miss}}) > 0.4$. In the Run-2 analysis the total background prediction uncertainty is dominated by the statistical uncertainty and the largest systematic uncertainties are due to the uncertainty in the rate of fake photons from jets and to the uncertainty in the jet energy scale.

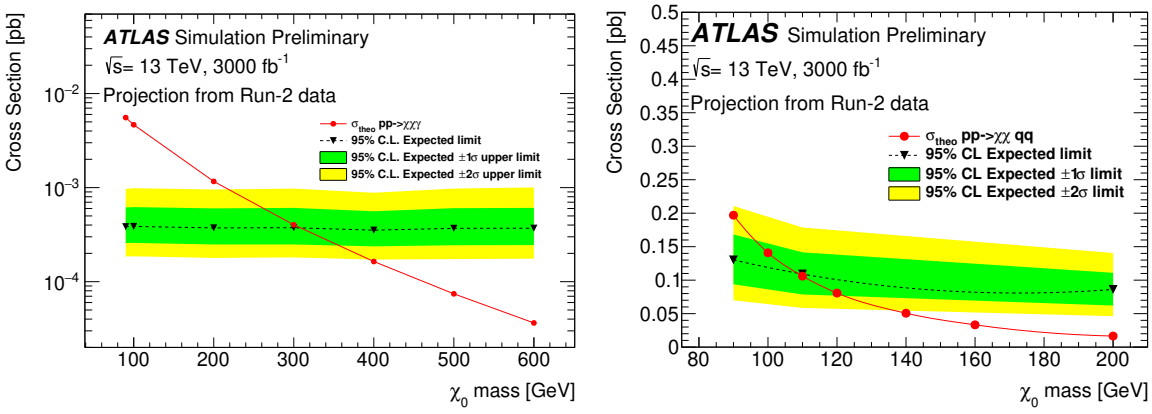

Fig. 3.3.4: Expected upper limits at 95% C.L. on the production cross section of χ as a function of χ_0 mass in (left) mono-photon final state and (right) VBF+$E_{\mathrm{T}}^{\mathrm{miss}}$ final state. Results are shown for an integrated luminosity of 3 ab^{-1}. The red line shows the theoretical cross section.

The reinterpretation of the mono-photon analysis in the WIMP triplet model uses full simulated MC signal samples and performs a simultaneous fit on the most inclusive signal region (SR), corresponding to $E_{\mathrm{T}}^{\mathrm{miss}} > 150$ GeV, that provides the best expected sensitivity. All backgrounds, including fake photons estimated with data-driven techniques, have been included in the fit rescaling the Run-2 results to the high luminosity scenario. All the systematic uncertainties on the MC background samples have been taken into account to obtain upper limits on the χ_0 production cross section. Projections of the expected upper limits on the production cross section of χ_0 at 95% C.L. for an integrated luminosity of 3 $\mathrm{ab}^{-1}$and $\sqrt{s} = 13$ TeV, are shown in Figure 3.3.4 (left). Masses of χ_0 below 310 GeV can be excluded at 95% C.L. by the analysis assuming the same systematic uncertainties adopted in Ref. [245]. The impact of the systematic uncertainty on the sensitivity of the analysis has been checked considering that the analysis will no more be limited by the statistical uncertainty at high luminosity. In a scenario in which the current systematic uncertainties are halved, an exclusion of χ_0 masses up to about 340 GeV could be reached. Thanks to the increased statistics, the analysis at high luminosity could be further optimised by performing a multiple-bin fit, thus on more bins in $E_{\mathrm{T}}^{\mathrm{miss}}$ improving the overall sensitivity of the analysis. This study is done for a c.o.m. energy of 13 TeV, a slight improvement in the signal significance is expected from the increase of the c.o.m. energy to 14 TeV foreseen for the HL-LHC.

VBF plus $E_{\mathrm{T}}^{\mathrm{miss}}$ final state

The VBF+$E_{\mathrm{T}}^{\mathrm{miss}}$ topology is characterised by two quark-initiated jets with a large separation in rapidity and $E_{\mathrm{T}}^{\mathrm{miss}}$. The sensitivity of the VBF+$E_{\mathrm{T}}^{\mathrm{miss}}$ analysis to the WIMP triplet model is presented as a reinterpretation of the Run-2 results for the high luminosity scenario foreseen for the HL-LHC. As pile-up is a key experimental challenge for event reconstruction in the VBF topology at the HL-LHC, a dedicated study of its impact is also shown using VBF $H \rightarrow$invisible as benchmark.

Projections at high luminosity for DM for EW triplet DM.
A search for an invisibly decaying Higgs boson produced via VBF has been performed by ATLAS using a dataset corresponding to an integrated luminosity of 36 fb^{-1} of pp collision at $\sqrt{s} = 13$ TeV [246]. The final state is defined by the presence of two energetic jets, largely separated in η and with $\mathcal{O}(1)$ TeV invariant mass, and large $E_{\mathrm{T}}^{\mathrm{miss}}$.

This analysis set limits on the BR $\mathcal{B}$ of the H$\rightarrow$ invisible. The main backgrounds arise from $Z \rightarrow \nu\nu$+jets and $W \rightarrow \ell\nu$+jets events. The contribution of W/Z is estimated from events in CRs enriched in $W \rightarrow \ell\nu$ (where the lepton is found) and $Z \rightarrow \ell\ell$ (with ℓ being electrons or muons) that are used to normalise the MC estimates to data through a simultaneous fitting technique and to extrapolate

the normalisation to the SR. The multijet background comes from multijet events where large $E_{\mathrm{T}}^{\mathrm{miss}}$ is generated mainly by jet mismeasurements. This is highly reduced by a tight $E_{\mathrm{T}}^{\mathrm{miss}}$ cut and is estimated via data-driven methods resulting in less than 1% of the total background.

The results are interpreted in the context of the WIMP model for an integrated luminosity of $3\ \mathrm{ab}^{-1}$. The same selections and analysis strategy are used to set limits on the cross section of the WIMP triplet produced via VBF; the only selection which has been changed is the request on the separation in pseudorapidity between the two leading jets ($\Delta\eta(j_1, j_2)$) which has been relaxed from > 4.8 to > 3.5, thus increasing the sensitivity to the model as, in addition to the pure VBF Feynman diagrams, also diagrams with strong production contribute to the signal. A SR is defined by selecting events passing the lowest unprescaled $E_{\mathrm{T}}^{\mathrm{miss}}$ trigger, containing no electron and muon, having exactly two jets with transverse momentum $p_T(j_1) > 80$ GeV and $p_T(j_2) > 50$ GeV, which are not back to back in the transverse plane ($\Delta\Phi(j_1, j_2) < 1.8$) and which are separated in pseudorapidity ($\Delta\eta(j_1, j_2) > 3.5$). Events are required to have large $E_{\mathrm{T}}^{\mathrm{miss}}$ (> 180 GeV), the two leading jets are separated from the $E_{\mathrm{T}}^{\mathrm{miss}}$ ($\Delta\Phi(j_1,\ E_{\mathrm{T}}^{\mathrm{miss}}) > 1$, $\Delta\Phi(j_2,\ E_{\mathrm{T}}^{\mathrm{miss}}) > 1$), the vectorial sum of all the jets (including the pile-up ones) is required to be $H_{\mathrm{T}}^{\mathrm{miss}} > 150$ GeV and the invariant mass of the dijet system is required to be $M(j_1, j_2) > 1$ TeV. The events in SR and in CRs are then split into three categories (*bins*) according to the invariant mass of the dijet system; the following $M(j_1, j_2)$ bins are considered: $1 - 1.5$ TeV, $1.5 - 2$ TeV and > 2 TeV.

A simultaneous fit in SR and CRs, using the three $M(j_1, j_2)$ bins to increase the signal sensitivity, is used for the $W/Z+$ jets background estimation and for the limit setting. Exclusion limits are set on the production cross section of the model using a one-sided profile likelihood ratio and the CLs technique [94, 95] with the asymptotic approximation [257]. Experimental and theoretical systematic uncertainties have been taken into account and are included in the likelihood as Gaussian-distributed nuisance parameters. The main experimental systematic uncertainties for the Run-2 VBF+$E_{\mathrm{T}}^{\mathrm{miss}}$ analysis come from JES and JER [258] and have been rescaled according to the HL expectations which are discussed in Ref. [7]. The main theoretical sources of uncertainty for the run-2 analysis come from choices on the resummation, renormalisation, factorisation and CKKW matching scale for the $W/Z+$jets backgrounds processes. A significant improvement in these systematic uncertainties is expected; therefore, the current run-2 theoretical systematic uncertainties on the $W/Z+$jets backgrounds have been rescaled down to reach the level of few $\%$ (5% of the run-2 theoretical systematic uncertainties is kept). Here is assumed that such an improvement in the theoretical systematics for VBF final state will be reached for the HL-LHC phase. The same correlation scheme that has been used in Ref. [246] is also used for the projections presented here. Uncertainties arising from the finite MC statistics of the samples used are assumed to be negligible.

The results obtained by rescaling the signals and backgrounds to an integrated luminosity of $3\ \mathrm{ab}^{-1}$ are shown in Figure 3.3.4 (right) and indicate that the lowest masses considered ($M_\chi \sim 110$ GeV) can be excluded at 95% C.L.. This study is done for a c.o.m. energy of 13 TeV, a slight improvement in the signal significance is expected from the increase of the c.o.m. energy to 14 TeV foreseen for the HL-LHC. The analysis is very sensitive to the systematic uncertainties and a further optimisation of the selection cuts on this model, together with the increase of the MC statistics in the VBF phase space, could help to achieve a better reach.

VBF analyses will probably benefit from a combination of $E_{\mathrm{T}}^{\mathrm{miss}}$ and VBF jet triggers; however, even with $E_{\mathrm{T}}^{\mathrm{miss}}$ thresholds raised by $50 - 100$ GeV with respect to the current ones, the analysis is still sensitive to this model for the masses considered.

The challenge of pile-up for VBF at HL-LHC.
In the study of the pile-up effects for VBF at the HL-LHC, jets are built from particle flow objects [259] using the anti-k_t algorithm with radius parameter $R = 0.4$ as implemented in FASTJET; they are only considered if $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 4.5$. Charged particle tracks are reconstructed from hits in the Itk.

	$\frac{\mathcal{B}(H\to\text{invs.})}{\mathcal{B}_{\text{Truth, Nominal}}(H\to\text{invs.})}$	Systematic Uncertainties			
		10%	5%	5% + fixed efficiency	1%
PU jet rejec	None	–	–	0.31	0.59
	$R_{p_{\text{T}}}$	–	–	0.28	0.48
	Truth	1.0	0.48	0.07	0.10

Table 3.3.1: The limit on the $H \to$ invisible BR using the full HL-LHC dataset ($3\ \text{ab}^{-1}$) normalised to the one for the Run-2 systematic uncertainties and truth-based pile-up tagging to show the relative gains and losses possible under various scenarios. A '–' indicates a value bigger than 1.

Tracks are associated to the jets and required to have $p_{\text{T}} > 0.9$ GeV and $p_{\text{T}} < 40$ GeV (to suppress fake tracks). The difference between the primary vertex (this is the vertex with the highest $\sum p_{\text{T}}^2$) z position and the track z_0 (longitudinal impact parameter) must be less than 2σ, where σ is the sum in quadrature of the track z_0 and the vertex z uncertainties.

One of the key discriminating observables between pile-up jets and hard-scatter jets is $R_{p_{\text{T}}}$ [260], which is the sum of the p_{T} of the tracks associated to the jet normalised by the jet p_{T}. Only tracks with $\Delta R < 0.3$ are considered in the calculation of $R_{p_{\text{T}}}$. Jets are declared 'hard-scatter' if $R_{p_{\text{T}}} > 0.05$ which corresponds to 85% hard-scatter efficiency and 2% pile-up jet efficiency when $|\eta| < 1.2$ and $|z^{\text{reco}} - z^{\text{true}}| < 0.1$. $E_{\text{T}}^{\text{miss}}$ is critical to the $H \to$ invisible search; as an optimisation for the $E_{\text{T}}^{\text{miss}}$ reconstruction for the upgraded ATLAS detector is not yet available, the negative sum of the transverse momenta of all reconstructed jets ($E_{\text{T,jet}}^{\text{miss}}$) is used in this analysis.

Due to limitations of MC statistics, a simplified version of the Run-2 VBF $H \to$ invisible analysis is used. In particular, all of the angular requirements with jets are removed and there is no binning in $M(j_1, j_2)$ and $E_{\text{T,jet}}^{\text{miss}}$ is required to be > 150 GeV. For the Run-2 analysis, the event selection efficiency for $Z \to \nu\bar{\nu}$ events is about 2×10^{-6} and about 0.5% for the signal with a $\mathcal{B}(H \to \text{invisible}) = 100\%$ (which is about 85% from VBF). Contrary to the Run-2 analysis, here the ggF $H \to$ invisible contribution has been neglected. The background is nearly half QCD $Z \to \nu\bar{\nu}$ and half QCD W+jets. Since only Z+jets are used in this analysis, BR limits are computed by doubling the Z+jets background. It is likely that with the extended coverage of the ITk relative to the current tracker the lost leptons will be suppressed and thus the W+jets background will be less than the Z+jets rate so this approximation is conservative.

A simplified statistical analysis is performed to assess the impact of several scenarios on the $H \to$ invisible BR limit with the full HL-LHC dataset. A one-bin statistical test with one overall source of systematic uncertainty is performed to determine if a particular signal yield is excluded. The signal yield is scanned to determine the largest BR that would be not excluded at the 95% C.L.. Table 3.3.1 presents the limits on the $H \to$ invisible BR normalised to the one for the run-2 systematic uncertainties and truth-based pile-up tagging to show the relative gains and losses under various pile-up scenarios, corresponding to the three rows, and with different assumptions on the systematic uncertainties, corresponding to the four columns: 10% (similar to run-2), 5%, 5% assuming the same signal efficiency as in Run-2 and the background efficiency to be 10% of the signal efficiency; and finally 1%. With a realistic reduction in the systematic uncertainty and tighter selection criteria, it may be possible to significantly improve the sensitivity. The limit improves from including a simple $R_{p_{\text{T}}}$-based pile-up jet rejection, though the gap with the truth-information-based tagger indicates that there is room (and reward) for developing a more sophisticated approach.

As an overall conclusion, with a combination of pile-up robustness studies, analysis optimisation, and theory uncertainty reduction, the EW triplet DM searches at the HL-LHC, both in mono-photon and VBF+$E_{\text{T}}^{\text{miss}}$ final states, may be significantly improved.

3.3.3 *Search for Higgs portal dark matter models at HL- and HE-LHC*

Contributors: Y. G. Kim, C. B. Park, S. Shin

In a variety of BSM models, the Higgs boson is often considered as a particle mediating the interactions between the dark matter and the SM particles, dubbed as *Higgs portal*. The Higgs portal models can be categorised by the spin of DM as scalar, fermionic, or vector Higgs portal models.

The scalar Higgs portal models consider a SM singlet scalar DM (S) which has interactions with the SM Higgs doublet (H) as [261, 262] $SS^*HH^\dagger$, which is a four-dimensional operator. This type of models is often considered as a simplest reference DM model so that there exist various complementary searches combining the results from the direct detection, indirect detection, and the LHC.

The second category of Higgs portal models is the fermionic Higgs portal model considering a fermion (ψ) as DM. The interaction term between the DM (ψ) and the SM Higgs doublet can be effectively given as [263]

$$\frac{\psi\bar{\psi}HH^\dagger}{\Lambda}\,, \tag{3.3.1}$$

assuming the interaction is mediated by additional heavy particle(s) with mass scale Λ and the DM ψ is a Dirac fermion. The searches at the LHC, e.g., mono-jet with missing energy, provide constraints directly to Λ and the mass of DM. Because this is a five-dimensional operator, a renormalisable simplified model was first introduced in Ref. [264] by adding a SM real singlet scalar S which mixes between the SM Higgs doublet and the singlet scalar. Beyond the minimal set-up in Ref. [264], one can also consider the SM scalar field S a complex scalar, pseudo scalar field [265–269]. Equipped with the mixing and the existence of additional mediator (singlet-like mass eigenstate), this kind of model has been widely used in consistently explaining various experimental/observational results within the context of DM, such as possible direct detection experimental anomalies for light DM region [270], γ-ray observation from the Galactic Centre [268, 269], baryon-antibaryon asymmetry [271], and so on.

The third category of Higgs portal models is the vector DM model with interaction term between the DM (V^μ) and the SM Higgs doublet [272] $V^\mu V_\mu HH^\dagger$. The vector dark matter can be, e.g., a $U(1)$ vector field which gets a mass term though the Stueckelberg mechanism.

In this report, we focus on the Dirac fermion DM model as a benchmark model and show proper strategies searching for the signals at HL- and HE-LHC. Note that the results would apply similarly to other kind of models, *i.e.* scalar or vector DM models.

Benchmark model: As a benchmark model we choose the Singlet Fermionic Dark Matter (SFDM) model [264, 268–270, 273] because the analysis methods and results are readily applicable to other type of models. The SFDM has a dark sector composed of a SM singlet real scalar field S and a singlet Dirac fermion field ψ which is the DM candidate. The dark sector Lagrangian with most general renormalisable interactions is given by

$$\mathcal{L}^{\rm dark} = \bar{\psi}(i\not{\partial} - m_{\psi_0})\psi + \frac{1}{2}\partial_\mu S\partial^\mu S - g_S(\cos\theta\,\bar{\psi}\psi + \sin\theta\,\bar{\psi}i\gamma^5\psi)S - V_S(S,\,H), \tag{3.3.2}$$

where

$$V_S(S,\,H) = \frac{1}{2}m_0^2S^2 + \lambda_1 H^\dagger HS + \lambda_2 H^\dagger HS^2 + \frac{\lambda_3}{3!}S^3 + \frac{\lambda_4}{4!}S^4. \tag{3.3.3}$$

The interactions of the singlet sector to the SM sector arise only through the Higgs portal $H^\dagger H$ as given above. Note that the Lagrangian in Eq. (3.3.2) generally includes both scalar and pseudoscalar interaction terms in the singlet sector, in contrast to the basic model in Ref.s [263, 264, 270], following the set-up explaining the galactic γ-ray signal [268, 269]. [2]

[2] See also Ref. [266].

	$\not{E}_T^{\rm DM}$ + jet	$\not{E}_T^{\rm DM}$ + ($h_1/h_2 \to$ SM particles)	No $\not{E}_T^{\rm DM}$
Single h_1	$pp \to h_1 \to \psi\psi$	N/A	SM Higgs precision
Single h_2	$pp \to h_2 \to \psi\psi$	N/A	$pp \to h_2 \to$ SM (m_{h_2})
Double h_1h_1: c_{111}	$pp \to h_1 \to h_1h_1 \to 4\psi$	$pp \to h_1 \to h_1h_1 \to 2\psi$ + SM	$pp \to h_1 \to h_1h_1$ (double Higgs production)
Double h_1h_1, h_1h_2: c_{112}	$pp \to h_2 \to h_1h_1 \to 4\psi$ $pp \to h_1 \to h_1h_2 \to 4\psi$	$pp \to h_2 \to h_1h_1 \to 2\psi$ + SM $pp \to h_1 \to h_1h_2 \to 2\psi$ + SM (m_{h_2})	$pp \to h_2 \to h_1h_1$ (m_{h_2}) $pp \to h_1 \to h_1h_2$ (m_{h_2})
Double h_2h_2, h_1h_2: c_{122}	$pp \to h_1 \to h_2h_2 \to 4\psi$ $pp \to h_2 \to h_1h_2 \to 4\psi$	$pp \to h_1 \to h_2h_2 \to 2\psi$ + SM (m_{h_2}) $pp \to h_2 \to h_1h_2 \to 2\psi$ + SM (m_{h_2})	$pp \to h_1 \to h_2h_2$ (m_{h_2}) $pp \to h_2 \to h_1h_2$ (m_{h_2})
Double h_2h_2: c_{222}	$pp \to h_2 \to h_2h_2 \to 4\psi$	$pp \to h_2 \to h_2h_2 \to 2\psi$ + SM (m_{h_2})	$pp \to h_2 \to h_2h_2$ (m_{h_2})

Table 3.3.2: Production channels of h_1/h_2, dubbed as "h_i production", categorised by the signal types. $\not{E}_T^{\rm DM}$ is the missing transverse energy originated from the DM, "SM particles" means the SM particles produced from the decay of the Higgs bosons (h_1 and h_2), and m_{h_2} means that we can observe a h_2 resonance signal.

The SM Higgs potential is given as $V_{\rm SM} = -\mu^2 H^\dagger H + \lambda_0 (H^\dagger H)^2$ and the Higgs boson gets a VEV after electroweak symmetry breaking (EWSB), $v_h =\simeq 246$ GeV. The singlet scalar field generically develops a VEV , v_s, and hence we can expand $S = v_s + s$. There is mixing between the states $h, s$and the physical mass states are admixtures of h and s, where the mixing angle is determined by $\tan\theta_s = y/(1+\sqrt{1+y^2})$ with $y \equiv 2\mu_{hs}^2/(\mu_h^2 - \mu_s^2)$. The expressions of each matrix element in terms of the Lagrangian parameters are given in Ref. [268, 269]. Then, the tree-level Higgs boson masses are obtained as

$$m^2_{h_1,\,h_2} = \frac{1}{2}\left[(\mu_h^2 + \mu_s^2) \pm (\mu_h^2 - \mu_s^2)\sqrt{1+y^2}\right], \tag{3.3.4}$$

where we assume that h_1 corresponds to the SM-like Higgs boson.

An interesting feature of this model is that there are extra scalar self-interaction terms. The cubic self-couplings c_{ijk} for $h_ih_jh_k$ interactions, *i.e.* $c_{111}h_1^3/3! + c_{112}h_1^2h_2/2 + c_{122}h_1h_2^2/2 + c_{222}h_2^3/3!$, are functions of the scalar couplings, vacuum expectation values, and θ_s, where the exact forms are written in Ref. [268, 269]. Note that c_{112} is proportional to $\sin\theta_s$ due to the fact that $\lambda_1 + 2\lambda_2 v_s$ is also proportional to $\sin\theta_s$, while the other couplings can remain non-vanishing.

Signals at the LHC: The search strategies for SFDM at the LHC rely on the production methods of the SM-like Higgs h_1 and the singlet-like Higgs h_2. Hence, we first categorise the production channels of h_1/h_2 as following.

- Single h_1/h_2 production from the Yukawa or gauge interactions
- Double h_1/h_2 production from the scalar self-interactions

The first category implies the conventional single Higgs production mechanisms such as gluon fusion, vector boson fusion, $t\bar{t}h$, Higgsstrahlung, *etc.*. Hence, for single h_1 production, the precise measurements of the SM Higgs production mechanisms, dubbed as *Higgs precision*, would provide the indirect hints of the SFDM, unless h_1 decays to DM pair. The second category includes exotic signatures depending on the values of trilinear couplings so we further divide the production channels affected by each coupling.

As a next step, the signal type should be classified for each production channel of h_1/h_2. Here, we categorise the signal types as

- $\not{E}_T^{\rm DM}$ + jets
- $\not{E}_T^{\rm DM}$ + ($h_1/h_2 \to$ SM particles)
- No $\not{E}_T^{\rm DM}$

where $\not{E}_T^{\rm DM}$ is the missing energy from the DM production, defined to separate from the missing energy from the neutrino production in the SM, e.g., $Z \to \nu\bar{\nu}$. Such a missing energy signal from the neutrino production belongs to the last category, "No $\not{E}_T^{\rm DM}$".

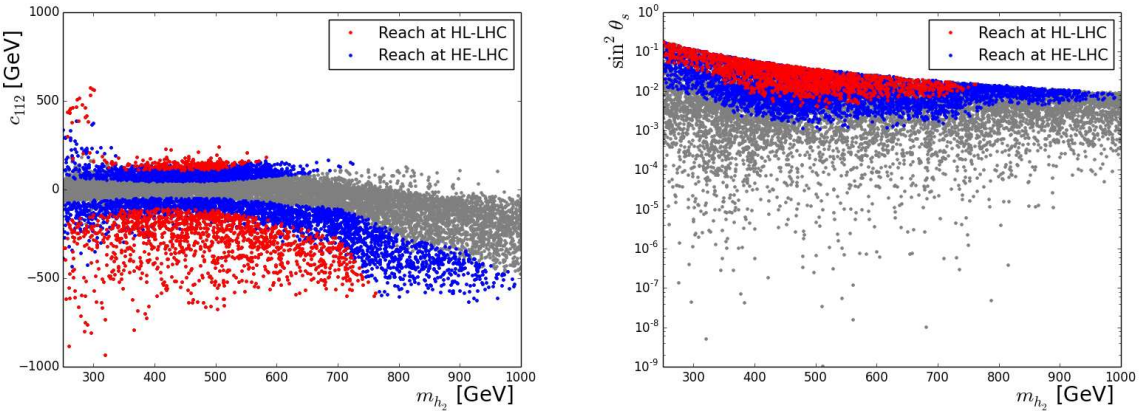

Fig. 3.3.5: Expected parameter reach by searching for on-shell $pp \to h_2 \to h_1 h_1$ at HL-LHC (HE-LHC) is shown with red (blue) scatter points in the $m_{h_2} - c_{112}$ (left) and $m_{h_2} - \sin^2\theta_s$ (right) plane. The gray scatter points are out of the reach of HE-LHC but satisfying the stability of the scalar potential $V_S(S,\, H) + V_{\rm SM}$ and the current constraints from Ref. [274].

Table 3.3.2 summarises the production channels of h_1/h_2 and the suitable signal type for each channel. As stated above, the double Higgs production channels are further classified by the trilinear coupling involved in the process. In many channels, searches for exotic resonance signals by the decay of h_2, remarked as (m_{h_2}), can be effective methods in probing the Higgs portal DM models. As long as the DM mass is larger than $m_{h_2}/2$, the BRs of $h_2 \to$ SM particles are the same as those expected for the hypothetical SM Higgs (with an arbitrary mass not restricted to ~ 125 GeV). Note that all the processes can occur altogether so one needs a combined analysis to confirm the scenario.

As preliminary but simple examples, we analyse the expected sensitivities of the on-shell processes $pp \to h_2 \to h_1 h_1$ and $pp \to h_1 \to h_2 h_2$, in the signal type "No $\not{E}_T^{\rm DM}$, assuming the Higgs bosons are produced on-shell. For the on-shell process $pp \to h_2 \to h_1 h_1$, we apply the search results for heavy scalar into $h_1 h_1 \to b\bar{b}b\bar{b}$ in ATLAS [274] with 36.1 fb^{-1} data at $\sqrt{s} = 13$ TeV. The sensitivity at HL-LHC is estimated from rescaling the upper limits in Ref. [274] by $\sqrt{36.1/3000}$ assuming the number of background events at $\sqrt{s} = 13$ TeV and $\sqrt{s} = 14$ TeV are similar. We also assume the signal significance is well approximated by signal/$\sqrt{\rm background}$ where the statistical uncertainty is dominant. On the other hand, it is non-trivial to obtain the sensitivity at HE-LHC. For simplicity, we only consider the ratio of the dominant background events (multi-jets [274]) at $\sqrt{s} = 27$ TeV and $\sqrt{s} = 13$ TeV, which is 2.9 from running MADGRAPH5NLO. In Fig. 3.3.5, we show the expected reach at HL-LHC (HE-LHC). The gray scatter points are out of the reach of HE-LHC. Note that all the scatter points satisfy the stability of the scalar potential $V_S(S,\, H) + V_{\rm SM}$ and the current constraints from Ref. [274]. From this result, we conclude that HL-LHC (HE-LHC) can constrain the parameter $|c_{112}|$ up to 100 (50), which correspond to $\sin^2\theta_s \sim 0.004$ (0.001).

For the on-shell process $pp \to h_1 \to h_2 h_2$, we apply the search results for $pp \to W h_1 \to W h_2 h_2 \to \ell\nu_\ell b\bar{b}b\bar{b}$ or $pp \to Z h_1 \to Z h_2 h_2 \to \ell\bar{\ell}b\bar{b}b\bar{b}$ in ATLAS [275] with 36.1 fb^{-1} data at $\sqrt{s} = 13$ TeV. Since the dominant background is $t\bar{t}$ + light jets, we apply the aforementioned method in obtaining the sensitivities at HL-LHC and HE-LHC for simplicity. In Fig. 3.3.6, we show the expected reach at HL-LHC (HE-LHC).The gray scatter points are out of the reach of HE-LHC but satisfying the stability of the scalar potential $V_S(S,\, H) + V_{\rm SM}$ and the current constraints from Ref. [275]. Interestingly, we estimate that HL-LHC can cover most of the parameter space unless $|c_{122}|$ is as small as ~ 5 GeV.

In summary, in this section we have explained the SFDM as a reference Higgs portal model. Since the existence of the extra scalar h_2 is a key ingredient of the model, we categorise the possible production channels of the two Higgs bosons (h_1 and h_2) and suitable signal types at the LHC. As a simple example,

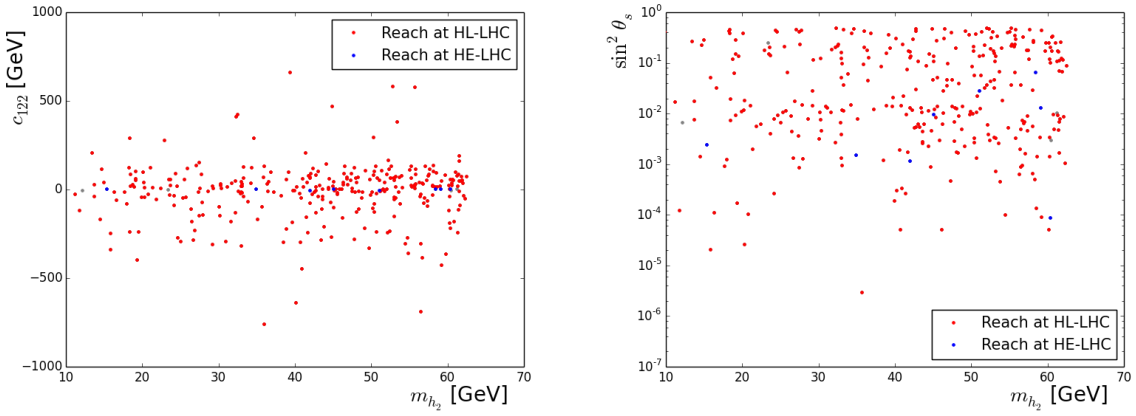

Fig. 3.3.6: Expected parameter reach by searching for on-shell $pp \to h_1 \to h_2 h_2$ (exotic Higgs decay) at HL-LHC (HE-LHC) is shown with red (blue) scatter points in the $m_{h_2} - c_{122}$ (left) and $m_{h_2} - \sin^2\theta_s$ (right) plane. The gray scatter points are out of the reach of HE-LHC but satisfying the stability of the scalar potential $V_S(S, H) + V_{\rm SM}$ and the current constraints from Ref. [275].

Field	Spin	$su(3) \times su(2)_L \times u(1)_Y$	$\mathbb{Z}_2$	Copies	DOF
χ	1/2	(1,1,0)	-1	1	4
ϕ_i	0	(1,1,-1)	-1	n	$2n$

we estimate the experimental sensitivities of HL-LHC and HE-LHC for two simple on-shell processes $pp \to h_2 \to h_1 h_1$ and $pp \to h_1 \to h_2 h_2$ with several naive assumptions.

3.3.4 Singlet dark matter with slepton-like partners at HL- and HE-LHC

Contributors: M. J. Baker and A. Thamm

In this contribution we use a simplified model framework to explore the prospects for the HL and HE-LHC to probe viable multi-TeV dark matter. We consider a bino motivated (gauge-singlet Dirac or Majorana fermion) dark matter candidate accompanied by n dark-sector scalars with unit hypercharge, table 3.3.3. We consider the three possible Yukawa couplings with SM electrons, muons and taus individually. A pure singlet with no other nearby states cannot efficiently annihilate, resulting in overclosure of the universe. However, when dark sector scalars are included, the observed relic abundance can be recovered for a relatively wide range of masses. In Ref. [276] we determine the couplings which produce the observed abundance of dark matter and calculate the reach of a range of present and future direct detection, indirect detection and collider experiments. In this summary, we will see that there is a large region of viable parameter space for Majorana dark matter which only future colliders, such as the HL- and HE-LHC, can probe.

In addition to kinetic and mass terms, the Lagrangian only has one new interaction term (ignoring the scalar quartic, which plays no role in our phenomenology)

$$\mathcal{L} \supset \overline{\chi}(i\partial\!\!\!/ - m_\chi)\chi + \frac{1}{2}|D_\mu \phi_i|^2 - \frac{1}{2}m_\phi^2 \phi_i^2 + (y_\chi \phi_i \overline{\chi} \ell_R + h.c.)\,, \tag{3.3.5}$$

where $D_\mu = \partial_\mu - ig'YB_\mu$ and the coupling is taken to be universal, *i.e.* y_χ is the same for all ϕ_i. We consider the cases $\ell_R = e_R, \mu_R$ and τ_R, and assume that all ϕ_i have the same mass, $m_{\phi_i} = m_\phi$, and that $m_\chi < m_\phi$. We parametrise their mass splitting by $\Delta = (m_\phi - m_\chi)/m_\chi$. For illustration, we focus on $n \in \{1, 10\}$. In a supersymmetric context, the DM particle χ would correspond to a bino and

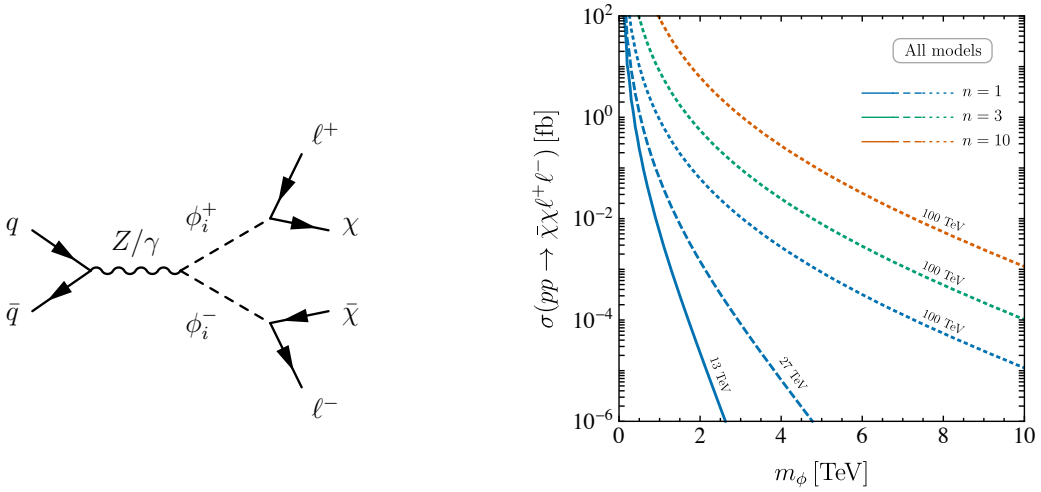

Fig. 3.3.7: Leading order partonic process contributing to $pp \to \phi^+\phi^- \to \bar{\chi}\chi\ell^+\ell^-$ (left) and its cross-section at 13 TeV, 27 TeV and 100 TeV including a K-factor of 2 (right).

the scalar ϕ_i can be identified with a right-handed slepton. In SUSY, the number of degrees of freedom of one right-handed slepton corresponds to $n = 1$, all right-handed sleptons corresponds to $n = 3$, while all right-and left-handed sleptons correspond to $n = 9$. We calculate the relic abundances in our models using MICROMEGAS V4.3.5 [277], and then restrict the new Yukawa couplings to lie on the relic surface when considering the reach of various experiments.

It is challenging to search for our dark matter models directly at a hadron collider, since the dark matter is a gauge singlet which only couples to leptons. The coannihilation partner, $\phi_i^\pm$, however is a charged scalar of similar mass. It will be pair produced in the process $pp \to \phi_i^+\phi_i^-$ with a subsequent decay to a lepton, ℓ, and χ, depicted in Fig. 3.3.7 (left), where $\mathcal{B}(\phi_i^\pm \to \chi\ell^\pm) = 1$. We focus on final states containing two opposite-sign same-flavour leptons and missing energy. As τ reconstruction at future colliders is particularly challenging to model, we do not provide collider limits for the τ models. However, it is clear that the collider reach on τ models will be somewhat worse than the limits on the models involving electrons and muons.

We present sensitivity projections for the HE-LHC with $\sqrt{s} = 27$ TeV assuming an integrated luminosity of 15 ab^{-1} [278] and for the FCC-hh with $\sqrt{s} = 100$ TeV and 20 ab^{-1} [279]. We estimate the sensitivity of future colliders to our models by adapting the analysis used in Ref. [85] to search for slepton pair production with subsequent decay to neutralinos and leptons.

The signal $pp \to \phi^+\phi^-$ is simulated using a custom SARAH V4.12.1 [280] model, we generate the signal and background parton level events using MADGRAPH5 V2.6.2 [67], simulate the showering using PYTHIA 6.4.28 [92] and perform the detector simulation with DELPHES V3.3.3 [33]. For our 27 TeV simulations, we use the default DELPHES card. For the simulations at 100 TeV we use the FCC DELPHES card implementing the configurations proposed by the FCC working group [281]. For the signal simulation, we adapt the card to treat the DM particle as missing energy. We use the LO partonic production cross-sections and multiply by a generous K-factor of 2, as we want to find the exclusion limits in the optimistic case, Fig. 3.3.7 (right). To validate our analysis, we reproduce the relevant backgrounds in Ref. [85].

The main SM backgrounds to our signal are WW, VV, WV, $t\bar{t}$, Wt and V+jets, where $V = Z, \gamma$. While only WW and VV are irreducible backgrounds, WV, $t\bar{t}$ and Wt contribute if a lepton or one or two b-jets are missed. The V+jets background is important at low values of m_{T2}, but is negligible above $m_{\text{T2}} \approx 100$ GeV. In order to isolate the signal, we impose the following cuts. Two opposite-sign same-flavour light leptons are required with $p_T > 35$ GeV and $p_T > 20$ GeV for leading and subleading

Channel	$\mu^+\mu^-\nu_{\text{all}}\bar{\nu}_{\text{all}}$		$\mu^+\mu^- l_{\text{all}}\nu$		Example Signal	
Energy [TeV]	27	100	27	100	27	100
No Cuts	2100	6900	560	1800	17	100
$p_T^{\mu_1(\mu_2)} > 35(20)$ GeV & Lepton veto	1100	620	120	160	12	14
Jet veto	690	530	45	61	3.3	9.4
$m_{\mu\mu} > 20$ GeV & $\lvert m_{\mu\mu} - m_Z\rvert > 10$ GeV	470	370	6.6	13	3.3	8.9
$m_{\text{T2}} > 200$ GeV	0.26	0.44	0.022	0.076	1.3	2.5

Table 3.3.4: Cross-sections at each stage in fb. The example signals are for the muon type model with $n = 10$ for the parameter points $m_\chi = 0.6$ TeV, $\Delta = 0.34$ (27 TeV) and $m_\chi = 0.8$ TeV, $\Delta = 0.2$ (100 TeV).

leptons, respectively. We veto events with any other leptons, which reduces the WV background. Removing events with $m_{\mu\mu} < 20$ GeV and $|m_{\mu\mu} - m_Z| < 10$ GeV significantly reduces backgrounds with a Z-boson in the final state. Finally we cut on the transverse mass [130, 131], $m_{\text{T2}} > 200$ GeV. For a process where two particles each decay to a lepton and missing energy, the m_{T2} distribution will have an end point at the mass of the heavier particle [282]. Although in Ref. [85] a cut of $m_{\text{T2}} > 90$ GeV is used, we increase this to $m_{\text{T2}} > 200$ GeV. This has a small effect on our signal efficiency, as we are mostly interested in dark matter candidates with mass larger than 200 GeV, while strongly reducing the background from $t\bar{t}$, Wt. However, even with this large cut, we find a significant background from WW, WV and VV, where at least one of the vector bosons is extremely off-shell. To include this effect in MADGRAPH we simulate $pp \to \ell^+\ell^-\nu_{\text{all}}\bar{\nu}_{\text{all}}$ and $pp \to \ell^+\ell^-\ell_{\text{all}}\nu$, where ν_{all} is ν_e, ν_μ or ν_τ and ℓ_{all} is any charged lepton. We do not find a similar large contribution from off-shell particles in the $t\bar{t}$ and Wt channels. Even though the cross-section of these gluon initiated channels grows faster than the di-boson processes as the collider energy is increased, they remain a subdominant background as the t is narrower and as this background only passes the cuts if a jet is missed, reducing the m_{T2} endpoint. Finally, we checked that the contribution from jets faking muons is negligible. In table 3.3.4 we show the cross-sections at each stage in the analysis for the background and for an example signal, $m_\chi = 0.6$ TeV, $\Delta = 0.34$ (27 TeV) and $m_\chi = 0.8$ TeV, $\Delta = 0.2$ (100 TeV), both for the $n = 10$ muon type model.

In Fig. 3.3.8 we show the differential distribution in m_{T2} for the muon-type model for the events passing all cuts, for the background and example signal. We see that $\mu^+\mu^-\nu_{\text{all}}\bar{\nu}_{\text{all}}$ is the dominant background, and $\mu^+\mu^-\ell_{\text{all}}\nu$ is around an order of magnitude smaller. This is due to both the smaller initial cross-section and the smaller efficiency. We see that both the background and the example signal falls sharply from $m_{\text{T2}} = 200$ GeV to $m_{\text{T2}} \approx 500$ GeV. However, the signal will continue to higher values of m_{T2} for other points in our parameter space. We also see that at 27 TeV, the $\mu^+\mu^-\nu_{\text{all}}\bar{\nu}_{\text{all}}$ continues out to higher values of m_{T2}, while at 100 TeV the situation is reversed.

To estimate the expected exclusion limit, we use a Poisson counting procedure for the signal and background events which pass all the cuts, based on a frequentist framework [257, 283]. In Fig. 3.3.9 we present the 90% C.L. sensitivity for the muon type models at a 27 TeV and a 100 TeV proton-proton collider. The parameter space probed is where m_χ is small and Δ is relatively large. The reach is independent of whether dark matter is Majorana or Dirac, since it depends on the ϕ-pair production cross-section and the fact that $\mathcal{B}(\phi_i^\pm \to \chi\ell^\pm) = 1$. The large m_χ region is not probed as m_ϕ increases with m_χ, and the ϕ-pair production cross-section decreases rapidly as m_ϕ increases, Fig. 3.3.7 (right). We see that in both cases the limits are strongest when there are more coannihilation partners. This is because the $pp \to \chi\bar{\chi}\ell^+\ell^-$ cross-section scales as n^2. For $n = 1$, the 27 TeV (100 TeV) machine can probe $m_\chi < 0.75$ TeV (1.2 TeV), for $n = 3$ it can probe $m_\chi < 1.3$ TeV (2.3 TeV) while for $n = 10$ the limits are $m_\chi < 2.0$ TeV (4.0 TeV). The small Δ region is not probed as in this region the momentum of the leptons is small and they are not efficiently reconstructed. This is a well known problem in the coannihilation region. The gap for lower Δ can be closed, e.g., by looking for ISR [284, 285] or for disappearing charged tracks [286–288].

We also overlay the direct and indirect detection bounds from [276], to give a summary of all the relevant current and future experimental constraints. We see that the situation is dramatically different

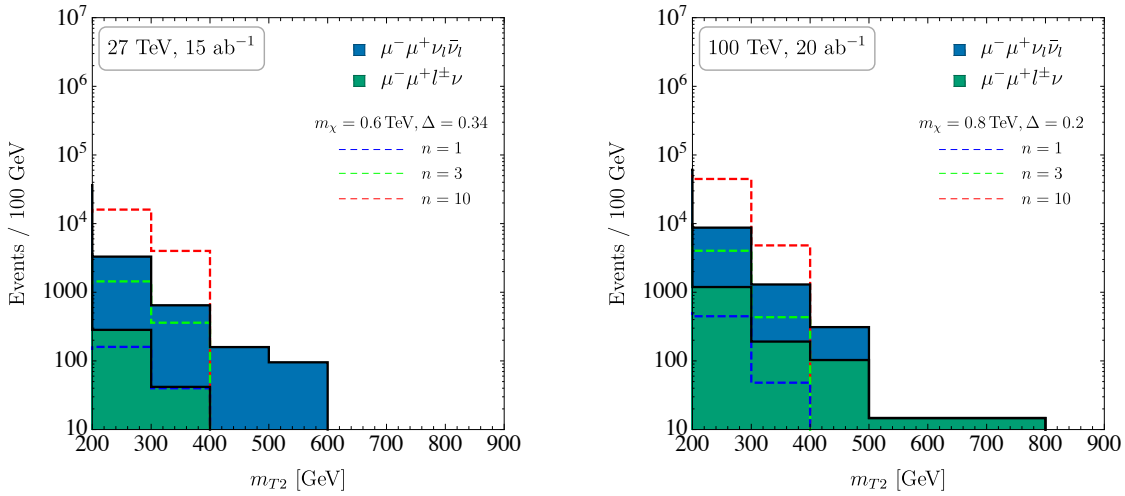

Fig. 3.3.8: m_{T2} distribution for background events passing all cuts for the muon model, and an example signal for $n = 1, 3, 10$, at 27 TeV (left) and 100 TeV (right). We do not use this information in determining the reach, but simply perform a cut-and-count analysis based on these events.

for Dirac and Majorana χ. For Dirac χ, small masses and mass splittings have already been excluded by LUX [289]. In the future, DARWIN [290] will probe the full parameter space, while colliders and indirect detection (only under the assumption of a cuspy dark matter halo profile) will be sensitive for relatively low masses and large or small Δ, respectively. We see that the challenging small Δ region at colliders is excluded by the existing bound from LUX.

For Majorana χ, on the other hand, DARWIN, with the maximum exposure, is limited to probing only small masses and small Δ, while there are no constraints from indirect detection. This is due to the velocity suppression of both the DM-nucleus and the annihilation cross-sections. The collider bounds are the same as in the Dirac case, since the mass term of χ does not enter into the production and decay of ϕ-pairs. In this case, future colliders are essential for probing the large Δ region of the parameter space.

Finally, the reach for electron final states is marginally worse than for muon final states due to the fact that the electron reconstruction efficiency is slightly worse than for muons. Again, we conclude that future colliders are essential for probing the large Δ region of the parameter space.

3.4 Dark sectors

As in our ordinary world, a dark sector could allow for long-range forces among its matter constituents. Evidence from both cosmology and astrophysics may supporting the possibility of long-range interactions among DM constituents (see, for instance, the role of massless dark photons in galaxy formation and dynamics [291–298]). In the following sections, prospect studies for searches for dark photons at HL- and HE-LHC are presented.

3.4.1 Prospects for dark-photon at the HL-LHCb

Contributors: P. Ilten, M. Williams and X. Cid Vidal, LHCb

A compelling scenario in the search for dark forces and other portals between the visible and dark sectors is that of the dark photon A'. In this case, a new $U(1)$ dark force, analogous to the electromagnetic (EM) force, can be introduced into the SM, where the dark photon is the corresponding force mediator which couples to dark matter (or matter) carrying dark charge. The A' can kinetically mix with the photon, allowing the A' to be observed in the spectra of final states produced by the EM current. This mixing can be thought of as a low-energy consequence of a loop process, potentially involving very high

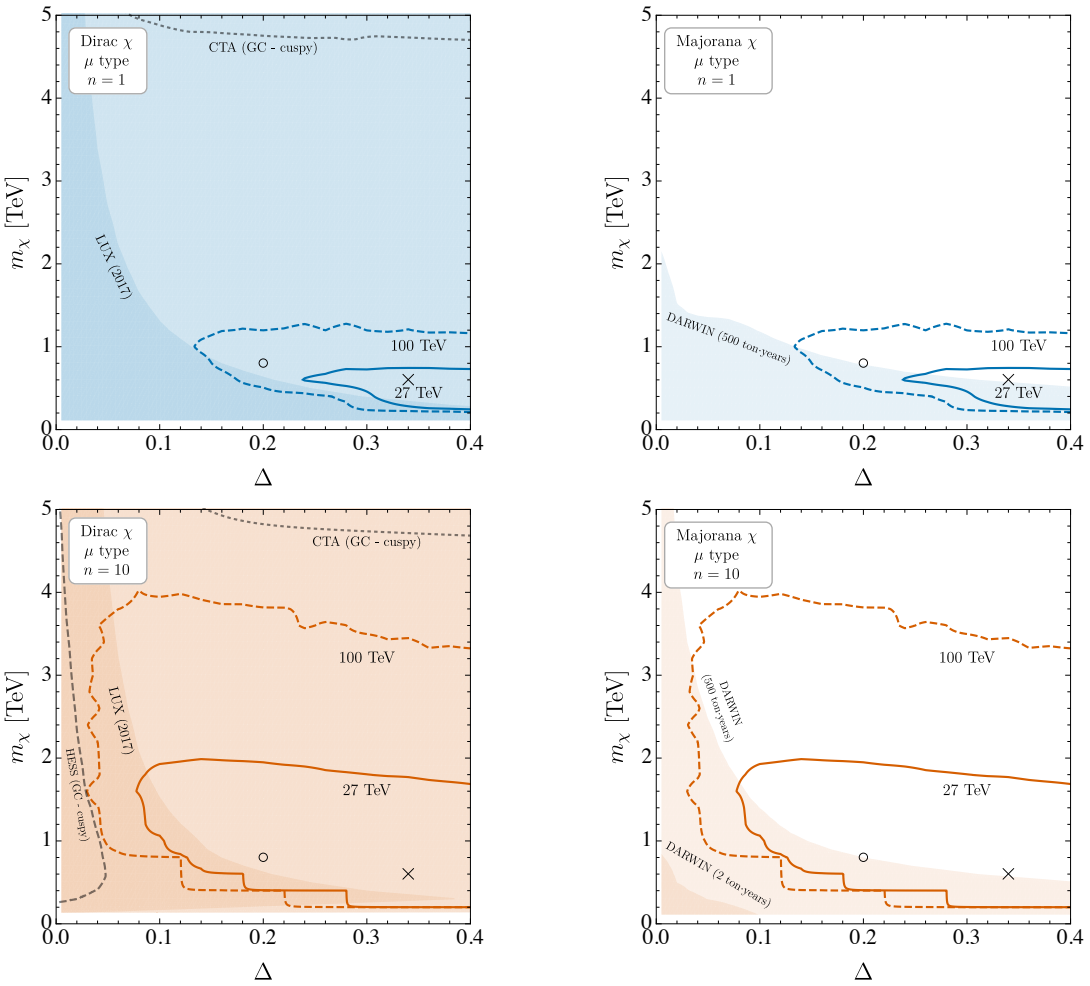

Fig. 3.3.9: Reach of future colliders at 90% C.L., current and future direct detection experiments at 90% C.L., and current and future indirect detection experiments at 95% C.L. for Dirac (left) and Majorana (right) DM interacting with a muon and one (top) and ten (bottom) coannihilation partners in the $\Delta - m_\chi$ plane. The lightly, moderately and strongly shaded regions correspond to the direct detection limits by the future DARWIN experiment with $500\,\text{ton} \cdot \text{years}$, $2\,\text{ton} \cdot \text{years}$ and the LUX limits, respectively, which are discussed in detail in Ref. [276]. The circle and cross signify our example signals shown in Fig. 3.3.8.

mass particles, that connect the visible and dark sectors.

The study of the A' model is based on two free parameters: the mixing term ε^2 and the invariant mass of the A', $m_{A'}$. The mixing term, ε^2, can be interpreted as the ratio of the dark force strength to the EM force strength. Note that for smaller values of ε^2 the dark photon can be long-lived and fly away from its production vertex. Figure 3.4.1 shows the $\varepsilon^2 - m_{A'}$ parameter space with current limits (grey fills, see Ref. [299] for details), current LHCb limits (black bands) [300], and prospects on the LHCb future reach (coloured bands). The light (dark) coloured band corresponds to discovery reach assuming 50 (300) fb^{-1} datasets. These are the expected integrated luminosities at LHCb at the end of Run-4 and Run-5 of the LHC, respectively. These discovery reaches assume increased pileup within LHCb will not have a significant effect on the dark photon reconstruction.

There are at least two complementary ways for LHCb to explore large portions of unconstrained A' parameter space. They address different regions of this space. The first involves prompt and displaced resonance searches using $D^{*0} \to D^0 e^+ e^-$ decays [301] (green bands in Fig. 3.4.1). The second is an inclusive di-muon search [302] (blue bands in Fig. 3.4.1) where the di-muon can be prompt or displaced. In both cases the lepton pair is produced from an EM current which kinetically mixes with

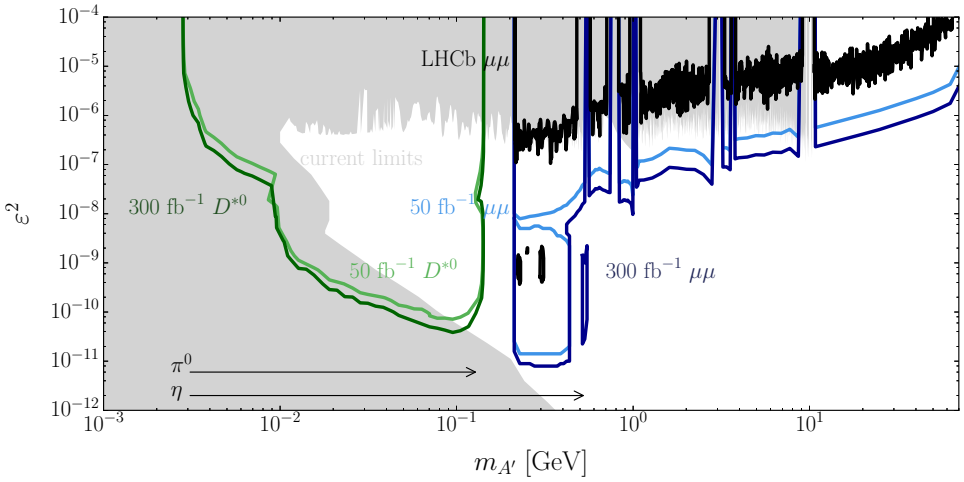

Fig. 3.4.1: Current limits (grey fills), current LHCb limits (black band), and proposed future experimental reach (coloured bands) on A' parameter space. The arrows indicate the available mass range from light meson decays into $e^+e^-\gamma$.

the A', producing a sharp resonance at the A' mass. In the first case, the A' is detected in its decay to an e^+e^- pair and in the second to a $\mu^+\mu^-$ pair. The advantage of these approaches is that they do not require the calculation of absolute efficiencies. In both cases, the signal can be normalised to the di-lepton mass sidebands near the A' resonance, where dark photon mixing with the SM virtual photon is negligible. In general, these search strategies depend on three core capabilities of LHCb: excellent secondary vertex resolution, particle identification, and real-time data-analysis. These features are also important for flavour physics, which mainly drives the design of the detector and its upgrades. In particular, the improvement in the impact parameter resolution, expected after the upgrade of the LHCb vertex locator, will be key to tackle the background produced by heavy quark decays.

For the LHCb sensitivities in Fig. 3.4.1, the sensitivity calculated using $D^{*0} \to D^0e^+e^-$ decays [301] is based on the normalisation to this channel, which at the same time is the main background for the prompt search. $D^{*0} \to D^0e^+e^-$ decays are generated using PYTHIA 8 [50], and the D^0 is reconstructed or partially reconstructed through its decay into at least two charged particles. The selection is designed to maximise the e^+e^- mass resolution and to minimise the background. The resolution and efficiencies are obtained using public LHCb information, combined with a simplified simulation of the upgraded vertex locator. For the di-muon search [302], a fiducial selection is designed so that the reconstruction efficiency is essentially flat across the dark photon parameter space, while minimising the presence of background. The relevant experimental resolutions and efficiencies, including those foreseen after subsequent detector upgrades, are taken from public LHCb documents. The normalisation channel, i.e $\mu^+\mu^-$ production originating from electromagnetic processes, and backgrounds are again studied using PYTHIA 8, corrected with experimental LHC inputs.

A first inclusive search for A' bosons decaying into muon pairs was performed by the LHCb collaboration [300] (black band in Fig. 3.4.1). This search, an implementation of the second strategy described above, used a data sample corresponding to an integrated luminosity of 1.6 fb^{-1} from pp collisions taken at $\sqrt{s} = 13$ TeV. Although the data sample used was significantly smaller than the one that will be available at the HL-LHC, this search already produced world-best upper limits in regions of $\varepsilon^2 - m_{A'}$ space. This search was limited by the presence of the LHCb hardware trigger, which severely compromised the detection efficiency of low mass dark photons at LHCb. However, this hardware level trigger will be removed from Run-3 of the LHC onwards. At the same time, this was the first simultaneous prompt and displaced A' search. With around 300 fb^{-1}, LHCb will either confirm or reject the presence of a dark photon for significant portions of the theoretically favoured parameter space. It should

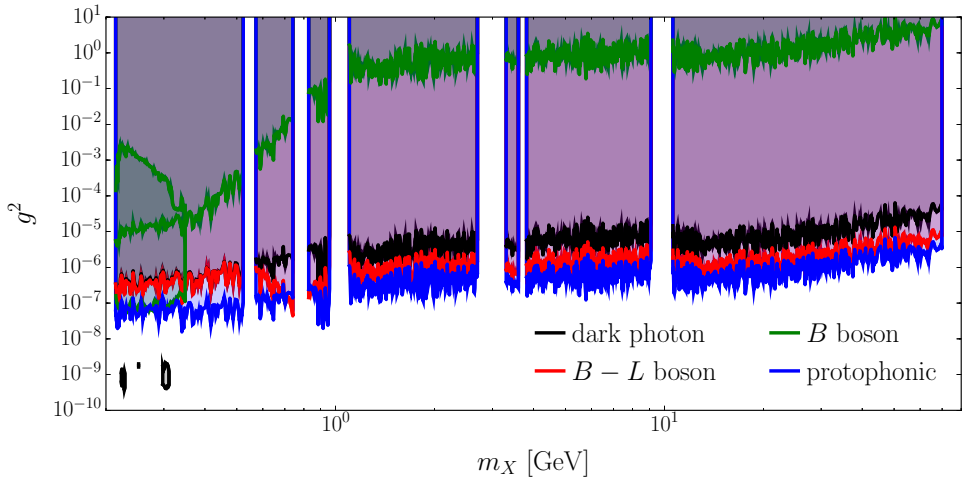

Fig. 3.4.2: Recast of the (blue) LHCb dark photon limits into the (red) B-L boson, (green) B boson, and (yellow) protophobic models using the DARKCAST tool [303].

be noted that, in non-minimal models, such as those producing dark photons through the Higgs portal, part of this parameter space can be further constrained by other experiments. Examples are given in Sections 3.4.2.1 and 3.4.3.

To cover the gap in reach between the two primary search strategies, presented above, production of A' bosons from light meson decays, $\pi^0 \to e^+e^-\gamma$ and $\eta \to e^+e^-\gamma$, is expected to be used. The parameter space coverage from light meson decays depends on the ability of the LHCb triggerless readout to quickly and efficiently reconstruct low mass and low momentum di-electron pairs. Additionally, the electron momentum resolution, degraded by incomplete bremsstrahlung recovery, dictates the di-electron mass resolution which drives parameter space coverage. More detailed studies are needed to quantify how searches for dark photons from light meson decays will help to constrain the dark photon parameter space.

One of the advantages of the dark photon model is that results can be recast into more complex vector current models, given some knowledge of the dark photon production mechanism and the detector efficiency for displaced dark photon reconstruction. Examples of these models are the $B-L$ boson which couples to the $B-L$ current, the B boson which is leptophobic and couples to baryon number, and a vector boson which mediates a protophobic force. All these models can be fully specified with two parameters: the global coupling g of the vector current for the model with the electromagnetic current, and the mass m_X of the mediating boson. For the dark photon model, this is just ε and $m_{A'}$, respectively. In Fig. 3.4.2 the initial inclusive di-muon results from LHCb [300] have been recast into these example models using the DARKCAST package [303]. Dark photon searches can also be recast to non-vector models, but such a recasting is no longer as straight forward.

3.4.2 Long-lived dark-photon decays at the HL-LHC

Among the numerous models predicting dark photons, one class of models that is particularly interesting for the LHC features the hidden sector communicating with the SM through a Higgs portal. Dark photons are produced through BSM Higgs decays. They couple to SM particles via a small kinetic mixing parameter ϵ, as described in Section 3.4.1. If ϵ is very weak, the lifetime of the dark photon can range from a few millimetres up to several meters. The lower ϵ is, the longer the dark photon lifetime will be, which then decays displaced from the primary vertex. The following searches from ATLAS and CMS target complementary scenarios and illustrate possible improvements in trigger and analysis strategies which can be used at HL-LHC.

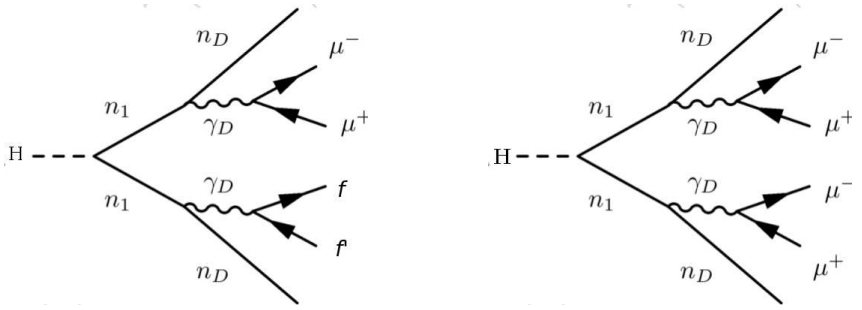

Fig. 3.4.3: Feynman diagram of the decay of SM Higgs boson to a final state containing two or more muons in Dark SUSY models. Decay chain leading to a final state containing exactly two (left) or four (right) muons.

3.4.2.1 Long-lived dark-photon decays into displaced muons at HL-LHC CMS

Contributors: K. Hoepfner, H. Keller, CMS

In the so-called Dark SUSY model [304, 305], an additional dark $U_D(1)$ symmetry is added as a supersymmetric SM extension. Breaking this symmetry gives rise to an additional massive boson, the dark photon γ_D, which couples to SM particles via a small kinetic mixing parameter ϵ. A golden channel for such searches is the decay to displaced muons.

The reconstruction of muons with large displacements is challenging both at trigger level and for the final event reconstruction, especially when the long lived particle decays outside the tracker volume and the precision of the tracker cannot be used for the analysis. To identify displacements of physical objects during reconstruction, the transverse impact parameter d_0 of the reconstructed track with respect to the primary interaction vertex is used. This analysis from CMS [306] relies on a dedicated muon reconstruction algorithm that is designed for non-prompt muons leaving hits only in the muon system. This is the displaced standalone (DSA) algorithm, using the same reconstruction techniques as prompt muons, but removing any constraint to the interaction point which is still present in the standard standalone (SA) algorithm. The DSA muon algorithm improves transverse impact parameter and transverse momentum (p_T) resolutions for displaced muons compared to the SA muon algorithm [307].

In the model studied here [306], dark photons are produced in cascade decays of the SM Higgs boson that would first decay to a pair of MSSM-like lightest neutralinos (n_1), each of which can decay further to a dark sector neutralino (n_D) and the dark photon, as shown in Fig. 3.4.3. For the branching fraction BR($H \to 2\gamma_D + \mathrm{X}$), where X denotes the particles produced in the decay of the SM Higgs boson apart from the dark photons, 20% is used. This value is in agreement with recent Run-2 studies [308] and taking into account the upper limit on invisible/non-conventional decays of the SM Higgs boson [309]. We assume neutralino masses $m(n_1) = 50$ GeV and $m(n_D) = 1$ GeV, and explore the search sensitivity for dark photon masses and lifetimes in the following ranges: $m(\gamma_D) = (1, 5, 10, 20, 30)$ GeV and $c\tau = (10, 10^2, 10^3, 5 \times 10^3, 10^4)$ mm. Final states with two and four muons are included in the analysis. In the former case, one dark photon decays to a pair of muons while the other dark photon decays to some other fermions (2-muon final state). In the latter case, both dark photons decay to muon pairs (4-muon final state). Both decay chains are shown in Fig. 3.4.3. The assumed Higgs production cross section via gluon-gluon fusion is 49.97 pb [310].

The main background for this search comes from multi-jet production (QCD), $t\bar{t}$ production, and Z/DY $\to \ell\ell$ events where large impact parameters are (mis)reconstructed. Cosmic ray muons can travel through the detector far away from the primary vertex and mimic the signature of displaced muons. However, thanks to their striking detector signature, muons from cosmic rays can be suppressed by rejecting back-to-back kinematics.

For each event, at least two DSA muons are required. If more than two exist, the ones with the highest p_T are chosen. The two muons must have opposite charge ($q_{\mu,1} \cdot q_{\mu,2} = -1$) and must be separated

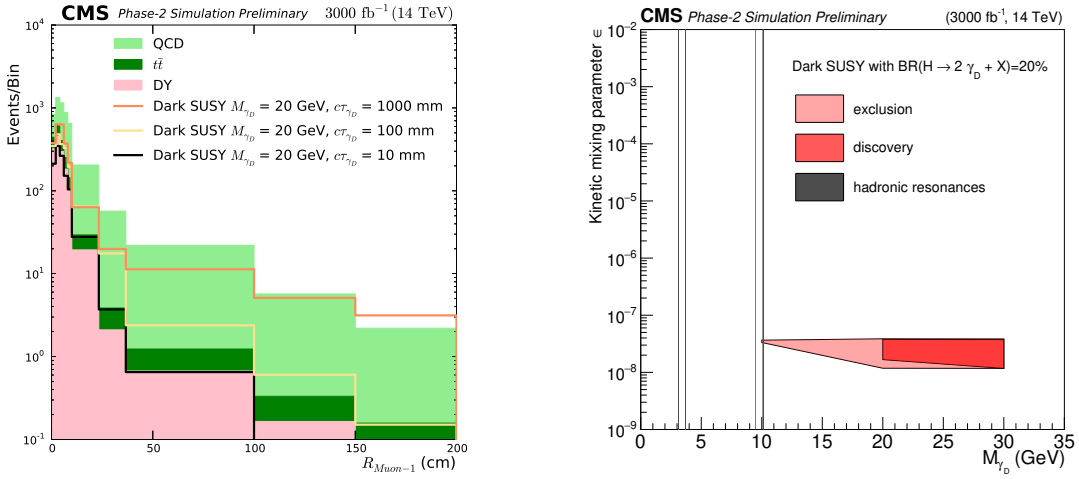

Fig. 3.4.4: Left: distance of the closest approach of the displaced muon track with maximum p_T to the primary interaction vertex, $R_{\mathrm{Muon}-1}$, for signal and background after the final event selection. Right: parameter scan in the $\epsilon - m_{\gamma_D}$ plane. The gray lines indicate the regions of narrow hadronic resonances where the analysis does not claim any sensitivity.

by $\Delta R = \sqrt{\Delta\phi^2 + \Delta\eta^2} > 0.05$. The three-dimensional angle between the two displaced muons is required to be less than $\pi - 0.05$ (not back-to-back) in order to suppress cosmic ray backgrounds. Additionally, $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}} \geq 50$ GeV is imposed to account for the dark neutralinos escaping the detector without leaving any signal.

In order to discriminate between background and signal, the three-dimensional distance from the primary vertex to the point of closest approach of the extrapolated displaced muon track, called R_{Muon}, is used. The event yield after full event selection of both selected muons as a function of $R_{\mathrm{Muon}-1}$ and $R_{\mathrm{Muon}-2}$ is used to search for the signal. Figure 3.4.4 (left) shows $R_{\mathrm{Muon}-1}$ of the first selected muon for signal and background samples.

The search is performed using a simple counting experiment approach. In the presence of the expected signal, the significance of the corresponding event excess over the expected background is assessed using the likelihood method. In order to evaluate the discovery sensitivity the same input is used as in the limit calculation, now with the assumption that one would have such a signal in the data. The discovery sensitivity is shown in the two-dimensional m_{γ_D}-$c\tau$ plane in Fig. 3.4.4 (right). This search is sensitive to large decay lengths of the dark photon.

In the absence of a signal, upper limits at 95% C.L. are obtained on a signal event yields with respect to the one expected for the considered model. A Bayesian method with a uniform prior for the signal event rate is used and the nuisance parameters associated with the systematic uncertainties are modelled with log-normal distributions. The resulting limits for the Dark SUSY models are depicted in Fig. 3.4.5. While the results shown in Fig. 3.4.5 (left) are for a dark photon with a decay length of 1 m as a function of the dark photon mass, Fig. 3.4.5 (right) shows the results for a dark photon mass of 20 GeV as a function of the decay length [306]. The relatively long lifetimes accessible in this search provide complementary sensitivity at lower values of ϵ.

3.4.2.2 Searching for dark-photons decays to displaced collimated jets of muons at HL-LHC ATLAS

Contributors: C. Sebastiani, M. Corradi, S. Giagu, A. Policicchio, ATLAS

Prospects for searches for Hidden Sectors performed by ATLAS are presented in this section [311]. The benchmark model used in this analysis is the Falkowsky-Ruderman-Volansky-Zupan (FRVZ) vector portal model. In this case, a pair of dark fermions f_{d2} is produced in the Higgs boson decay. As shown

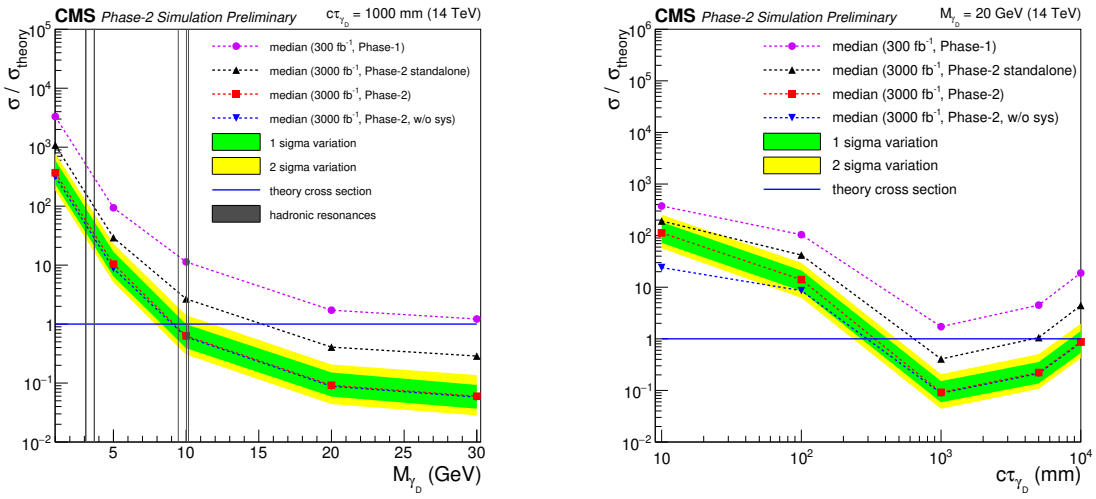

Fig. 3.4.5: 95% C.L. upper limits on production cross section $\sigma/\sigma_{\text{theory}}$ for various dark photon mass hypotheses and a fixed decay length of $c\tau = 1000$ mm (left) and a fixed mass of $M_{\gamma_D} = 20$ GeV(right). Green and yellow shaded bands show the one and two sigma range of variation of the expected 95% C.L. limits, respectively. The black dashed lines ("Phase-2 standalone") compare the expected sensitivity of the displaced muon search to the algorithm with a beamspot constraint. The gray lines indicate the regions of narrow hadronic resonances where the analysis does not claim any sensitivity.

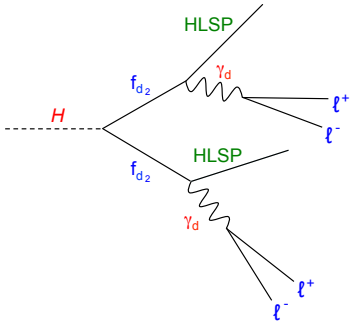

Fig. 3.4.6: The Higgs boson decay to hidden particles according to the FRVZ model.

in Fig. 3.4.6, the dark fermion decays in turn to a γ_d and a lighter dark fermion assumed to be the Hidden Lightest Stable Particle (HLSP). The dark photon, assumed as vector mediator, mixes kinetically with the SM photon and decays to leptons or light hadrons. The branching fractions depend on its mass. At the LHC, these dark photons would typically be produced with large boost, due to their small mass, resulting in collimated structures containing pairs of leptons and/or light hadrons, known as lepton-jets (LJs). If produced away from the interaction point (IP), they are referred to as "displaced LJs". The mean lifetime τ of the dark photon is a free parameter of the model, and is related to the kinetic mixing parameter ϵ by the relation:

$$\beta\gamma c\tau \propto \left(\frac{10^{-4}}{\epsilon}\right)^2 \left(\frac{100\text{ MeV}}{m_{\gamma_d}}\right)^2 \text{s}.$$

Two new muon trigger algorithms are also studied to improve the selection efficiency of displaced muon pairs. MC samples have been produced at 13 and 14 TeV c.o.m. energy for the FRVZ model assuming μ equal to 65 and 200, respectively, and various possible $c\tau$. The samples are used to assess the sensitivity of the analysis and study new triggers.

The standard ATLAS triggers are designed assuming prompt production of particles at the interaction point and therefore are very inefficient in selecting the products of displaced decays. The searches

for γ_d decays are thus based on events selected by specialised triggers dedicated to the selection of events with displaced muon pairs. However these triggers are still far from optimal. If the dark photon is highly boosted, muons are collimated and the trigger efficiency is limited by the finite granularity of the current hardware trigger level. In terms of an interval of the azimuthal angle ϕ and pseudorapidity η, the granularity is $\Delta\eta \times \Delta\phi \simeq 0.2 \times 0.2$ (Region of Interest, RoI). If the dark photon is not boosted sufficiently, the out-going muons from a displaced decay are more open and may not point to the IP. The current hardware trigger level has a tight constraint on IP pointing resulting in non-optimal selection efficiency of displaced non-pointing muon tracks.

The new ATLAS detector setup and Trigger & Data Acquisition system for the HL-LHC will offer the opportunity to develop new trigger algorithms overcoming the current limitations. Two new trigger selections have been studied in this work: one dedicated to triggering on collimated LJs in boosted scenarios, based on requiring muons in a single RoI and referred to as *L0 multi-muon scan*; a second one dedicated to triggering on non-boosted scenarios, loosening the pointing requirements applied in Run-2 and referred to as *L0 sagitta muon*. A summary of the two triggers is given below, for details see [311].

L0 multi-muon scan: this new approach allows to include in the sector logic multiple trigger candidates in the same RoI and leads to a new trigger selection with lower p_T thresholds resulting in a higher efficiency without increasing sensibly the trigger rate. The new trigger algorithm is designed to analyse hit patterns in the Muon Spectrometer. As a first step, the algorithm searches for the pattern with the highest number of hit points, called best pattern, in the MS to form the primary L0 muon candidate. Then all the other possible hit patterns, not compatible with the best pattern, are searched for in the same RoI to form the secondary L0 muon candidates. A quality cut is applied to reduce the influence of noisy hits, requiring patterns with hits on at least three different RPC layers. Patterns are requested to not share RPC hits. If at least one secondary pattern is found, an additional L0 muon is assumed to be found in the RoI. The new L0 trigger algorithm is defined by the logical OR of a single muon L0 with $p_T = 20$ GeV threshold and a multi-muon L0 with $p_T = 10$ GeV threshold. Based on signal MC samples, an overall improvement up to 7% is achieved with respect to the baseline $p_T = 20$ GeV selection, in particular for small opening angle between the two muons from the γ_d decays.

L0 sagitta muon: this approach allows to recover for loss of efficiency in case of out-going muons from non-boosted γ_d that may not be pointing to the IP. The L1 Run-2 trigger has a tight constraint on selecting only pointing muons resulting in non optimal selection of these exotic signatures. A benchmark FRVZ sample with 10 GeV γ_d mass is used to for this study. The sagitta, defined as the vertical distance from the midpoint [3] of the chord [4] to the arc [5] of the muon trajectory itself, can be used to estimate the momentum of a charged particle travelling inside a magnetic field. The sagitta of a muon track can be computed at the L0 trigger level using $\eta - \phi$ measurement points in the various RPC stations. The map between the inverse of the sagitta and the muon transverse momentum has been studied using a MC sample of single muons generated according to a uniform transverse momentum distribution. The mean value of the inverse of the sagitta for $p_T = 20$ GeV pointing truth muons is $s^{-1} = 9 \times 10^{-6}$ mm^{-1}. High transverse momentum non-pointing muons can be thus selected using a L0 muon trigger with low $p_T = 5$ GeV threshold, computing the inverse of the sagitta and requesting a cut on $s^{-1} \leq 9 \times 10^{-6}$ mm^{-1}. Overall, a $\sim 20\%$ improvement in efficiency is achieved by adding this new trigger according to MC signal studies.

Overall, with these new approaches it is possible to choose a lower single muon p_T threshold as compared to the Run-2 configuration, improving the selection efficiency of events with displaced muon pairs without increasing significantly the trigger rate, see Fig. 3.4.7.

The evaluation of the expected sensitivity of the displaced dark photon search after Run-3 and

[3] The midpoint is defined as the middle point of a segment

[4] The chord of a circle is a line segment that connects two points of the circle itself

[5] The arc is a portion of the circumference of a circle.

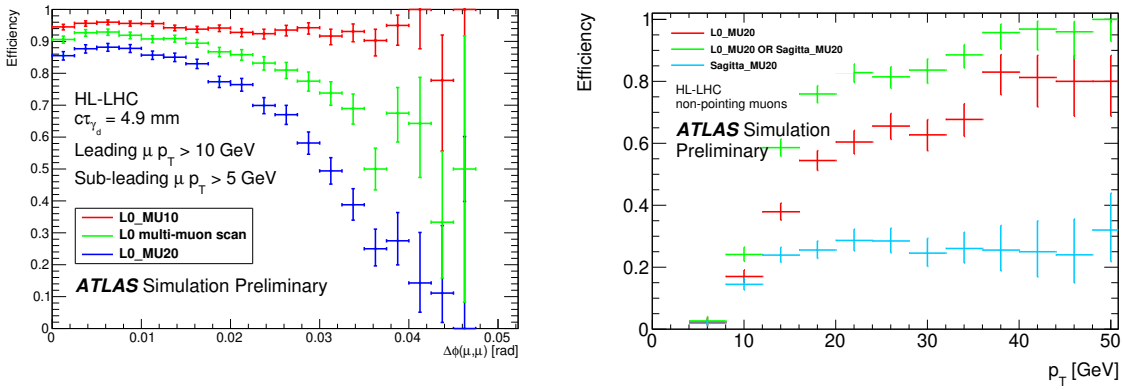

Fig. 3.4.7: Left: Efficiency for different trigger selections as a function of the opening angle of the two muons of the dark photon decay (the new L0 multi-muon scan trigger is shown in green). As a reference, two single-muon selections are shown for 10 (L1_MU10) and 20 (L1_MU20) GeV p_T threshold. Right: Trigger efficiency comparison for a FRVZ sample (the new L0 sagitta muon trigger is shown in green) as a function of the muon transverse momentum.

Excluded $c\tau$ [mm] muonic-muonic	Run-2	Run-3	HL-LHC	HL-LHC w/ L0 muon-scan
$\mathcal{B}(h \to 2\gamma_d + X) = 10\ \%$	$2.2 \leq c\tau \leq 111$	$1.15 \leq c\tau \leq 435$	$0.97 \leq c\tau \leq 553$	$0.97 \leq c\tau \leq 597$
$\mathcal{B}(h \to 2\gamma_d + X) = 1\ \%$	-	$2.76 \leq c\tau \leq 102$	$2.18 \leq c\tau \leq 142$	$2.13 \leq c\tau \leq 148$

Table 3.4.1: Ranges of γ_d $c\tau$ excluded at 95% C.L. for $h \to 2\gamma_d + X$ assuming $\mathcal{B}(h \to 2\gamma_d + X) = 10\%$ and $\mathcal{B}(h \to 2\gamma_d + X) = 1\%$ and dark photon mass of 400 MeV.

HL-LHC operations is based on the 2015+2016 Run-2 ATLAS analysis where multivariate techniques are used for signal discrimination against the backgrounds. The benchmark signal model used in the Run-2 search is a FRVZ model with 400 MeV γ_d mass and lifetime $c\tau = 49$ mm. The branching fraction of the γ_d decay to muons is 45%. Only the dominant ggF Higgs production mechanism is considered. One of the main SM backgrounds to the dark photon signal is multijet production. Samples of simulated 14 TeV multijet events are used to compute scale factors to rescale the data-driven estimates at 13 TeV c.o.m. energy to 14 TeV. These samples are also used to evaluate the systematic uncertainties. Other sources of background include cosmic rays. This is assumed to scale with duration of data taking, and the cosmic ray background from the Run 2 analysis has been scaled accordingly.

Uncertainties have been extrapolated from the Run-2 reference analysis. The statistical sources of uncertainties have been scaled with the expected integrated luminosity, for both Run-3 and HL-LHC. The systematic uncertainties for Run-3 have been assumed to be the same as in the Run-2 analysis. For the HL-LHC projection systematic uncertainties have been evaluated according to the specifications of the ATLAS collaboration for upgrade studies. Overall, the dominant uncertainties ($\sim 20\%$) are expected to be arising from pile-up.

Results for the three different scenarios (Run 3, HL-LHC and HL-LHC with trigger improvements) are presented in Table 3.4.1 for dark photons with $m_{\gamma_d} = 400$ MeV. The excluded $c\tau$ ranges assuming Higgs into dark photons branching ratio of 10% and 1% respectively are shown. The exclusion limits are re-interpreted in the context of the vector portal model. The exclusion contour plot in the plane defined by the dark photon mass and the kinetic mixing parameter ϵ is presented in Fig. 3.4.8, assuming a Higgs decay branching fraction to the hidden sector of 1% and where gaps correspond to hadronic decays not covered by this analysis.

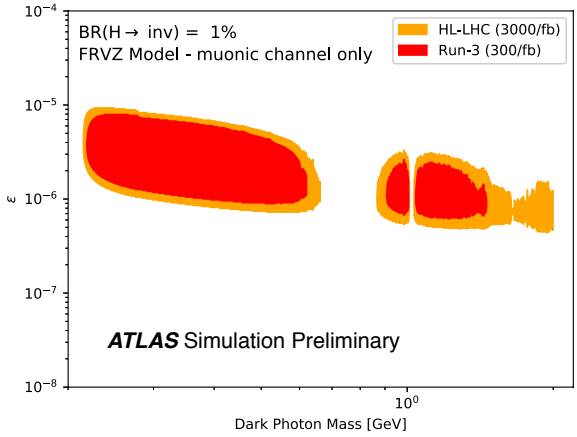

Fig. 3.4.8: Exclusion contour plot in the plane defined by the γ_d mass and the kinetic mixing parameter ϵ. Two different scenarios are shown assuming a Higgs decay branching fraction to the hidden sector of 1%: $300\ \mathrm{fb}^{-1}$ after Run-3 (red) ad $3\ \mathrm{ab}^{-1}$ after HL-LHC including multi-muon scan trigger improvement (orange).

3.4.2.3 Summary of sensitivity for dark photons from Higgs decays

The discovery reach from the ATLAS and CMS searches for dark photons can be compared to that from the generic γ_d search results shown in Fig. 3.4.1. This is reported in Fig. 3.4.9 as a function of the dark photon mass and ϵ^2: the reach of minimal models is shown together with that of models with additional assumptions on the dark photon production mechanism via Higgs decays. A 10% decay rate of the Higgs boson into dark photons is assumed for the latter. Under these assumptions, the HL-LHC ATLAS search will allow to target a crucial region with dark photon mass between 0.2 and 10 GeV and low ϵ^2, while the CMS search will cover higher γ_d masses and even lower mixing parameters. This is complementary to the LHCb and low-energy experiments reach as well as with the coverage of prompt-lepton searches at the LHC.

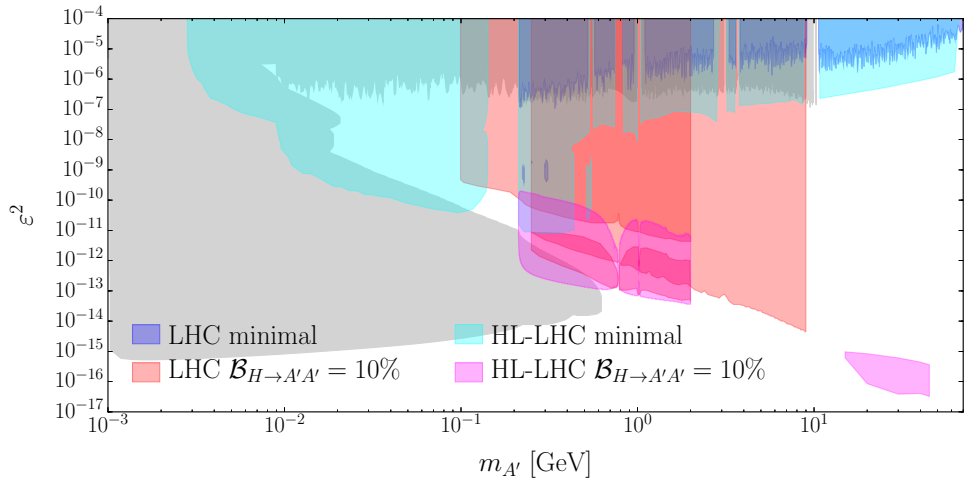

Fig. 3.4.9: Summary of the contour reach of searches for dark photons from Higgs decays. The purple, grey and blue areas are explained in Section 3.4.1, and correspond to the minimal dark photon model, with best sensitivity achieved by LHCb and low-energy experiments. The red and pink areas, explained in Section 3.4.2.2 and Section 3.4.2.1, correspond to results from ATLAS and CMS where dark photons are produced through a Higgs boson decay with a branching fraction of 10%.

3.4.3 Searching for dark photons via Higgs-boson production at the HL- and HE-LHC

Contributors: S. Biswas, E. Gabrielli, M. Heikinheimo, B. Mele

The dark-sector scenario proposed in Ref. [312, 313] is studied in this section. It aims at naturally solving the Flavour hierarchy problem, while providing suitable candidates for DM constituents. In particular, the scenario envisages the existence of stable dark-fermion fields, acting as DM particles, and heavy messenger scalar fields that communicate the interactions between the dark and the SM sectors. Both dark fermions and messenger fields are charged under an unbroken $U(1)$ interaction in the dark sector, whose non-perturbative dynamics are responsible for an exponential hierarchy in the dark fermion spectrum. Consequently, exponentially spread Yukawa couplings are radiatively generated by the dark sector, thus naturally solving the Flavour hierarchy problem.

A crucial aspect of this flavour model is that it foresees the existence of a massless dark photon. Until recently, most attention in collider physics has been given to the search for massive dark photons, whose $U(1)$ gauge field can naturally develop a *tree-level* millicharge coupling with ordinary matter fields. On the contrary, strictly massless dark photons, although very appealing from the theoretical point of view, in general lack tree-level couplings to SM fields. Indeed, the latter (even if induced, for instance, by a kinetic mixing with the ordinary photon field) can be rotated away, and reabsorbed in the gauge- and matter-field redefinition [314]. Nevertheless, thanks to the messenger fields, massless dark photons can develop higher-dimensional effective interactions with the SM fields which are suppressed by the effective scale controlling the corresponding higher-dimensional-operator coupling. Then, new dedicated search strategies for the massless dark photons are required with respect to the massive case.

The Higgs boson could play a crucial role in the discovery of massless dark photons at the LHC. As discussed in Ref. [315], by using as a benchmark the model in Ref. [312], an effective $H\gamma\bar{\gamma}$ interaction can be generated at one loop by the exchange of virtual messenger fields in the 3-point loop function. This interaction can be parametrised as $\mathcal{L}_{H\gamma\bar{\gamma}} = \frac{1}{\Lambda_{H\gamma\bar{\gamma}}} H F^{\mu\nu} \bar{F}_{\mu\nu}$, where $F^{\mu\nu}$ and $\bar{F}_{\mu\nu}$ are the field strength of the photon γ and the dark photon $\bar{\gamma}$, respectively [315]. While in general the higher-dimensional dark-photon interactions with the SM fields are suppressed, in the present case the Higgs boson can enter a nondecoupling regime in particular model parameter regions, just as happens in the SM for the Higgs couplings to two photons or gluons in the large top-quark mass limit. The effective high-energy scale $\Lambda_{H\gamma\bar{\gamma}}$ will then be proportional to the EW Higgs VEV v, rather than the characteristic new-physics mass scale. In particular, it will be given by

$$\Lambda_{H\gamma\bar{\gamma}} \;=\; \frac{6\pi v}{R\sqrt{\alpha\alpha_D}} \frac{1-\xi}{\xi^2} \tag{3.4.1}$$

where $\xi = \Delta/\bar{m}^2$ is a mixing parameter, with Δ the left-right mixing term in the messenger square-mass matrix, $\bar{m}$ is the average messenger mass, α and α_D the electromagnetic and the dark $U(1)$ fine structure couplings, respectively, while R is a product of quantum charges [316].

This regime can give rise to an exotic signature corresponding to the Higgs decay

$$H \to \gamma\bar{\gamma},$$

given by a monochromatic photon plus *massless missing momentum* (both resonating at the Higgs boson mass) with BRs $\mathcal{B}_{\gamma\bar{\gamma}}$ as large as a few percent. Below we report the results of a study of the LHC searches for this decay signature in gluon-fusion Higgs production in both the HL- and HE-LHC phases, assuming that $\mathcal{B}_{\gamma\bar{\gamma}}$ is the only parameter that affects the corresponding production mechanism.

The search strategy for the $gg \to H \to \gamma\bar{\gamma}$ process was outlined in Ref. [315] for 8 TeV and in Ref. [317] for 14 TeV, where we also discussed the vector-boson-fusion process. The final state consists of a single photon and missing transverse momentum, possibly accompanied by one or more jets arising from initial state radiation. The event selection criteria proposed in Ref. [317] were:

– one isolated ($\Delta R > 0.4$) photon with $p_T^\gamma > 50$ GeV, and $|\eta^\gamma| < 1.44$;

	$\sigma \times A$ [14 TeV]	$\sigma \times A$ [27 TeV]
$H \to \gamma\bar{\gamma}$ $(\mathcal{B}_{\gamma\bar{\gamma}} = 1\%)$	101	236
γj	202	–
$jj \to \gamma j$	432	4738
$e \to \gamma$	93	169
$W(\to \ell\nu)\gamma$	123	239
$Z(\to \nu\nu)\gamma$	283	509
total background	1133	5655

Table 3.4.2: Event yields in femtobarn for signal and backgrounds after the cuts $p_T^\gamma > 50$ GeV, $\not{E}_T > 50$ GeV, 100 GeV $< \mathrm{M}_\mathrm{T}^{\gamma\bar{\gamma}} <$ 130 GeV. The γj and jj backgrounds are obtained via the rescaling k-factors described in the text. A is the acceptance described in the text.

- missing transverse momentum satisfying $\not{E}_T > 50$ GeV;
- transverse mass in the range 100 GeV $< \mathrm{M}_\mathrm{T}^{\gamma\bar{\gamma}} <$ 130 GeV;
- no isolated leptons within $|\eta^\ell| < 2.5$,

where the transverse-mass variable is defined as $M_T^{\gamma\bar{\gamma}} = \sqrt{2p_T^\gamma \not{E}_T(1-\cos\Delta\phi)}$, and $\Delta\phi$ is the azimuthal distance between the photon transverse momentum p_T^γ, and the missing transverse momentum $\not{E}_T$.

The most important SM backgrounds are: *(i)* γj, where missing energy is created from mismeasurement of the jet energy and/or neutrinos from heavy flavour decays, and *(ii)* jj where in addition to the above, a central jet is misidentified as a photon. In our analysis we assume a probability of 0.1% for mis-tagging a jet as a photon, and a 90% reconstruction efficiency for real photons. In addition to the QCD backgrounds, we identify the following EW backgrounds: $Z\gamma$, where the Z decays into neutrinos; $W\gamma$, where the W decays leptonically (excluding taus) and the charged lepton is outside the acceptance of $|\eta^\ell| < 2.5$; and $W \to e\nu$, where the electron is misidentified as a photon. We also assume a 0.5% probability for the electron to photon mis-tagging.

We have analysed the EW backgrounds at parton level with MADGRAPH 5 V2.3.3. For the QCD backgrounds we use MADGRAPH 5 interfaced with PYTHIA, and follow the procedure outlined in Ref. [317]. In particular, we have generated event samples at 8 TeV and applied the *SUSY benchmark* event selection criteria described in the CMS analysis [318], not including the "χ^2", "$E_\mathrm{T}^\mathrm{miss}$ significance" and "α" cuts. With these omissions, the event selection criteria is very similar to our selection criteria described above. We then approximate the effect of these further, more sophisticated cuts on the QCD backgrounds, by matching our event samples with the background yield after these cuts reported in Ref. [318]. This results in a rescaling k-factor of $k = 0.11$ for the γj background, and $k = 0.058$ for the jj background at 8 TeV. Finally, we have generated the signal event samples with ALPGEN interfaced with PYTHIA, and included the gluon fusion Higgs production processes with zero to one jets.

Assuming the same rescaling factors for the QCD backgrounds at 14 and 27 TeV, we obtain the signal and background event yields reported in Table 3.4.2, clearly showing a worsening of the signal-to-background ratio at larger energies.

We then tried an alternative strategy to control the QCD background, by analysing the effect of applying a jet veto within $|\eta^j| < 4.5$, where a jet is defined as a cluster of hadrons within a cone of size $R = 0.4$ and $p_T \geq 20$ GeV, using a simple cone algorithm. In this case we no longer apply the rescaling k-factors obtained from our previous analysis, as now the cut-flow deviates from the CMS analysis presented in Ref. [318]. The resulting event yields are shown in Table 3.4.3. Based on the event yields reported in Tables 3.4.2 and 3.4.3, we estimate the reach of the HL-LHC and HE-LHC in terms of the BR of the decay mode $H \to \gamma\bar{\gamma}$ as shown in Table 3.4.4. On the basis of the present analysis, a quite good potential for HL-LHC is expected, that would allow for a (5σ) discovery reach on the corresponding

	$\sigma \times A$ [14 TeV]	$\sigma \times A$ [27 TeV]

$W(\to \ell\nu)\gamma$	123	239
$Z(\to \nu\nu)\gamma$	283	509
total background	1385	32153

Table 3.4.3: Event yields in femtobarn for signal and backgrounds after the cuts $p_T^\gamma > 50$ GeV, $\not{E}_T > 50$ GeV, $100\ \text{GeV} < \text{M}_\text{T}^{\gamma\bar{\gamma}} < 130$ GeV, and jet veto within $|\eta^j| < 4.5$. A is the acceptance described in the text.

$\mathcal{B}_{\gamma\bar{\gamma}}(\%)$	$3\ \text{ab}^{-1}$@14 TeV		$15\ \text{ab}^{-1}$@27 TeV	
significance	2σ	5σ	2σ	5σ
CMS inspired	0.012	0.030	0.0052	0.013
jet veto in $\lvert\eta^j\rvert < 4.5$	0.020	0.051	0.021	0.053

Table 3.4.4: Discovery (5σ) and exclusion (2σ) reach for the $H \to \gamma\bar{\gamma}$ BR (in %) at the HL-LHC and HE-LHC.

$\mathcal{B}_{\gamma\bar{\gamma}}$ down to 3×10^{-4}, for $3\ \text{ab}^{-1}$ of integrated luminosity, provided the CMS inspired analysis of the jj background can be reliably applied in this case. Same conclusions hold for the HE-LHC project, where a 1×10^{-4} (5σ) discovery reach can be achieved, for $15\ \text{ab}^{-1}$of expected luminosity, assuming that the CMS inspired analysis of the jj background is still reliable at 27 TeV. On the other hand, if a jet veto in $|\eta^j < 4.5|$ is applied instead, lower sensitivities on $\mathcal{B}_{\gamma\bar{\gamma}}$ can be obtained, leading to discovery just for $\mathcal{B}_{\gamma\bar{\gamma}}$ down to 5×10^{-4} at both HL-LHC and HE-LHC facilities.

We nevertheless think that a more realistic detector simulation and optimisation strategy would be needed in order to make the present reach estimates more robust. In Ref. [317], one can also find a study of the vector-boson-fusion channel sensitivity to $\mathcal{B}_{\gamma\bar{\gamma}}$ at 14 TeV.

4 Long Lived Particles

There are many examples of BSM physics where new particles that can be produced at the LHC will be long lived, on collider timescales, and may travel macroscopic distances before decaying. Long lifetimes may be due to small couplings, small mass splittings, a high multiplicity of the decay final state, or a combination of these effects. Details, such as the quantum numbers of the long lived particle (LLP) and the decay products, the typical boost of the LLP and its lifetime, will determine the best search strategy. In all cases, LLPs present unique challenges for the experiments, both in terms of reconstruction/analysis and triggering, especially in the high pile up environment of the HL-LHC. A wide variety of signatures can be produced by these later decaying LLPs which depend on their charge, decay position, branching fractions, masses, and other properties, and which traditional analyses are unlikely to be sensitive to.

If the LLP is charged and decays while still in the tracker to final state particles that are either neutral or too soft to be reconstructed it will appear as a disappearing track: hits in the first few layers of the tracker with no corresponding hits in the outer layers, see Section 4.1. Such a scenario occurs in models (e.g., SUSY) with nearly degenerate charged and neutral states, where the charged pion in the decay is too soft to be seen as a track. A complementary study in the context of disappearing track searches is presented in Section 4.1.2, where the potential of LLP searches at $e^- p$ colliders is presented. We present studies for disappearing tracks searches using simplified models of $\tilde{\chi}^{\pm}$ production which lead to exclusions of chargino masses up to $m(\tilde{\chi}_1^{\pm}) = 750$ GeV (1100 GeV) for lifetimes of 1 ns for the higgsino (wino) hypothesis. When considering the lifetime predicted by theory, masses up to 300 GeV and 830 GeV can be excluded in higgsino and wino models, respectively. This improves the 36 fb^{-1} Run-2 mass reach by a factor of $2-3$.

Decays of LLPs where the decay products are not missed but instead include multiple tracks will lead to events containing at least one displaced vertex (DV). Such a signal is sensitive to both charged and neutral LLPs. If the displacement of the vertex is large, $\gamma c\tau \gtrsim 1$ m, then the only available hits are in the muon system, limiting the final states to muons as in Section 3.4.2.1 and Section 4.2.2.

If the lifetime is shorter the DV can be reconstructed in the tracker. One such analysis of gluinos decaying to a displaced jet and $E_{\text{T}}^{\text{miss}}$ is presented Section 4.2.1. Searches for long lived dark photons decaying to muons and/or jets are reported in Section 3.4.1 and Section 3.4.2. The signature of long-lived dark photons decaying to displaced muons can be reconstructed with dedicated algorithms and is sensitive to very small coupling $\epsilon^2 \sim 10^{-14}$ for masses of the dark photons between 10 and 35 GeV. Furthermore, LHCb is the only LHC experiment to be fully instrumented in the forward region $2 < \eta < 5$ and has proved to be sensitive to LLPs. This is particularly true in the low mass (few GeV) and low lifetime (few picoseconds) region of the LLPs. Prospects studies from LHCb on LLPs resulting from Higgs decays are shown in Sections 4.2.3 and 4.2.4.

For displacement of several meters LLPs will transit all of the detector before decaying. Heavy LLPs that are also charged, so called heavy stable charged particles (HSCPs), will behave in a similar fashion to a muon. However, due to their increased mass it may be possible to distinguish them from muons through their time of flight, Section 4.3.1, or anomalous energy loss, Section 4.3.2. Finally, two examples of specialised techniques for LLP with jet-like signatures are presented in Section 4.4, using timing or EM calorimeter information.

In addition to searching for LLPs in ATLAS, CMS, and LHCb there are complementary proposals to build new detectors specifically focused on LLP searches, often for light new physics produced in rare meson decays. A detailed discussion of their capabilities is beyond the scope of this work, and will be discussed elsewhere. The Beyond Collider experiments are AL3X (A Laboratory for Long-Lived eXotics) [319], CODEX-b (COmpact Detector for EXotics at LHCb) [320], FASER (ForwArd Search ExpeRiment) [321–323], milliQan [324,325], MATHUSLA (MAssive Timing Hodoscope for Ultra Stable neutraL pArticles) [326,327], and SHiP (Search for Hidden Particles) [328,329]. They use alternative search strategies and often give complementary coverage of the available parameter space. In addition

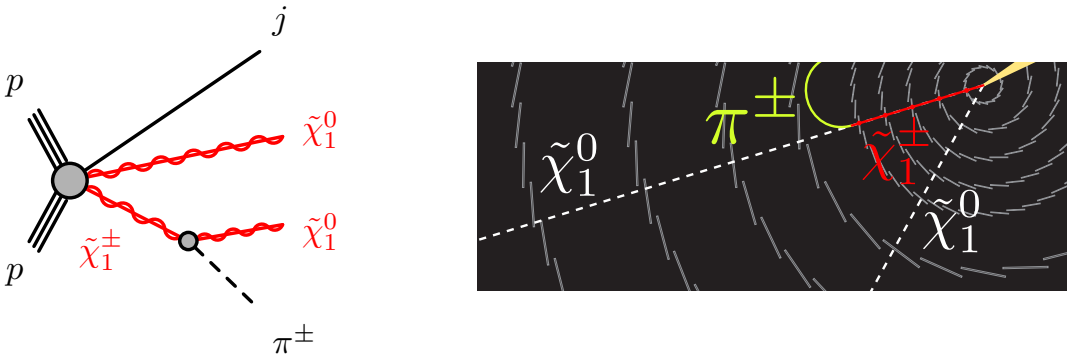

Fig. 4.1.1: Diagram depicting $\tilde{\chi}_1^\pm\tilde{\chi}_1^0$ production (left), and schematic illustration of a $pp \to \tilde{\chi}_1^\pm\tilde{\chi}_1^0 +$ jet event in the HL-LHC ATLAS detector, with a long-lived chargino (right). Particles produced in pile-up pp interactions are not shown. The $\tilde{\chi}_1^\pm$ decays into a low-momentum pion and a $\tilde{\chi}_1^0$ after leaving hits in the pixel layers.

to the afore-mentioned study on disappearing tracks, complementary studies on LLPs *e.g.* from higgs decays have been performed in the context of a future e^-p collider, resulting in good sensitivity for a wide range in $c\tau$ and mass [330].

4.1 Disappearing Tracks

A disappearing track occurs when the decay products of a charged particle, like a supersymmetric chargino, are not detected (disappear) because they either interact only weakly or have soft momenta and hence are not reconstructed. In the following, prospect studies for HL-, HE- and new proposed e^-p collider are presented, illustrating the potential of this signature as well as its experimental challenges.

4.1.1 Prospects for disappearing track analysis at HL-LHC

Contributors: S. Amoroso, J. K. Anders, F. Meloni, C. Merlassino, B. Petersen, J. A. Sabater Iglesias, M. Saito, R. Sawada, P. Tornambe, M. Weber, ATLAS

The disappearing track search [102] investigates scenarios where the $\tilde{\chi}_1^\pm$, and $\tilde{\chi}_1^0$ are almost mass degenerate, leading to a long lifetime for the $\tilde{\chi}_1^\pm$ which decays after the first few layers of the inner detector, leaving a track in the innermost layers of the detector. The chargino decays as $\tilde{\chi}_1^\pm \to \pi^\pm\tilde{\chi}_1^0$. The $\tilde{\chi}_1^0$ escapes the detector and the pion has a very low energy and is not reconstructed, leading to the disappearing track signature. Diagram and schematic illustration of production and decay process are shown in in Fig. 4.1.1. The main signature of the search is a short "tracklet" which is reconstructed in the inner layers of the detector and subsequently disappears. The tracklet reconstruction efficiency for signal charginos is estimated using fully simulated samples of $\tilde{\chi}_1^\pm$ pair production with $m(\tilde{\chi}_1^\pm) = 600$ GeV. Tracklet reconstruction is performed in two stages. Firstly "standard" tracks, hereafter referred to as tracks are reconstructed. Afterwards the track reconstruction is then rerun with looser criteria, requiring at least four pixel-detector hits. This second reconstruction uses only input hits which are not associated with tracks, referred to as "tracklets". The tracklets are then extrapolated to the strip detectors, and any compatible hits are assigned to the tracklet candidate. Tracklets are required to have $p_T > 5$ GeVand $|\eta| < 2.2$. Candidate leptons, which are used only to veto events, are selected with $p_T > 20$ GeV and $|\eta| < 2.47$ (2.7) for electrons (muons).

The signal region (SR) optimisation is performed by scanning a set of variables which are expected to provide discrimination between the signal scenario under consideration and the expected SM background processes. The final state contains zero leptons, large $E_{\mathrm{T}}^{\mathrm{miss}}$ and at least one tracklet, and events are reweighted by the expected efficiencies of tracklet reconstruction. The small mass splitting between the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ implies they are generally produced back to back with similar transverse momentum. Hence it is necessary to select events where the system is boosted by the recoil of at least one

	SR
Total SM	4.6 ± 1.3
V+jets events	0.17 ± 0.05
$t\bar{t}$ events	0.02 ± 0.01
Fake tracklets	4.4 ± 1.3

Table 4.1.1: Yields are presented for the disappearing track SR selection with an integrated luminosity of 3 ab^{-1}at $\sqrt{s} = 14$ TeV. The errors shown are the total statistical and systematic uncertainty.

energetic ISR jet. The minimum azimuthal angular distance between the first four jets (ordered in p_{T}) and the $E_{\mathrm{T}}^{\mathrm{miss}}$ is required to be greater than 1, in order to reject events with mis-measured $E_{\mathrm{T}}^{\mathrm{miss}}$.

There are two main background contributions: SM particles that are reconstructed as tracklets, and events which contain fake tracklets. The SM particles reconstructed as tracklets are typically hadrons scattering in the detector material or electrons undergoing bremsstrahlung. The probability of an isolated electron or hadron leaving a disappearing track is calculated using samples of single electrons or pions passing through the current ATLAS detector layout, and is then scaled to take into account the ratio of material in the current ATLAS inner detector and the upgraded inner tracker. The second background contribution arises from events which contain "fake" tracklets. These events arise from $Z \to \nu\nu$ or $W \to \ell\nu$ (where the lepton is not reconstructed) and are scaled by the expected fake tracklet probability:

$$p_{\mathrm{fake,tight}}^{\mathrm{ITk}} = p_{\mathrm{fake,tight}}^{\mathrm{ATLAS}} \times \frac{R_{\mathrm{fake,loose}}^{\mathrm{ITk}}}{R_{\mathrm{fake,loose}}^{\mathrm{ATLAS}}} \times \frac{\epsilon_{z_0}^{\mathrm{ITk}}}{\epsilon_{z_0}^{\mathrm{ATLAS}}}. \tag{4.1.1}$$

In this equation, $p_{\mathrm{fake,tight}}^{\mathrm{ATLAS}}$ is the fake rate of the current Run-2 analysis [331], computed using a d_0 sideband for the track reconstruction, $R_{\mathrm{fake,loose}}^{\mathrm{ITk}}$ is the fake rate in the same d_0 sideband for ITk computed with a neutrino particle gun sample, such that all tracks are purely a result of pile-up interactions, $R_{\mathrm{fake,loose}}^{\mathrm{ATLAS}}$ is the fake rate in the d_0 sideband for ATLAS computed on data, $\epsilon_{z_0}^{\mathrm{ITk}}$ is the selection efficiency of the tracklet z_0 selection in ITk, and $\epsilon_{z_0}^{\mathrm{ATLAS}}$ is the selection efficiency of the tracklet z_0 selection in ATLAS.

Systematic uncertainty projections for both searches have been determined starting from the systematic uncertainties studied in Run-2 and evolving them to a level which the ATLAS and CMS collaborations have agreed to consider as a sensible extrapolation to HL–LHC. Hence, the theory modelling uncertainties are expected to halve while the recommendations for detector-level and experimental uncertainties are dependent upon the systematic uncertainty under consideration and are scaled appropriately from the Run-2 analysis. When setting exclusion limits, an additional systematic uncertainty of 20% is set to account for the theoretical systematic uncertainty on the models under consideration. The dominant uncertainties in the disappearing track analysis arise from the modelling of the fake tracklet component, and the total uncertainty on the background yield is extrapolated to be 30%.

Table 4.1.1 presents the expected yields in the SR for the disappearing track search for each background source, corresponding to an integrated luminosity of 3 ab^{-1}. As seen in the table the dominant background source corresponds to events with a "fake" tracklet, arising predominantly from $Z \to \nu\nu$ events with an ISR jet and high $E_{\mathrm{T}}^{\mathrm{miss}}$, which contain spurious hits that are reconstructed as a tracklet.

Limits at 95% C.L. on the chargino lifetime are shown in Fig. 4.1.2 as a function of the $\tilde{\chi}_1^{\pm}$ mass. The simplified models of chargino production considered include chargino pair production and chargino-neutralino production (both $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^0$ and $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$. The potential for the full HL-LHC dataset is expected to exclude at the 95% C.L. chargino lifetimes, assuming a wino-like (higgsino-like) LSP, of between 7 ps (10 ps) and 4 μs (1.5 μs) for light charginos with a mass of 100 GeV. Heavier wino-like (higgsino-like) charginos are excluded up to $m(\tilde{\chi}_1^{\pm}) = 1100$ GeV (750 GeV) for lifetimes of 1 ns. The discovery

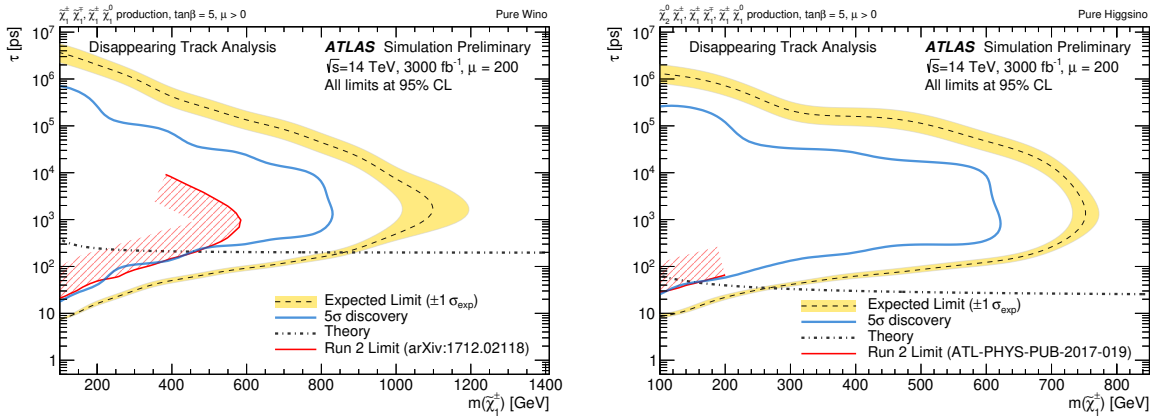

Fig. 4.1.2: Expected exclusion limits at 95% C.L. from the disappearing track search using of 3 $\mathrm{ab}^{-1}$of 14 TeV proton-proton collision data as a function of the $\tilde{\chi}_1^{\pm}$ mass and lifetime. Simplified models including both chargino pair production and associated production $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^0$ are considered assuming pure-wino production cross sections (left) and pure-higgsino production cross sections (right). The yellow band shows the 1σ region of the distribution of the expected limits. The median of the expected limits is shown by a dashed line. The red line presents the current limits from the Run-2 analysis and the hashed region is used to show the direction of the exclusion. The expected limits with the upgraded ATLAS detector would extend these limits significantly. The chargino lifetime as a function of the chargino mass is shown in the almost pure wino LSP scenario (light grey) calculated at one loop level. The relationship between the masses of the chargino and the two lightest neutralinos in this scenario is $m(\tilde{\chi}_1^{\pm}) = (m(\tilde{\chi}_1^0) + m(\tilde{\chi}_2^0))/2$. The theory curve is a prediction from a pure higgsino scenario.

potential of the analysis would allow for the discovery of wino-like (higgsino-like) charginos of mass 100 GeV with lifetimes between 20 ps and 700 ns (30 ps and 250 ns), or for a lifetime of 1 ns would allow the discovery of wino-like (higgsino-like) charginos of mass up to 800 GeV (600 GeV).

Finally, Fig. 4.1.3 presents the 95% C.L. expected exclusion limits in the $\tilde{\chi}_1^0, \Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$ mass plane, from both the disappearing track and dilepton searches. The yellow contour shows the expected exclusion limit from the disappearing track search, with the possibility to exclude $m(\tilde{\chi}_1^{\pm})$ up to 600 GeV for $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) < 0.2$ GeV, and could exclude up to $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 0.4$ GeV for $m(\tilde{\chi}_1^{\pm}) = 100$ GeV. The blue curve presents the expected exclusion limits from the dilepton search, which could exclude up to 350 GeV in $m(\tilde{\chi}_1^{\pm})$, and for a light chargino mass of 100 GeV would exclude mass differences between 2 and 15 GeV. Improvements that are expected with the upgraded detector, and search technique improvements may further enhance the sensitivity to these models. For example the sensitivity of the disappearing tracks search can be enhanced by optimising the tracking algorithms used for the upgraded ATLAS detector allowing for an increase in tracklet efficiency, the possibility of shorter tracklets produced requiring 3 or 4 hits, and further suppression of the fake tracklet component. The dilepton search sensitivity would be expected to improve by increasing the reconstruction efficiency for low p_T leptons. The addition of the electron channel would also further enhance the search sensitivity.

4.1.2 Complementarities between LHeC and HL-LHC for disappearing track searches

Contributors: K. Deshpande, O. Fischer, J. Zurita

In higgsino-like SUSY models, the Higgsinos' tiny mass splittings give rise to finite lifetimes for the charginos, which is enhanced by the significant boost of the c.o.m. system and can be used to suppress SM backgrounds [330]. The small mass splittings allow the Higgsinos to decay into $\pi^{\pm}, e^{\pm}, \mu^{\pm}$ + invisible particles, with the single visible charged particle having transverse momenta in the $\mathcal{O}(0.1)$ GeV range. In the clean environment (*i.e.* low pile up) of the e^-p collider, such single low-energy charged tracks can be reliably reconstructed, if the minimum displacement between primary and secondary vertex is at least 40 μm, and the minimum p_T of the charged SM particle is at least 100 MeV.

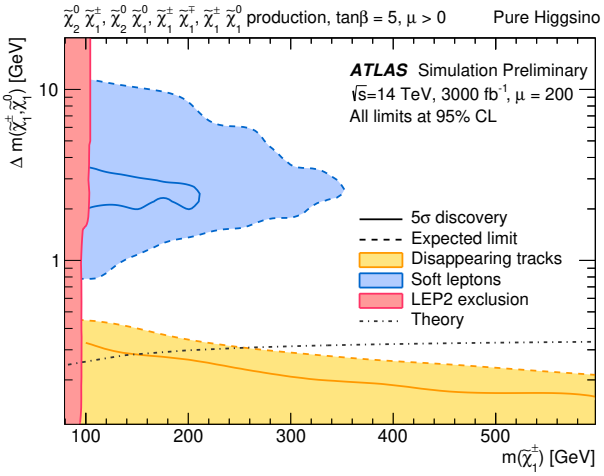

Fig. 4.1.3: Expected exclusion at the 95% C.L. from the disappearing track and dilepton searches in the $\Delta m(\tilde{\chi}_1^\pm, \tilde{\chi}_1^0)$, $m(\tilde{\chi}_1^\pm)$ mass plane. The blue curve presents the exclusion limits from the dilepton search. The yellow contour presents the exclusion limit from the disappearing track search. The figure also presents the limits on chargino production from LEP. The relationship between the masses of the chargino and the two lightest neutralinos in this scenario is $m(\tilde{\chi}_1^\pm) = \frac{1}{2}(m(\tilde{\chi}_1^0) + m(\tilde{\chi}_2^0))$. The theory curve is a prediction from a pure higgsino scenario taken from Ref. [211].

It was shown in Ref. [330] that the results do not crucially depend on the exact choice of these parameters. The associated DIS jet with $p_T > 20$ GeV ensures that the event is recorded and determines the position of the primary vertex. The charginos' decay into a neutral Higgsino and a number of SM particles with small p_T defines the secondary vertex.

Tau leptons with their proper lifetime of ~ 0.1 mm constitute an important and irreducible background. VBF can single- ($\tau^+\nu_\tau$) and pair produce taus ($\tau^+\tau^-$) together with a jet with $p_T > 20$ GeV, $|\eta| < 4.7$ at LHeC with cross sections of ~ 0.6 and ~ 0.3 pb, respectively. Kinematically, the τ decay products can be suppressed to 10^{-3} (keeping $\mathcal{O}(1)$ of the signal) by requiring $|\eta| > 1$ (in the proton beam direction), $\not{E}_T \gtrsim 30$ GeV) and the LLP final state energy to be very low ($\lesssim 1.5\Delta m$ for a given chargino lifetime). Furthermore, in the space of possible final states and decay lengths, the τ's will populate very different regions than the chargino signal, such that further suppression is possible.

The probability of detecting a chargino is computed by choosing the charged particle momentum from the appropriate phase space distribution in the chargino rest frame, then computing the minimum distance the chargino must travel for the displacement of the resulting charged track to be visible. The sensitivities of detecting at least one ($N_{1+\mathrm{LLP}}$), or two displaced vertices ($N_{2\mathrm{LLP}}$) are shown by the contours in Fig. 4.1.4 for $\mu > 0$. The darker (lighter) shading represents the contour with the lowest (highest) estimate of event yield, obtained by minimising (maximising) with respect to the two different hadronisation scenarios, and P_{jet} reconstruction assumptions. The difference between the light and dark shaded regions can be interpreted as a range of uncertainty in projected reach.

This sensitivity for Higgsinos via LHeC searches is competitive in mass reach to the monojet projections for the HL-LHC, being sensitive to masses around 200 GeV for the longest theoretically motivated lifetimes (see also Section 4.1.3). The LHeC search has the crucial advantage of actually observing the charged Higgsino parent of the invisible final state. Disappearing track searches at the HL-LHC presented in this report probe higher masses for the longest lifetimes, but lose sensitivity at shorter lifetimes. By comparison, the LHeC search is sensitive to lifetimes as short as microseconds. It is important to note how the robustness of the mass reach of e^-p colliders arise also from the fact that results are not exponentially sensitive to uncertainties in the Higgsino velocity distribution.

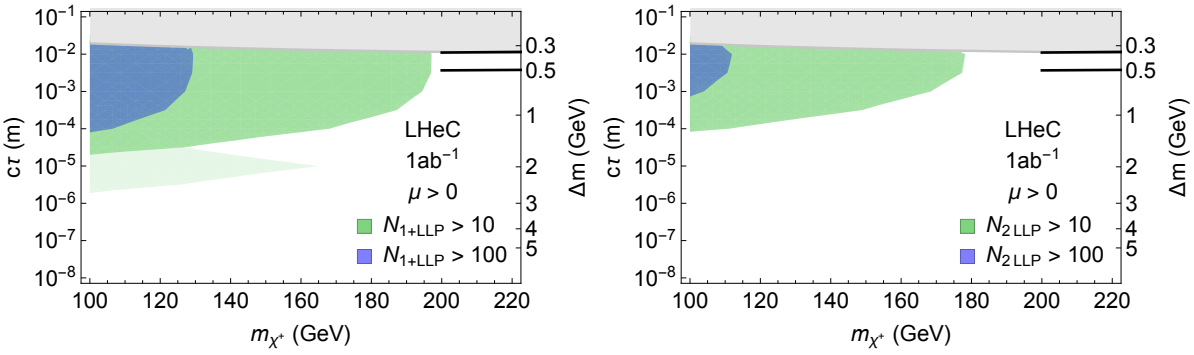

Fig. 4.1.4: Regions in the $(m_{\chi^\pm}, c\tau)$ Higgsino parameter plane where more than 10 or 100 events with at least one (left) or two (right) LLPs are observed at the LHeC. Light shading indicates the uncertainty in the predicted number of events due to different hadronisation and LLP reconstruction assumptions. Approximately 10 signal events should be discernible against the τ-background at 2σ, in particular for 2 LLPs, so the green shaded region represents an estimate of the exclusion sensitivity. For comparison, the black curves are the optimistic and pessimistic projected bounds from HL-LHC disappearing track searches from Ref. [288]. The figure is from Ref. [330].

4.1.3 Searching for Electroweakinos with disappearing tracks analysis at HL- and HE-LHC

Contributors: T. Han, S. Mukhopadhyay, X. Wang

Prospects for a disappearing charged track search are finally presented for three different scenarios of collider energy and integrated luminosity: HL-LHC, HE-LHC, and FCC-hh/SppC (100 TeV, 30 ab^{-1}). The studies are documented in Ref. [155] and are complementary to the monojet prospects reported in Section 3.1.3 for higgsino-like SUSY scenarios.

As in Section 3.1.3, the significance is defined as $S/\sqrt{B + (\Delta_B B)^2 + (\Delta_S S)^2}$ where S and B are the total number of signal and background events, and Δ_S, Δ_B refer to the corresponding percentage systematic uncertainties, respectively.

Background and signal systematic uncertainties are assumed as $\Delta_B = 20\%$ and $\Delta_S = 10\%$ respectively. In Fig. 4.1.5 we compare the reach of the HL-LHC, HE-LHC and FCC-hh/SppC options in the disappearing charged track analysis for wino-like (left) and Higgsino-like (right) DM search. The solid and dashed lines correspond to modifying the central value of the background estimate[6] by a factor of five. With the optimistic estimation of the background, wino-like DM can be probed at the 95% C.L. up to 900, 2100, and 6500 GeV, at the 14, 27, and 100 TeV colliders respectively. For the Higgsino-like scenario, these numbers are reduced to 300, 600, and 1550 GeV, primarily due to the its shorter lifetime and the reduced production rate. For the conservative estimation of the background, the mass reach for the wino-like states are modified to 500, 1500, and 4500 GeV, respectively, at the three collider energies. Similarly, for the Higgsino-like scenario, the reach becomes 200, 450, and 1070 GeV. Results for HL-LHC are also in reasonable agreement with experimental prospect studies. The signal significance in the disappearing track search is rather sensitive to the wino and Higgsino mass values (thus making the 2σ and 5σ reach very close in mass), due to the fact that the signal event rate decreases exponentially as the chargino lifetime in the lab frame becomes shorter for heavier masses.

The improvements in going from the HL-LHC to the HE-LHC, and further from the HE-LHC to the FCC-hh/SppC are very similar to those obtained for the monojet analysis, namely, around a factor of two and three, respectively. Results for both analyses are summarised in Table 4.1.2.

[6] Background is estimated by extrapolating ATLAS Run-2 analysis [332]. See [155] for details.

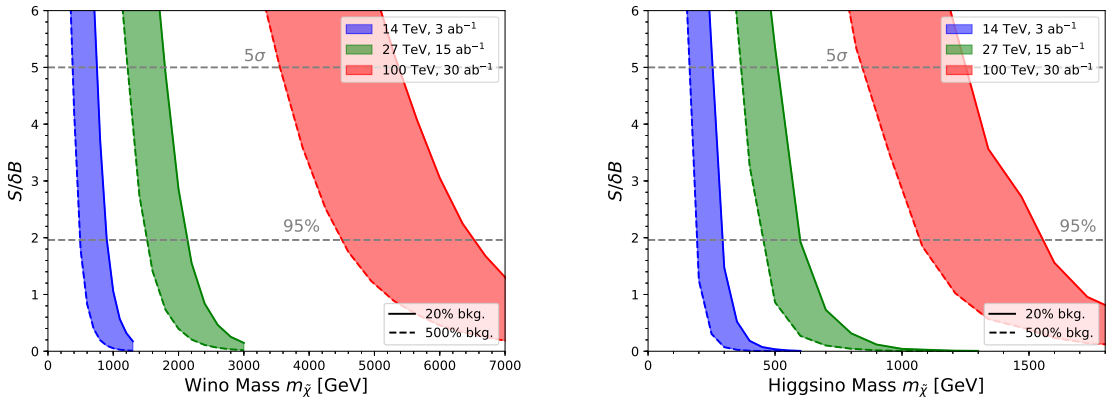

Fig. 4.1.5: Comparative reach of the HL-LHC, HE-LHC and FCC-hh/SppC options in the disappearing charged track analysis for wino-like (left) and Higgsino-like (right) DM search. The solid and dashed lines correspond to modifying the central value of the background estimate by a factor of five.

95% C.L.	Wino Monojet	Wino Disappearing Track	Higgsino Monojet	Higgsino Disappearing Track
14 TeV	280 GeV	900 GeV	200 GeV	300 GeV
27 TeV	700 GeV	2.1 TeV	490 GeV	600 GeV
100 TeV	2 TeV	6.5 TeV	1.4 TeV	1.6 TeV

Table 4.1.2: Summary of DM mass reach at 95% C.L. for an EW triplet (wino-like) and a doublet (Higgsino-like) representation, at the HL-LHC, HE-LHC and the FCC-hh/SppC colliders, in optimistic scenarios for the background systematics.

4.2 Displaced Vertices

Many models of new physics predict long-lived particles which decay within the detector but at an observable distance from the proton-proton interaction point (displaced signatures). If the decay products of the long-lived particle include multiple particles reconstructed as tracks or jets, the decay can produce a distinctive signature of an event containing at least one displaced vertex (DV). In the following sections, a number of prospects studies from ATLAS, CMS and LHCb are presented. Results are interpreted in the context of supersymmetric or higgs-portal scenarios but are applicable to any new physics model predicting one or more DVs, since the analyses are not driven by strict model assumptions.

4.2.1 LLP decaying to a Displaced Vertex and $E_{\mathrm{T}}^{\mathrm{miss}}$ at HL-LHC

Contributors: E. Frangipane, L. Jeanty, L. Lee Jr, H. Oide, S. Pagan Griso, ATLAS

There are several recent papers at the LHC which have searched for displaced vertices, including Ref.s [300, 333–335]. The projection presented here [336] requires at least one displaced vertex reconstructed within the ATLAS ITk, and events are required to have at least moderate missing transverse momentum ($E_{\mathrm{T}}^{\mathrm{miss}}$), which serves as a discriminant against background as well as an object on which to trigger. The analysis sensitivity is projected for a benchmark SUSY model of pair production of long-lived gluinos, which can naturally arise in models such as Split SUSY [337]. Each gluino hadronises into an R-hadron and decays through a heavy virtual squark into a pair of SM quarks and a stable neutralino with a mass of 100 GeV.

This study makes use of Monte Carlo simulation samples to obtain the kinematic properties of signal events, which are then used to estimate the efficiency for selecting signal events. The pair production of gluinos from proton-proton collisions at $\sqrt{s} = 13$ TeV was simulated in PYTHIA 6.428 [92] at leading order with the AUET2B [338] set of tuned parameters for the underlying event and the CTEQ6L1

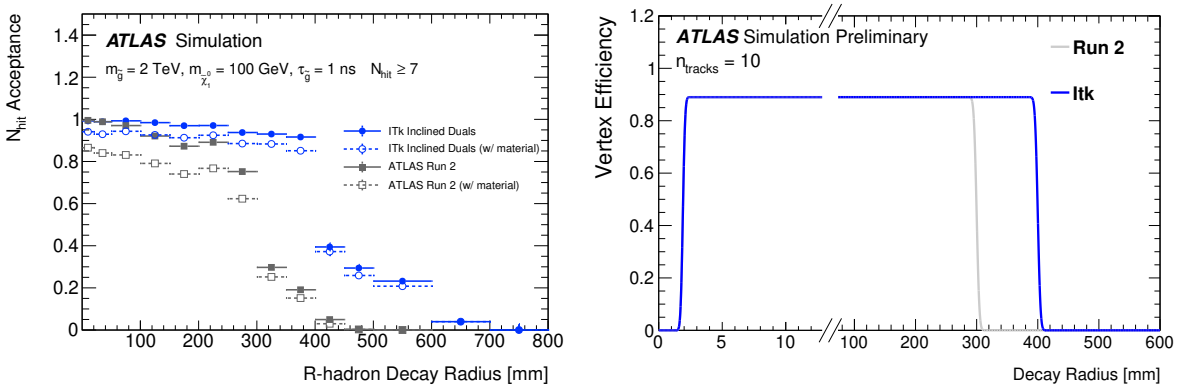

Fig. 4.2.1: Left: probability that a charged particle, with $p_T > 1$ GeVproduced in the decay of a 2.0 TeV R-hadron with a lifetime of 1 ns, passes through at least seven silicon layers, as a function of the decay radius of the R-hadron, for both the Run-2 and ITk detector layouts [256]. The probability is shown with and without the simulated effect of material producing hadronic interactions. Right: parametrised efficiency for reconstructing a displaced vertex with $n_{\text{tracks}} = 10$, as a function of the decay radius of the parent particle, as measured in Run-2 simulation and extrapolated to the ITk geometry.

parton distribution function (PDF) set [52]. After production, the gluino hadronises into an R-hadron and is propagated through the ATLAS detector by GEANT4 [54, 254] until it decays. PYTHIA 6.428 is called to decay the gluino into a pair of SM quarks and a neutralino and models the three-body decay of the gluino, fragmentation of the remnants of the light-quark system, and hadronisation of the decay products. The gluino lifetime ranges from 0.1 ns to 10 ns, and the neutralino mass is fixed to 100 GeV. To normalise the expected number of signal events in the full HL-LHC dataset, the cross-sections for pair production of gluinos are calculated at next-to-leading order at $\sqrt{s} = 14$ TeV and resummation of soft-gluon emission is taken into account at next-to-leading-logarithm accuracy (NLO+NLL) following the procedure outlined in Ref. [339].

Particle-level Monte Carlo events are used to obtain kinematic distributions for the signal. The expected track reconstruction performance is estimated by factorising it into an acceptance and an efficiency term, and assuming that the efficiency performance of the Run-2 algorithm, currently close to 100%, will be reproduced for ITk for particles which pass the acceptance. The tracking acceptance is based on the number of hits left by a charged particle traversing the silicon sensors; at least seven hits are required for both the current ID and the future ITk. To calculate the ITk acceptance for the tracks of interest, a full simulation of the ITk geometry is used. Only charged decay products with $p_T > 1$ GeV are considered and material interactions with the active and passive material of the detector are taken into account. Figure 4.2.1 (left) shows the acceptance as function of the production transverse position (radius) of the particle. The steep drop off in efficiency in the present ID at around 300 mm corresponds to the farthest radial extent of the first layer of the SCT, after which it is unlikely that a typical particle would traverse seven strip layers. In the ITk, the equivalent drop-off does not occur until after 400 mm due to the larger spacing between the silicon layers.

The current displaced vertexing performance is parametrised as a function of the transverse decay position (r_{DV}) and number of reconstructed tracks (n_{tracks}) coming from the long-lived particle decay. To extrapolate from the Run-2 efficiency to the expected performance in ITk, the same fit values are used for each bin of n_{tracks}, while the radial distance at which the vertexing efficiency starts to drop is moved from 300 mm to 400 mm to reflect the change in the location of the inner silicon strip layer, as shown for one particular example in Fig. 4.2.1 (right).

The event selection closely follows the requirements in the recent Run-2 search for a DV and MET [333]. Events are required to have at least one DV within the ITk volume and at least five tracks from the gluino decay must be reconstructed. The tracks and vertices are reconstructed with a probability

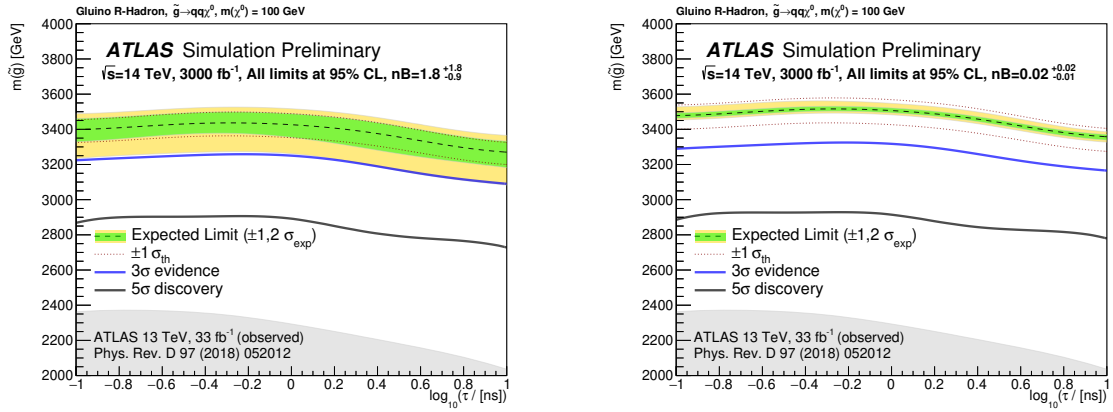

Fig. 4.2.2: Projected sensitivity for the upper limit on the mass of a gluino R-hadron that can be observed with 3σ and 5σ confidence or excluded at 95% C.L., as a function of the gluino lifetime, for a background of $1.8^{+1.8}_{-0.9}$ events (left) and a background of $0.02^{+0.02}_{-0.01}$ events (right). These results are valid for a gluino which decays to SM quarks and a stable neutralino with a mass of 100 GeV. Results assume 3 ab^{-1}of collisions at $\sqrt{s} = 14$ TeV collected with the upgraded ATLAS detector, and are compared to the observed ATLAS exclusion limits for a dataset of 33 fb^{-1} at $\sqrt{s} = 13$ TeV.

given by the procedures described above; only charged decay products with $p_T > 1$ GeV, $|\eta| < 5$, and with 6 mm $< r_{\text{prod}} < 400$ mm are considered. To exclude hadronic interactions of SM particles, the vertex must not be located within a region of the detector filled with solid materials, and the invariant mass of the reconstructed vertex must be larger than 10 GeV. The event must pass the MET trigger and offline requirements of the Run-2 search, *i.e.* MET> 250 GeV; the efficiency of passing the MET trigger and offline MET requirements is taken from the Run-2 analysis, as parametrised in Ref. [340] as a function of the generator-level MET and the R-hadron decay positions.

The background for this search is entirely instrumental in nature. For this projection, two different extrapolations of the size of current background are performed. The default extrapolation assumes that the background and its uncertainty will scale linearly with the size of the dataset, resulting in an expected background of $1.8^{+1.8}_{-0.9}$ events. However, several handles could be tightened in the analysis selection to continue to reject background without introducing appreciable signal efficiency loss. For example, additional requirements on the vertex goodness-of-fit or the compatibility of each track with the vertex could be imposed to further reduce backgrounds from low-mass vertices which are merged or crossed by an unrelated track. Therefore, a more optimistic scenario is also considered in which the total background and uncertainty are kept to the current level of $0.02^{+0.02}_{-0.01}$ events.

The signal selection uncertainties are taken to have the same relative size as in the existing Run-2 analysis. Uncertainties on the signal cross-section prediction are taken by varying the choice of PDF set and factorisation and renormalisation scales, with a reduction of 50% applied to the uncertainties to account for improvements by the time the analysis will be performed.

Using the number of expected signal and background events with their respective uncertainties, the expected exclusion limit at 95% C.L. on the gluino mass, as a function of lifetime, is calculated assuming no signal presence. In the case that signal is present, the 3σ and 5σ observation reaches are also calculated. The results are shown in Fig. 4.2.2 for both background scenarios.

The significant increase in sensitivity relative to the ATLAS result with 33 fb^{-1} at $\sqrt{s} = 13$ TeV comes in part from the increase in collision energy and integrated luminosity. For longer lifetimes, a significant gain in selection efficiency and therefore reach is also due to the larger volume of the silicon tracker, which allows displaced tracks and displaced vertices to be reconstructed at larger radii. This pushes the radius at which tracks from long-lived particles can be efficiently reconstructed from 300 to 400 mm, with corresponding gain in acceptance for lifetimes of 10 ns and greater. While the results pre-

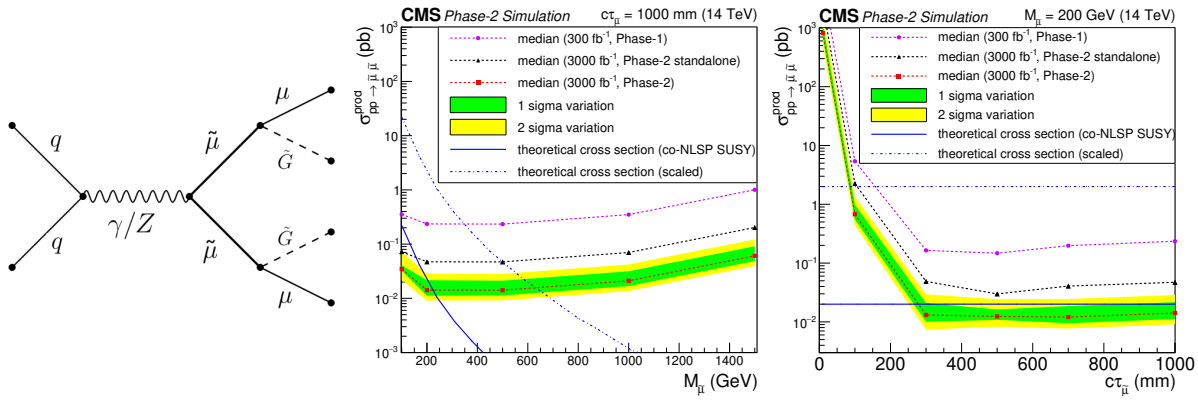

Fig. 4.2.3: Left: Feynman diagram for smuon production. Middle and right: expected 95% C.L. upper limits on long-lived smuons for various mass hypotheses and $c\tau = 1$ m. In both panels, the theoretical cross section for the specific model is represented by the blue solid line. For different SUSY breaking scales, $\tan\beta$ or otherwise modified parameters, the cross sections may be 100 times larger, reflected by the blue dash-dotted line. Green (yellow) shaded bands show the one (two) sigma range of variation of the expected 95% C.L. limits. Phase-2 results with an average 200 pileup events and an integrated luminosity of 3 $\text{ab}^{-1}$are compared to results obtained with 300 fb^{-1}. The black line shows the sensitivity without the DSA algorithm, which reduces the reconstruction efficiency by a factor three. The panel in the middle shows the limit as a function of the smuon mass and the right panel as a function of the decay length.

sented here were studied only for a fixed neutralino mass of 100 GeV, based on the results in Ref. [333], comparable sensitivity is expected over a large range of neutralino masses. As the neutralino mass increases for a fixed gluino mass, the multiplicity and momentum of the visible SM particles decreases, which in turn decreases the efficiency of the requirements on the track multiplicity, vertexing reconstruction, and vertex invariant mass as the difference between the neutralino mass and the gluino mass, m_{DV}, falls below 400 GeV.

4.2.2 Displaced muons at HL-LHC

Contributors: K. Hoepfner, H. Keller, CMS

A growing class of new physics models predict long-lived particles potentially leading to displaced signatures. In this study from CMS we discuss the potential for a SUSY GMSB model with heavy smuons decaying to a SM muon and a gravitino (yielding MET) [306, 341]. Figure 4.2.3 (left) shows the model under study. In this model the smuon is produced in pairs, and is degenerate in mass yielding long lifetimes. In such scenarios the smuon may decay after $\mathcal{O}(1\text{ m})$ or more such that the only detectable hits are in the muon system. Consequently the analysis uses a dedicated reconstruction algorithm for stand-alone muons (DSA) without a constraint on the vertex position.

It is both challenging to trigger and to reconstruct displaced muons, especially if the displacements are large. Triggers and reconstruction algorithms, generally including the primary vertex position, will not be very efficient in reconstructing tracks with large impact parameters. If the particle is sufficiently boosted, the transverse impact parameter is small(er) but the decay may occur well outside the tracker volume. In both cases, the stand-alone capabilities of the muon system constitute the only possibility for detection.

The main background for this search comes from multi-jet production (QCD), $t\bar{t}$ production, and Z/DY events if large impact parameters are (mis)reconstructed. Cosmic ray muons have been studied in Run-2 and are independent of the instantaneous luminosity. In the barrel they are efficiently rejected by the timing of the hits in the upper leg. Cosmic ray muons do not originate at the vertex and therefore pass the upper barrel sectors in reverse direction from outside in. The fraction of cosmic ray muons in the endcaps is negligible. Given the very low cross section of the signal process, it is essential to re-

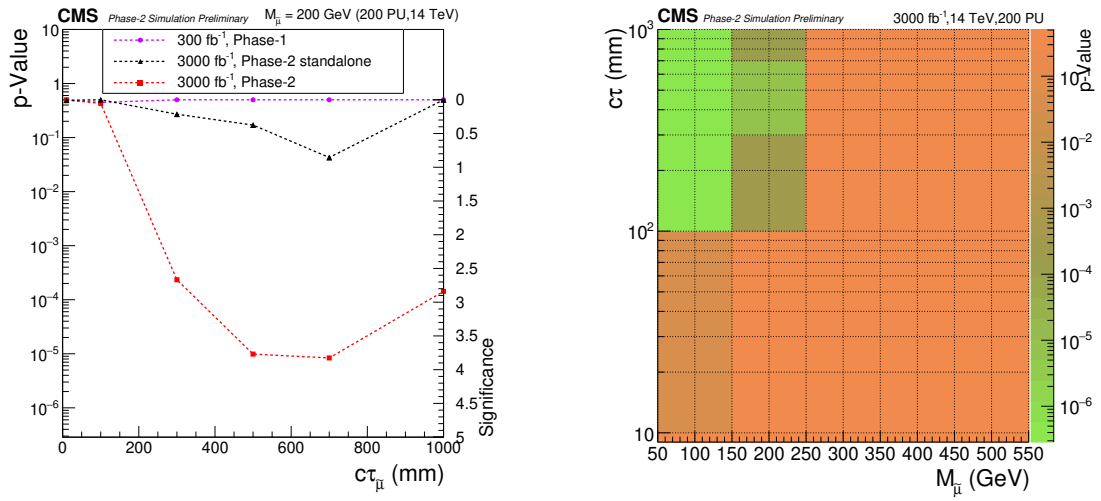

Fig. 4.2.4: Left: discovery significance and p-value for a fixed smuon mass of $M\tilde{\mu} = 200$ GeV. The displaced significance is compared to the algorithm with a beamspot constraint ("Phase-2 standalone"). Right: discovery sensitivity in the 2D parameter space of mass and decay length.

duce the background efficiently. The best background discriminator is the impact parameter significance $d_0/\sigma(d_0) \geq 10$. The muons should move in roughly opposite directions and MET should be larger than 50 GeV to account for the two gravitinos. After this selection the signal efficiency is about $4-5\%$ for $c\tau = 1000$ mm, nearly independent of the smuon mass, and $10^{-5} - 10^{-4}$ for QCD, $t\bar{t}$, and DY backgrounds.

Figure 4.2.3 shows expected exclusion limits for the gauge-mediated SUSY breaking model with the smuon being a (co-)NLSP for the predicted cross section as well as for a factor 100 larger cross section. The exclusion limits are shown as functions of smuon mass in Fig. 4.2.3 (middle) and decay length in Fig. 4.2.3 (right). The sensitivity also depends on $c\tau$ because shorter decay lengths shift the signal closer to the background. The expected exclusion limit is around 200 GeV for $c\tau = 1000$ mm with 3 ab^{-1}. For the same mass, a discovery sensitivity of 3σ significance can be reached, as shown in Fig. 4.2.4. This also illustrates the importance of the lepton trigger thresholds to be kept at a few times 10 GeV, even in the environment of 200 pileup interactions. Figure 4.2.4 also shows the discovery sensitivity in the 2-dimensional parameter space of smuon mass and decay length.

4.2.3 LLPs decaying into muons and jets at the HL-LHC

Contributors: A. Bay, X. Cid Vidal, E. Michielin, L. Sestini and C. Vázquez Sierra, LHCb

The LHCb experiment has proved to be highly competent with regard to direct searches for LLPs, being able to complement ATLAS and CMS in certain parameter space regions [342]. In this section, we provide prospects in the search for R-Parity Violating (RPV) supersymmetric neutralinos decaying semileptonically into a high-p_T muon and two jets. The results are taken from Ref. [343] which extrapolates the analysis in Ref. [344]. The neutralinos are assumed to be produced through an exotic decay of the SM Higgs boson. Prospects are shown for the expected datasets after both planned LHCb Upgrade I and Upgrade II (Run-3–Run-4 and Run-5 onwards, respectively).

The trigger efficiency for this analysis is conservatively assumed to remain unchanged with respect to the published result. However, assuming a 100% efficient first level trigger, after the removal of the hardware trigger level in Run-3, the overall trigger efficiency could improve by a factor of $2-3$. Regarding pile-up effects, a moderate penalty factor is applied to account for the increased pile-up expected in Runs 3-5 at LHCb. In order to expand the projections, the results are interpolated for different masses and lifetimes that are not considered in simulation. The interpolation is linear and two-dimensional.

$m_{\tilde{\chi}_1^0}$ (GeV/c^2)	$c\tau_{\tilde{\chi}_1^0}$ (mm)	Acceptance (%)	Total (%)	Background yield (1.7 fb^{-1})
20	**3**	28.0	0.27	2
	15	28.1	0.30	1
	30	27.8	0.24	3
30	**3**	28.7	0.78	4
	15	28.4	1.21	4
	30	28.7	0.75	2
50	**15**	31.5	2.33	2
	30	31.7	1.58	1
60	**10**	35.2	1.38	1
	50	35.5	2.84	2
	100	35.2	2.63	3

Table 4.2.1: Examples of the acceptance and total efficiencies assumed to detect a $\tilde{\chi}_1^0$ decaying semileptonically at a pp collision energy of $\sqrt{s} = 13$ TeV at the LHCb detector. Reference background yields at an integrated luminosity of 1.7 fb^{-1} are also presented. Differences in these yields are due to the effect of a multivariate classifier which is trained differently for each mass-lifetime case.

The results are obtained from a preliminary, unoptimised analysis of a subset of data collected for pp collisions at c.o.m. energy of 13 TeV. To account for a possible deterioration in the background rejection due to multiple primary interactions at high luminosity, a penalty factor of two has been applied to the background yield. The signal efficiency is obtained from the full simulation of the Higgs boson produced via gluon-gluon fusion at 13 TeV. As explained, no other change in the signal and background efficiencies due to the upgrade of the detector is considered. The difference between 13 and 14 TeV energies is assumed to be negligible. Some examples of the efficiencies and background yields assumed for these calculations can be found in Table 4.2.1.

With the updated signal and background yields, the sensitivity projections are computed. The upper limits on the branching fraction of the Higgs boson decay to a pair of neutralinos are calculated for different assumptions of neutralino masses and lifetimes and for different values of integrated luminosity. The Higgs boson production cross section is assumed to be that of the SM [345]. The actual limit is computed by comparing the 14 TeV efficiencies and background yields to Run-1, and by extrapolating the results published in Ref. [344]. The systematic uncertainties, which are sub-dominant for this result in the published analysis, are assumed to be the same as those in Run-1.

The results are shown in Fig. 4.2.5, for different integrated luminosities. These plots display the RPV neutralino mass and lifetime ranges excluded at 95% C.L.. The ranges are shown for different assumed integrated luminosities and branching fractions of the Higgs boson decay to a pair of RPV neutralinos. The region for which the mass of the neutralino is above 60 GeV is not shown in these projections, since no simulation was available. It is worth to notice that the lifetime range covered ($0.2 < c\tau < 200$mm) is constrained by the physical length of the VELO detector, since the LLP is required to decay within the VELO region in order to be able to reconstruct it. For the HL-LHC, most of the LHCb accessible neutralino phase space can be excluded for a branching fraction of the $H \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ decay larger than 0.5%.

4.2.4 LLPs decaying into dijets at the HL-LHC

Contributors: X. Cid Vidal, E. Michielin, L. Sestini and C. Vázquez Sierra, LHCb

In this section, prospects are obtained for Hidden Valley (HV) [346, 347] pions (π_v) decaying hadronically into a pair of jets at LHCb. The π_v, which can be long-lived, are assumed to be produced through an exotic decay of the SM Higgs boson. The prospects in this chapter are taken from Ref. [343], whose analysis is based on a projection of the results published in Ref. [348].

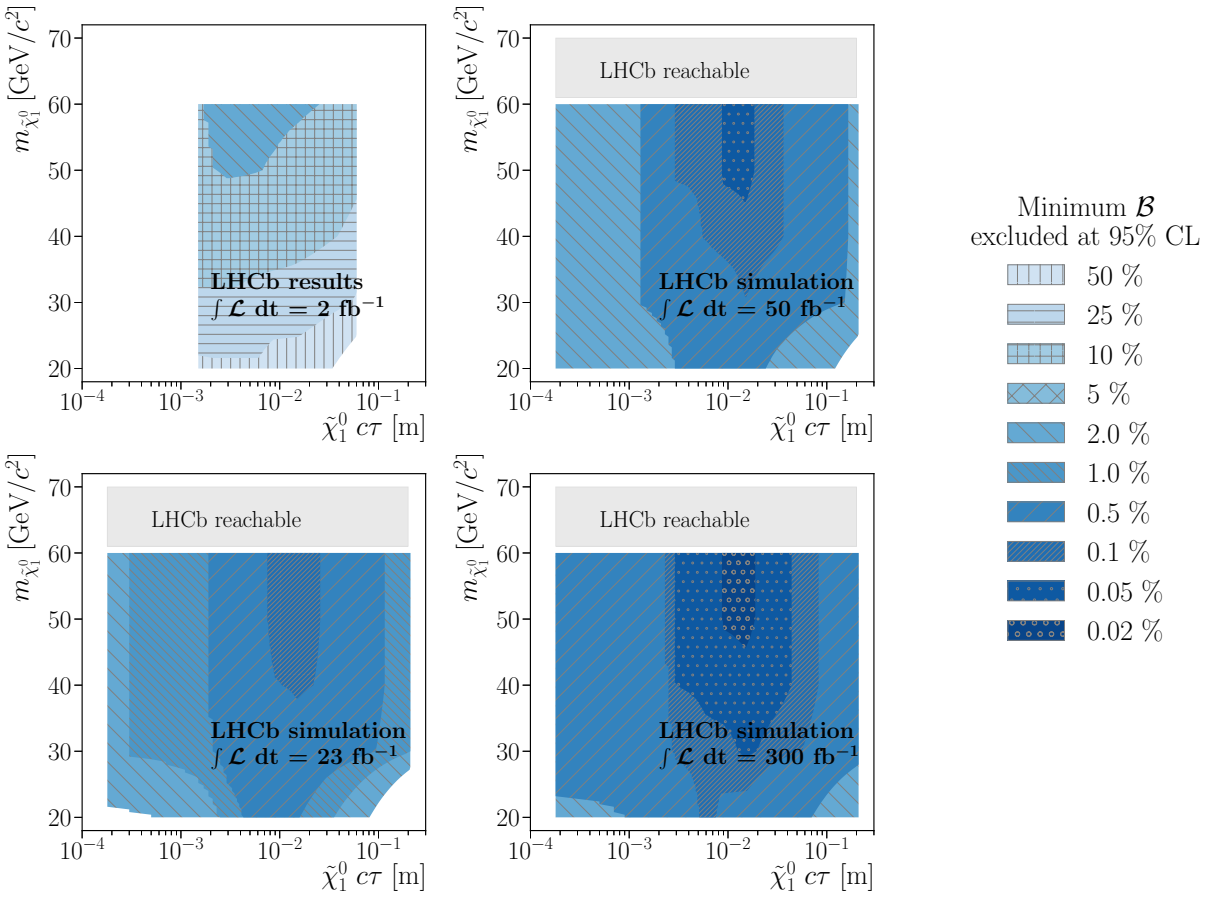

Fig. 4.2.5: Projected sensitivities of the search for RPV supersymmetric neutralinos decaying semileptonically and produced through a Higgs boson exotic decay. The results are extrapolated from Run-1 results (top left), for luminosities of 23 fb^{-1} (top right), 50 fb^{-1} (bottom left) and 300 fb^{-1} (bottom right). The results are presented in terms of the excluded parameter space of the neutralinos for different upper limits at 95% C.L. on the branching fractions of the Higgs boson decay.

The simulation of the HV pions through the Higgs portal is fully specified by the mass and the lifetime of the π_v particles, allowed to decay exclusively as $\pi_v \to \mathrm{b\bar{b}}$ since this decay mode is generally preferred in this model.

The assumptions made concerning signal efficiencies and background yields are similar to those discussed in Section 4.2.3. However, in this case, no penalty for the pile-up is applied. Signal and background yields are obtained taking into account the increase of cross sections (from $\sqrt{s} = 8$ TeV to $\sqrt{s} = 14$ TeV) and of the integrated luminosities. The scaling of the signal includes both the increase in the cross section of the Higgs boson production and that of the amount of signal falling in the acceptance of the LHCb detector. As an example, Table 4.2.2 shows some of the acceptance and total efficiencies assumed for this extrapolation for different masses and lifetimes of the HV pion. The background is scaled by a factor obtained using simulated $b\bar{b}$ events, which are expected to be the dominant contribution. The assumed yields, extrapolated from Ref. [348], can be found in Table 4.2.3 for an integrated luminosity of 23 fb^{-1}. Following the same reference, the yields are divided in bins of the radial coordinate of the HV pion decay vertex position.

With the updated backgrounds and expected signal yields, the $\mathrm{CL_S}$ method [95] is used to compute the expected upper limits for different assumptions in the integrated luminosity and of the Higgs decay branching fraction. The Higgs boson production cross section is assumed to be that of the SM [345]. The systematic uncertainties, which are not dominant for the computation of these limits in the published

$c\tau_{\pi_v}$ (mm)	Efficiency (%)	m_{π_v} GeV/c^2			
		25	**35**	**43**	**50**
3	Acceptance	26.8	21.2	17.4	14.6
	Total	0.9	1.7	1.5	1.1
30	Acceptance	16.1	15.1	13.7	12.3
	Total	0.2	0.4	0.4	0.3

Table 4.2.2: Examples of the acceptance and total efficiencies assumed to detect a π_v particle decaying to a pair of jets at a pp collision energy $\sqrt{s} = 14$ TeV at the LHCb detector. The main inefficiencies arise from the requirements to have π_v particle in the VELO and to have the decay products in the LHCb acceptance and from the reconstruction of the secondary vertex.

R_{xy} (mm)	$0.4-1$	$1-1.5$	$1.5-2$	$2-3$	$3-5$	$5-50$
Background yield (23 fb^{-1})	1.1×10^5	5.4×10^5	3.3×10^5	9.8×10^5	2.1×10^6	3.3×10^5

Table 4.2.3: Background yields assumed for the HV pion analysis at an integrated luminosity of 23 fb^{-1}. The yields are divided in bins of $R_{xy} = \sqrt{x^2+y^2}$, where x, y are the coordinates of the π_v particle decay vertex position.

analysis, are considered to be the same as in Run-1, and added as a correction factor to the limits obtained using just statistical uncertainties. With all these assumptions, the HV pion masses and lifetimes excluded at 95% C.L. are obtained. The results are shown in Fig. 4.2.6. The plots display, for different assumed integrated luminosities and branching fractions of the Higgs boson decay to a pair of HV pions, the ranges excluded at 95% C.L.. These ranges are shown as a function of the HV pion mass and lifetime. As in Section 4.2.3, the lifetime range covered is constrained by the physical length of the VELO detector. LHCb expects to exclude the existence of π_V with masses between 35 and 50 GeV/c^2 and lifetimes in the $c\tau$ range $0.1-1$ cm, pair-produced through the decay of the Higgs boson, for branching fractions of such decay above 1%. The mass region below ~ 25 GeV/c^2 is expected to be accessible studying the substructure of merged jets [349].

4.3 Heavy Stable Charged Particles at HL-LHC

Several extensions of the SM predict the existence of new heavy particles with long lifetimes. If their lifetime exceeds a few nanoseconds, such particles can travel through the majority of the detector before decaying and therefore appear as stable. In the following, two dedicated studies performed using the upgraded CMS detector at the HL-LHC are presented for particles with non-zero electric charge and for particles with anomalously high energy loss through ionisation in the silicon sensors. Emphasis is given to detector requirements necessary to perform such specialised searches.

4.3.1 Heavy stable charged particle search with time of flight measurements

Contributors: C. Carrillo, J. Goh, M. Gouzevitch, G. Ramirez-Sanchez, CMS

In this section, we consider particles with non-zero electric charge which are referred to as heavy stable charged particles (HSCPs). We concentrate on the performance in terms of specific HSCP parameters in a model-independent way rather than providing an interpretation in a dedicated model. Given the wide range of new models, it is important to stay sensitive to a wide range of unusual signatures such as very slowly moving particles. The results presented here are from the CMS Collaboration based on Ref. [341].

HSCPs will leave a direct signal in the tracker and muon systems of CMS and can be reconstructed similarly to muons. Depending on their mass, HSCPs can potentially move much more slowly than muons, which are typically travelling nearly at the speed of light ($\beta \approx 1$). Therefore, HSCPs can be identified using their time-of-flight (TOF) from the centre of CMS to the muon systems. This is

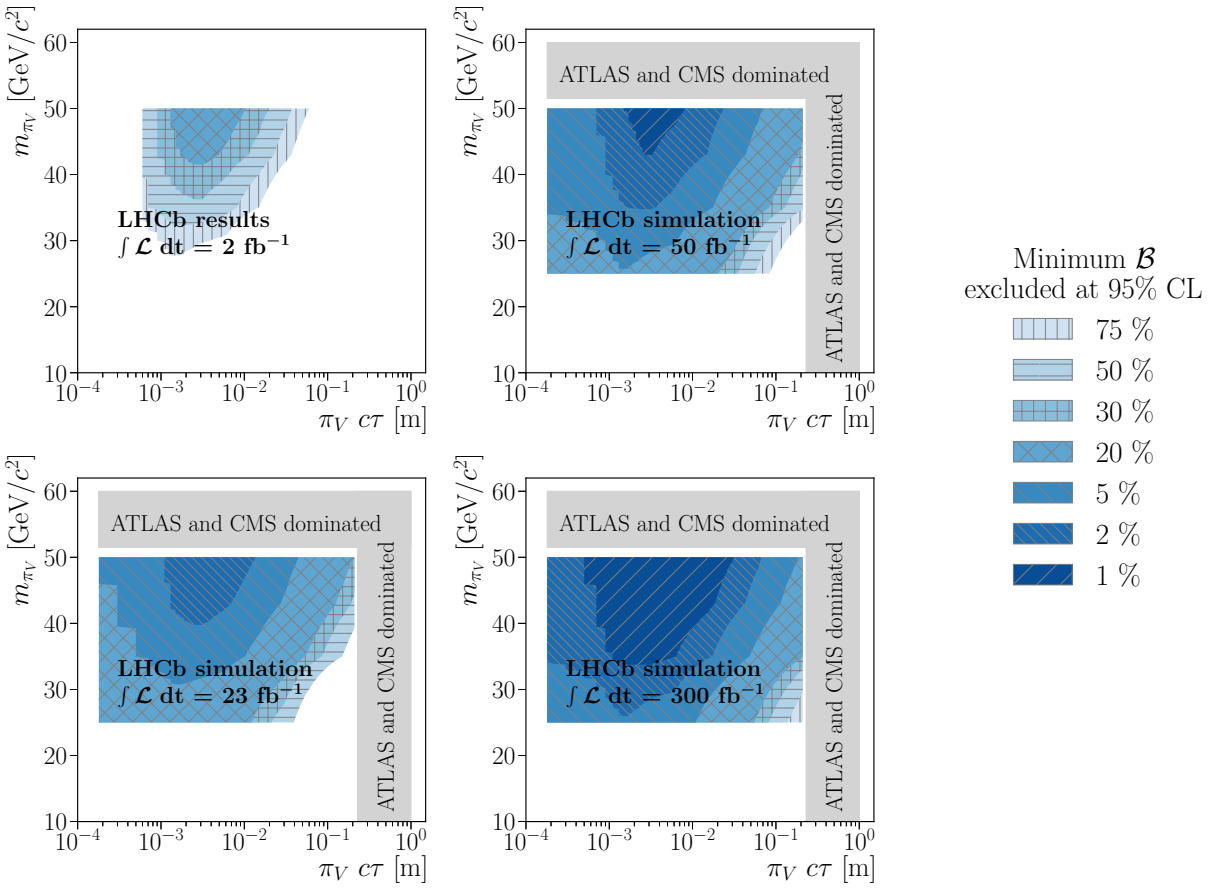

Fig. 4.2.6: Projected sensitivities of the search for HV pions decaying hadronically and produced through a Higgs boson exotic decay. The results are extrapolated from Run-1 results (top left), for luminosities of 23 fb^{-1} (top right), 50 fb^{-1} (bottom left) and 300 fb^{-1} (bottom right). The results are presented in terms of the excluded parameter space of the HV pions for different upper limits at 95% C.L. on the branching fractions of the Higgs boson decay.

illustrated in Fig. 4.3.1 for a slowly moving HSCP in comparison to relativistic muons, here from the decay of Z bosons. The latter are centred around zero time with respect to their uniquely identified bunch crossing. This study builds on the improvements from the upgrade of the RPC link boards in the CMS muon barrel and endcaps [341]. While the time resolution of the present RPC system is around 25 ns, the upgraded link board systems are expected to reach resolutions near 1 ns for the entire RPC system. This upgrade enables new analysis strategies at both the trigger and offline levels.

An HSCP trajectory is reconstructed as a slowly moving muon introducing the parameter β quantifying the (non)-relativistic velocity of the particle. The velocity may be computed by measuring the time of flight in the muon detectors at large distances from the collision point. Particles moving slowly through the muon systems leave hits with a linear pattern in hit-position versus time. The hits can be spread across several bunch crossings. Therefore, muon detectors with precise timing can provide important information for the HSCP signal searches.

Figure 4.3.2 (left) shows the achievable mass resolution for a supersymmetric $\tilde{\tau}$ lepton of 1.6 TeV mass. The resolution for the HSCP mass obtained for Phase-2 at the trigger level is comparable to that realised in Run-2 studies based on offline time-of-flight information from other muon detectors in CMS. The information provided by the RPC trigger can be used as an independent cross check of the reconstructed mass. Figure 4.3.2 (right) illustrates the expected reconstruction efficiency as a function of η and β. For $|\eta < 1.5|$, an efficiency of up to 90% can be reached for values of $\beta > 0.25$. In Run-2,

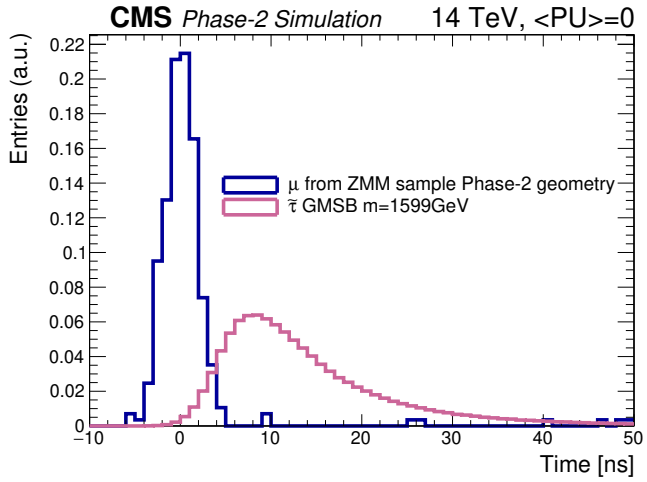

Fig. 4.3.1: Example of an RPC hit time measurement distribution for muons from the SM process $Z \to \mu\mu$ in comparison to events from semi-stable staus with a mass of about 1600 GeV, produced in $pp \to \tilde{\tau}\tilde{\tau}$ processes. The relativistic muons pass through the detector at the speed of light, hence their time of arrival is centred around zero. Decay products from the slowly moving staus arrive much later, for the given mass on average by 10 ns.

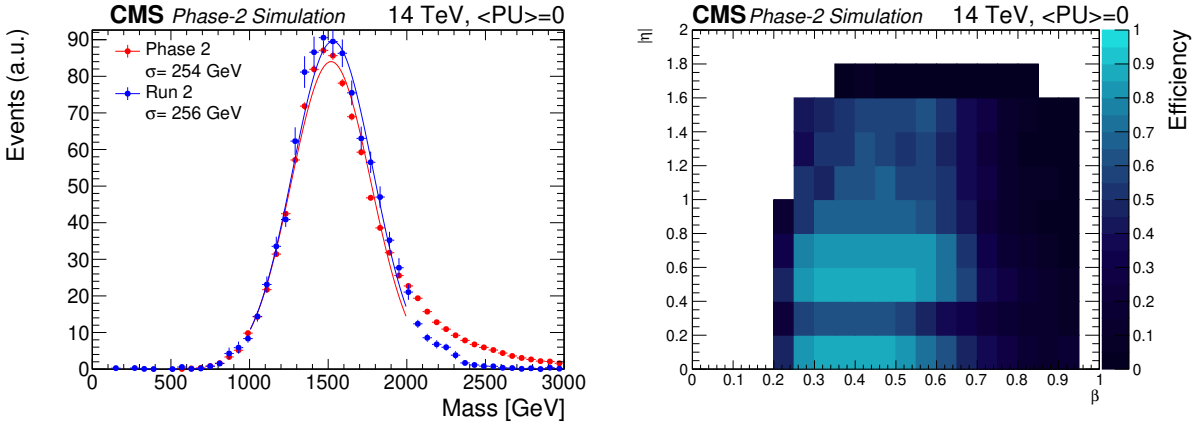

Fig. 4.3.2: Left: comparison of the mass resolution for a 1.6 TeV stau. In Run-2 the plotted resolution can only be achieved offline, while the upgraded RPC link-boards in Phase-2 provide a similar mass resolution already at the trigger level. Right: reconstruction efficiency for HSCPas a function of β and η given by the colour code of the z-axis. With the Phase-2 upgrade, events with $\beta < 0.5$ can be triggered with nearly 90% efficiency for $|\eta| < 0.8$.

the trigger is highly efficient between $0.6 < \beta < 1$, but only about 20% efficient for $\beta < 0.5$ [350, 351]. The large gain in efficiency for very slowly moving particles in Phase-2 enabled by the upgrade of the RPC trigger can be exploited in a model independent HSCP search.

4.3.2 Heavy stable charged particle search with energy loss

Contributors: J. Pazzini, J. Zobec, CMS

It may happen that the only signs of new physics are rather exotic signatures that cannot be detected with conventional analyses. An example for such a signature is the production of heavy stable charged particles with long lifetimes that move slowly through the detector, heavily ionising the sensor material as they pass through. The supersymmetric particles stau ($\tilde{\tau}$) and gluino ($\tilde{g}$) are possible examples. Often, the cross section for such processes is expected to be very small and hence the HL-LHC provides a good environment for searching for such particles. Depending on their mass and charge, we can expect anomalously high energy loss through ionisation ($\mathrm{d}E/\mathrm{d}x$) in the silicon sensors with respect

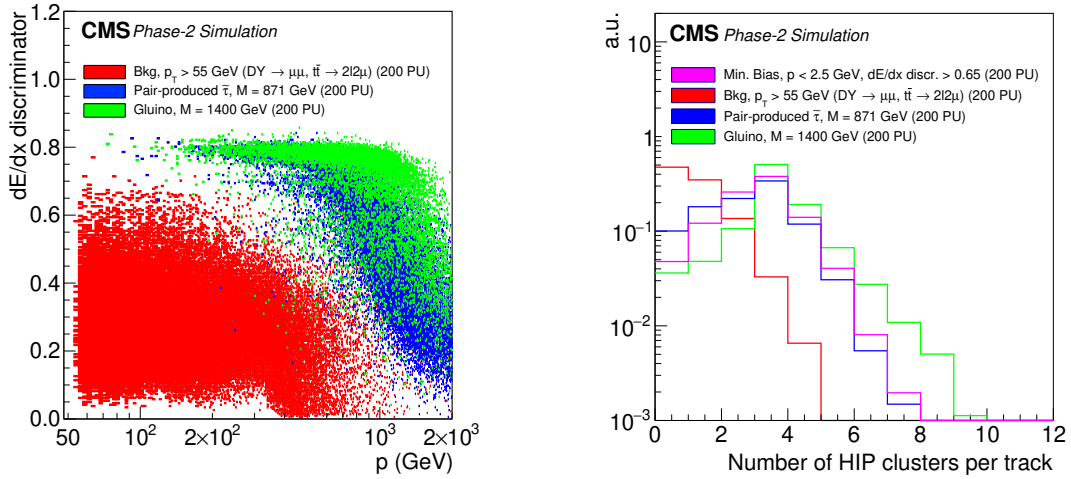

Fig. 4.3.3: Left: distribution of the $\mathrm{d}E/\mathrm{d}x$ discriminator versus track momentum (p) for tracks with high momentum ($p_T > 55$ GeV) in background events (red) and candidate signal particles. Pair produced $\tilde{\tau}$s with a mass of 871 GeV (blue), and a gluino with a mass of 1400 GeV (green), are shown. Right: the distribution of the number of high threshold clusters with HIP flag per track for the HSCP signals, gluinos (green) and $\tilde{\tau}$s (blue), highly ionising and low-momentum protons and kaons (magenta), and tracks with high momentum ($p_T > 55$ GeV) in background events (red).

to the typical energy loss for SM particles (≈ 3 MeV/cm for minimum ionising particles (MIPs) with $10 - 1000$ GeV momentum).

The present strip tracker in the CMS detector features analogue readout, and the pixel detector featured analogue readout at Phase-0 and features digital readout at Phase-1, allowing for excellent $\mathrm{d}E/\mathrm{d}x$ measurements. The Phase-2 CMS Inner Tracker will continue providing $\mathrm{d}E/\mathrm{d}x$ measurements, enabled by its Time over Threshold readout, while the Outer Tracker cannot provide such information, given that the readout is binary [352]. To increase the sensitivity for signatures with anomalously high ionisation loss, a second, programmable, threshold has been implemented in the readout electronics of some modules of the Outer Tracker, and a dedicated readout bit signals if a hit is above this second threshold [352]. Searches for heavy stable (or quasistable) charged particles (HSCPs) can thus be performed by measuring the energy loss in the Inner Tracker and by discriminating HSCPs from minimum ionising particles based on the "HIP flag" in the Outer Tracker. A threshold corresponding to the charge of 1.4 MIPs is used in the simulation, and the gain in sensitivity obtained by using the HIP flag is studied [352].

An estimator of the degree of compatibility of the track with the MIP hypothesis is defined to separate candidate HSCPs from tracks from SM background sources. The high resolution $\mathrm{d}E/\mathrm{d}x$ measurements provided by the Inner Tracker modules are used for the computation of the $\mathrm{d}E/\mathrm{d}x$ discriminator. In Fig. 4.3.3 (left) the distribution of $\mathrm{d}E/\mathrm{d}x$ versus track momentum (p) for high momentum tracks ($p_T > 55$ GeV) selected in background events and candidate signal particles is shown. Two HSCP signals, pair produced $\tilde{\tau}$s with a mass of 871 GeV and a gluino with a mass of 1400 GeV, are compared to tracks from SM processes. In Fig. 4.3.3 (right) the distribution of the number of high threshold clusters with HIP flag per track is shown for the HSCP signals (gluinos and $\tilde{\tau}$s) compared to signal-like highly ionising and low-momentum protons and kaons in simulated minimum bias samples and to tracks with high momentum ($p_T > 55$ GeV) in simulated background events. The tracks in background events have a low number of high threshold clusters with HIP flag compared to those observed for tracks in HSCP signal events and slow moving protons and kaons in minimum bias events.

Figure 4.3.4 shows the performance of the discriminator by evaluating the signal versus background efficiency curves to identify tracks from signal events and reject those originating from backgrounds. The performance curves are evaluated for two different strategies for the discriminator: the

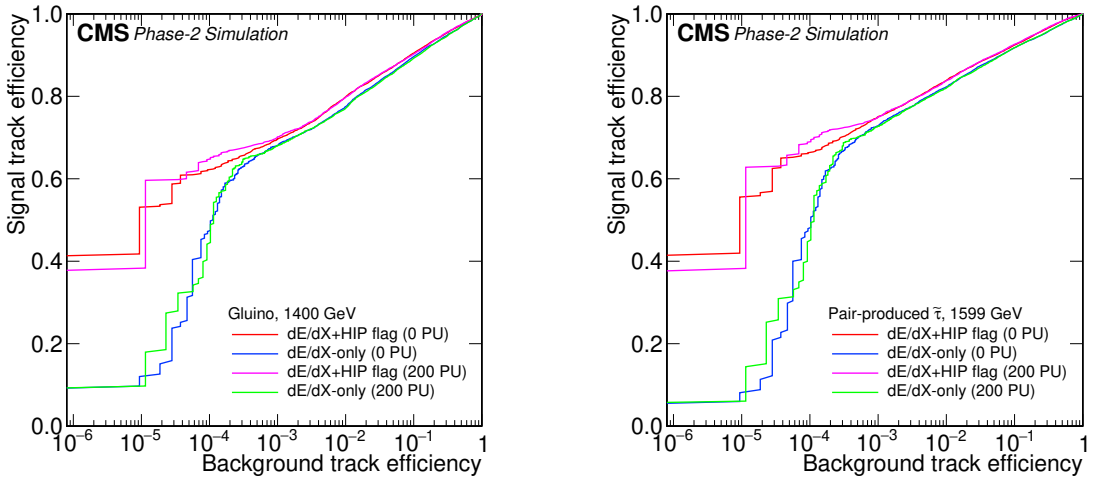

Fig. 4.3.4: Performance of the $\mathrm{d}E/\mathrm{d}x$ discriminator for selecting pair produced $\tilde{\tau}$s (left) and gluinos (right) in events with 0 PU and 200 PU. The signal versus background efficiency performance curves for a discriminator making use of both the pixel information and the Outer Tracker HIP flag (red and magenta) demonstrate a better performance compared to a discriminator trained to exploit only the $\mathrm{d}E/\mathrm{d}x$ information from the pixel modules (blue and green), for a background rejection of 10^{-6}.

original $\mathrm{d}E/\mathrm{d}x$ discriminator, which relies solely on the Inner Tracker modules ("$\mathrm{d}E/\mathrm{d}x$-only"), and a recomputed discriminator which includes the HIP flags from Outer Tracker modules ("$\mathrm{d}E/\mathrm{d}x$+HIP bit"). The signal versus background efficiency performance curves in Fig. 4.3.4 demonstrate that for a background efficiency of 10^{-6}, analogous to the Phase-1 analysis performance, the $\mathrm{d}E/\mathrm{d}x$+HIP-based discriminator leads to an expected signal efficiency of 40%, around 4 to 8 times better than the $\mathrm{d}E/\mathrm{d}x$-only discriminator. In the $\mathrm{d}E/\mathrm{d}x$-only scenario, the efficiency for the HSCP signal is about 8 times smaller than that obtained in Phase-1 [351] and about 64 times the Phase-1 luminosity would be required to reach the Phase-1 sensitivity, making this search almost untenable. The inclusion of the HIP flag for the Outer Tracker restores much of the efficiency, so that the same sensitivity as in Phase-1 will be realised with about four times the luminosity of Phase-1. The Phase-1 sensitivity will be surpassed with the full expected integrated luminosity of the HL-LHC. This study demonstrates the critical impact of the HIP flag in restoring the sensitivity of the CMS tracker for searches for highly ionising particles.

4.4 Additional examples of specialised techniques for LLP at HL-LHC

Two examples of specialised techniques relevant for LLPs are presented in this section. First, CMS illustrates the importance of precise timing detectors providing efficient measure the time of flight of LLPs between primary and secondary vertices. Second, ATLAS shows how jets arising from neutral LLPs decaying within the hadronic calorimeter can be characterised to efficiently reduce pile-up dependencies and therefore improve the sensitivity to new physics of this kind.

4.4.1 Fast timing signatures for long-lived particles

Contributors: D. del Re, A. Ledovskoy, C. Rogan, L. Soffi, CMS

A precision MIP timing detector (MTD) allows one to assign timing for each reconstructed vertex and to measure the time of flight of LLPs between primary and secondary vertices. This section presents studies from the CMS Collaboration from Ref. [353] exploring the potential of such techniques at the HL-LHC.

Using the measured displacement between primary and secondary vertices in space and time, the velocity of LLPs in the lab frame $\vec{\beta}_P^{LAB}$ (and γ_P) can be calculated. In such scenarios, the LLP can decay

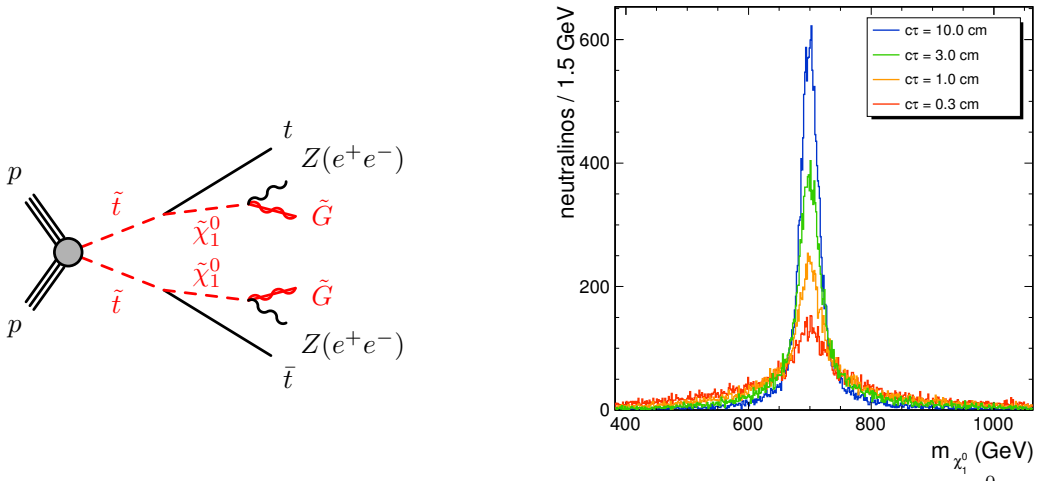

Fig. 4.4.1: Diagram for top-squark pair production and decay (left) and reconstructed mass of the $\tilde{\chi}_1^0$ (right) for decays with $M(\tilde{t}) = 1000$ GeV and $M(\tilde{\chi}_1^0) = 700$ GeV. Mass distributions are shown for various values of $c\tau$ of $\tilde{\chi}_1^0$.

to fully-visible or partially-invisible systems. Using the measured energy and momentum of the visible portion of the decay, E_P^{LAB} and $\vec{P}_P^{LAB}$, one can calculate its energy in the LLP rest frame as

$$E_V^P = \gamma_P \left(E_V^{LAB} - \vec{P}_V^{LAB} \cdot \vec{\beta}_V^{LAB} \right) = \frac{m_P^2 - m_I^2 + m_V^2}{2m_P}, \tag{4.4.1}$$

where m_P, m_V, and m_I are the masses of the LLP, the visible and the invisible systems, respectively. Assuming the mass of the invisible system is known, the subsequent mass of the LLP can be reconstructed as

$$m_P = E_V^P + \sqrt{E_V^{P\,2} + m_I^2 - m_V^2}. \tag{4.4.2}$$

The reconstruction of the decay vertex for neutral LLPs decaying to visible or partially-invisible decay products is enabled, thus offering unprecedented sensitivity in these searches at the LHC. The benefits of precision timing on such LLP searches is illustrated in two representative SUSY examples.

The first example is a gauge mediated SUSY breaking (GMSB) scenario where the $\tilde{\chi}_1^0$ couples to the gravitino $\tilde{G}$ via higher-dimension operators sensitive to the SUSY breaking scale. In such scenarios, the $\tilde{\chi}_1^0$ may have a long lifetime [354]. It is produced in top-squark pair production with $\tilde{t} \to t + \tilde{\chi}_1^0$, $\tilde{\chi}_1^0 \to Z + \tilde{G}$, and $Z \to e^+e^-$. The decay diagram is shown in Fig. 4.4.1 (left).

Events were generated with PYTHIA 8 [68]. The masses of the top-squark and neutralino were set to 1000 GeV and 700 GeV, respectively. Generator-level quantaties were smeared according to the expected experimental resolutions. A position resolution of 12 μm in each of three directions was assumed for the primary vertex [355]. The secondary vertex position for the e^+e^- pair was reconstructed assuming 30 μm track resolution in the transverse direction [355]. The momentum resolution for electrons was assumed to be 2%. And finally, the time resolution of a charged track at the vertex was assumed to be 30 ps.

The mass of the LLP was reconstructed with Eq.s (4.4.1) and (4.4.2) assuming the gravitino is massless by setting $m_I = 0$. Figure 4.4.1 (right) shows the distribution of the reconstructed mass of the neutralino for various $c\tau$ values of the LLP. The fraction of events with a separation between primary and secondary vertices of more than 3σ in both space and time as a function of MTD resolution is show in Fig. 4.4.2 (left). The mass resolution, defined as half of the shortest mass interval that contains 68% of events with 3σ displacement, as a function of MTD resolution is shown in Fig. 4.4.2 (right)

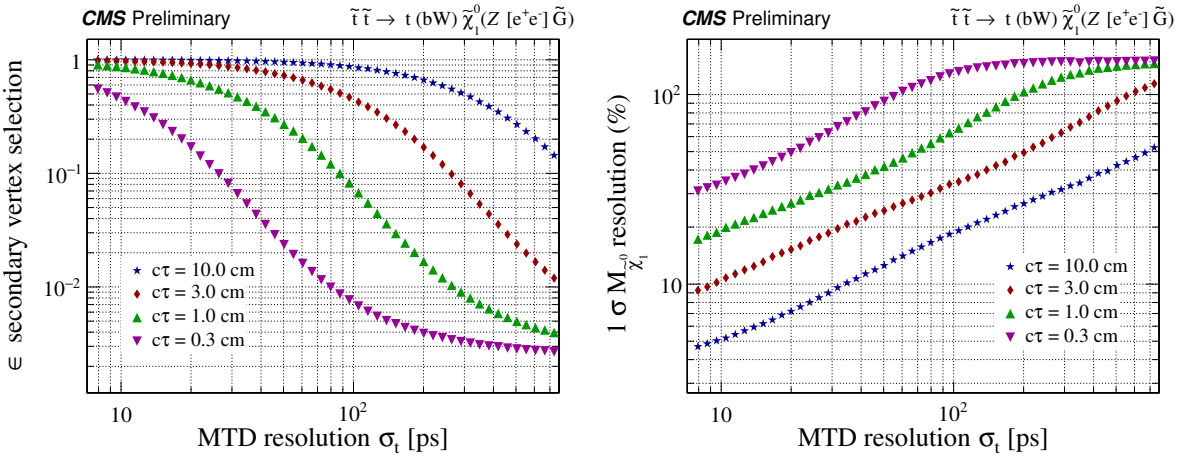

Fig. 4.4.2: Efficiency (left) and mass resolution (right) as a function of timing resolution of MTD for reconstruction of $\tilde{\chi}_1^0$ mass in SUSY GMSB example of $\tilde{\chi}_1^0 \rightarrow \tilde{G} + e^+e^-$ with $M(\tilde{\chi}_1^0) = 700$ GeV considering events with separation of primary and seconday vertices more than 3σ in both space and time.

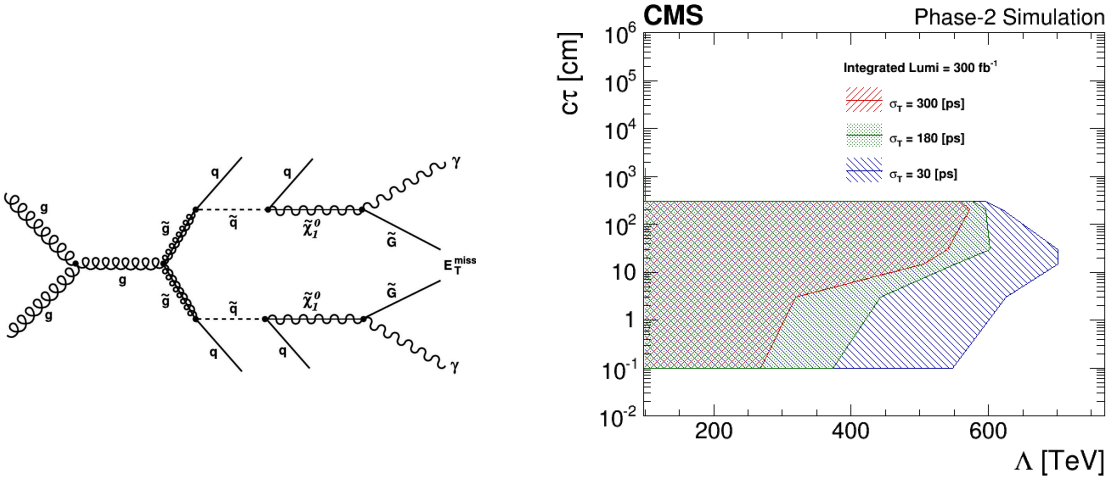

Fig. 4.4.3: Left: diagram for SUSY process that results in a diphoton final state through gluino production at the LHC. Right: sensitivity to GMSB $\tilde{\chi}_1^0 \rightarrow \tilde{G} + \gamma$ signals expressed in terms of neutralino lifetimes and masses assuming a timing detector with different values of resolution and an integrated luminosity of 300 fb^{-1}.

The second SUSY example is a GMSB benchmark scenario [346] where the lightest neutralino ($\tilde{\chi}_1^0$) is the next-to-lightest supersymmetric particle, and can be long-lived and decay to a photon and a gravitino ($\tilde{G}$), which is the LSP. Figure 4.4.3(left) shows a diagram of a possible gluino pair-production process that results in a diphoton final state.

For a long-lived neutralino, the photon from the $\tilde{\chi}_1^0 \rightarrow \tilde{G} + \gamma$ decay is produced at the $\tilde{\chi}_1^0$ decay vertex, at some distance from the beam line, and reaches the detector at a later time than the prompt, relativistic particles produced at the interaction point. The time of arrival of the photon at the detector can be used to discriminate signal from background. The time of flight of the photon inside the detector is the sum of the time of flight of the neutralino before its decay and the time of flight of the photon itself until it reaches the detector. Since the neutralino is a massive particle, the latter is clearly negligible with respect to the former. It becomes clear in this sense that in order to be sensitive to short neutralino lifetimes ($\mathcal{O}(\text{cm})$), the measurement of the photon time of flight is a crucial ingredient of the analysis. The excellent resolution of the MTD detector ($\mathcal{O}(30\ \text{ps})$) can therefore be exploited to determine with high accuracy the time of flight of the neutralino, and therefore of the photon, also in case of a short

lifetime.

A simple analysis has been performed at generator level in order to evaluate the sensitivity of a search for displaced photons at CMS in the scenario where a 30 ps timing resolution is available from the MTD. Events were generated with PYTHIA 8. The values of the Λ scale parameter were considered in the range $100 - 500$ TeV, and the neutralino lifetimes ($c\tau$) explored in the range $0.1 - 300$ cm. After requiring the neutralino decaying within the CMS ECAL acceptance and the photon energy being above a "trigger-like" threshold, the generator-level photon time of flight was smeared according to the expected experimental resolutions. A cut at photon time greater than 3σ of the considered time resolution is applied and the assumption of background being zero in this "signal region" is made. The signal efficiency of such a requirement is computed and translated, assuming the theoretical cross-sections provided in Ref. [346], in an upper limit at 95% C.L. of C.L. on the production cross-section of the $\tilde{\chi}_1^0 \to \tilde{G} + \gamma$ process.

Assuming a timing resolution of the order of 300 ps, (thus requiring photon time greater than 1 ns) close to the Run1 CMS performance [356], the analysis sensitivity in terms of neutralino mass and lifetime is computed and shown in Fig. 4.4.3 (right) for a reference luminosity of 300 fb^{-1}, along with comparisons with improved timing resolution. For the hypothesis of $\sigma_T = 180$ ps a timing cut is applied at 450 ps and for the $\sigma_T = 30$ ps the timing is required to be larger than 100 ps at selection level. As shown in the figure, the increase of the signal efficiency at small lifetime, made possible with the precise MTD, allows to extend the sensitivity region in the explored phase space of short lifetime and large masses of the neutralino.

4.4.2 Jets reconstruction techniques for neutral LLPs

Contributors: S. Pagan Griso, R. Rosten, ATLAS

Traditional methods may fail to reconstruct, or may improperly reconstruct, objects associated with LLP decays. Searches for LLPs that are neutral under the SM gauge group might be targeted exploiting hadronic calorimeters. The techniques developed are described in the following, for more details see Ref. [357].

Jets resulting from neutral LLPs decaying within the hadronic calorimeter have several properties that are uncommon in jets originating at the interaction point. Within the inner detector, they naturally lack associated tracks. They likewise lack associated energy deposits in the electromagnetic calorimeter. Furthermore, the reconstructed jets are narrower than for a similar shower originating at the interaction point (IP) due to large displacement of the decay vertex. These properties, as well as those of the jet's constituents, can be used to discriminate between jets from displaced decays and those originating from the IP. On the other hand, the reconstructed jets are similar to those associated with non-collision backgrounds (NCB). Standard jet cleaning tools tend to reject jets resembling those associated with NCB, which is a primary reason the vast majority of non-LLP-dedicated jet searches will miss this signature, while the searches for an LLP would require a dedicated jet quality selection.

The unusual signature of neutral LLP decays within the hadronic calorimeter encourages the use of dedicated triggers. At Level-1, the narrowness of the jets allows tau-candidates to be used to keep the energy threshold low while avoiding prescaling. In the higher level trigger, the low electromagnetic fraction and lack of pointing tracks can be further used to reject most jets. However, rates due to NCB, particularly beam-induced background (BIB), necessitate the use of a dedicated BIB-removal algorithm to keep rates acceptably low.

At Level-1, these dedicated triggers have benefited from the use of the Level-1 topological triggers. These have allowed for a cut on a rough estimate of the electromagnetic fraction to be applied at Level-1, allowing for the energy threshold to remain lower even as the lowest energy unprescaled Level-1 tau trigger gets pushed to higher and higher thresholds. Keeping this rate down at higher pile-up will be crucial to gathering high-statistics, high-purity samples for offline analysis. The increased longitudinal

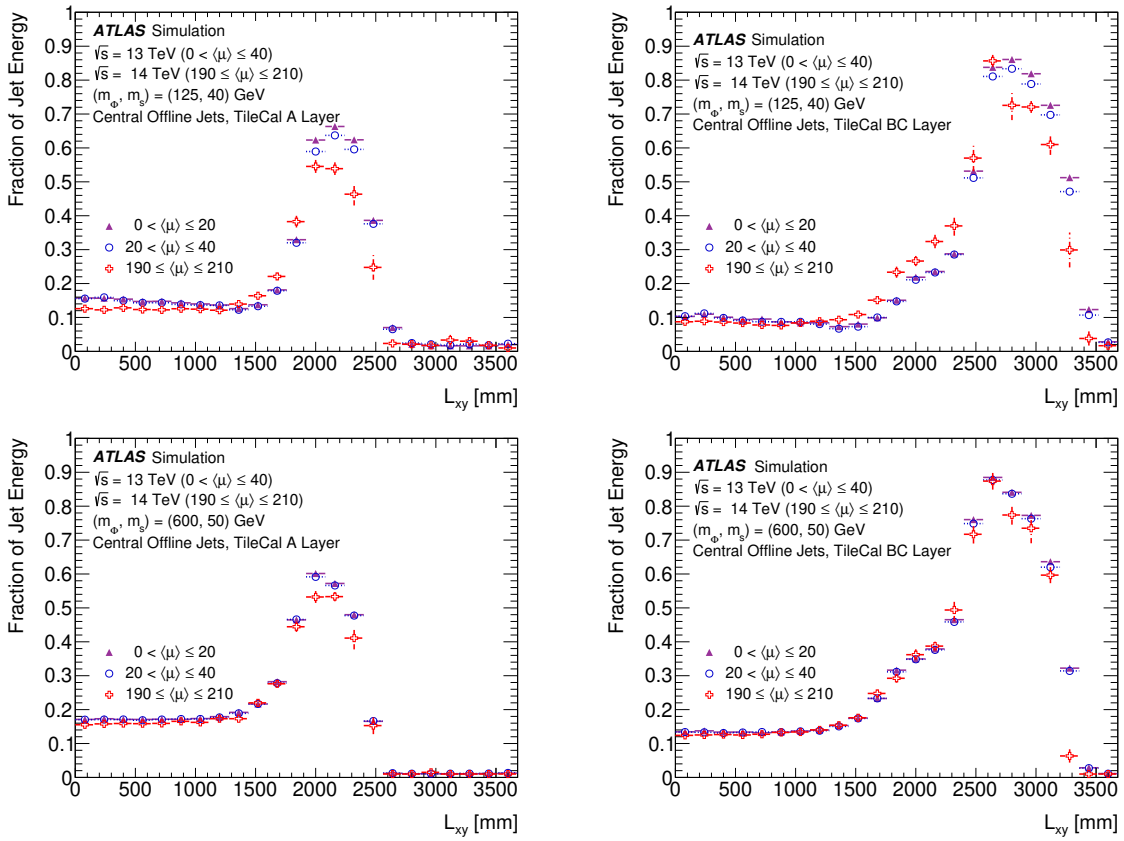

Fig. 4.4.4: Top: fraction of the jet energy deposited in A-layer (left) and BC-layer (right) of the Tile as a function of the transverse decay position of the LLP in events with a 125 GeV Higgs boson decaying to two 25 GeV LLPs. Bottom: same for events with a 600 GeV boson decaying to two 150 GeV LLPs.

Level-1 granularity in Phase-II is especially promising for such a trigger. It may allow for a quick assessment of the energy deposited per layer in a jet, which has already been found to be a good discriminator offline for LLP jets.

Pile-up presents challenges for LLP searches at the analysis level as well. Soft energy deposits in the electromagnetic calorimeter in line with energy deposits from a neutral LLP result in jets with a higher than allowed fraction of their energy in the electromagnetic calorimeter. An alternative to using this coarse fraction is to consider the energy deposited per layer.

The model used in the generation of LLP signatures is a simplified hidden-sector toy model with a sector, containing particles neutral under the SM gauge group, weakly coupled to the SM sector. Interactions between sectors may occur via a communicator particle. Due to the weak coupling between sectors, the lifetime of these particles can be long. The process here is one in which a scalar boson, ϕ, which is also the communicator, is produced during the pp collision in ATLAS and decays to a pair of hidden sector particles s. Each LLP s, in turn, decays with long lifetimes via the communicator to heavy SM states. Heavy states are preferred due to the Yukawa coupling to the ϕ boson.

Figures 4.4.4 show some examples of the fraction of total jet energy at the EM-scale deposited by the LLPs produced within the $|\eta| < 0.7$ rapidity range in the given layer for different slices of the average μ as a function of the LLP transverse decay position L_{xy}. For lighter pairs of LLPs, s and their parent particle ϕ, the effects of increasing pile-up are small, but possibly not negligible. This may motivate the introduction of multivariate analysis (MVA) technique for identifying jets consistent with displaced LLP decays. Such an MVA can be in the form of a regression that attempts to identify the decay position of the jet-initiation particle. It can be made directly pile-up-aware by including pile-up as one of its

training variables. However, as long as the MVA is given the fraction of energy in the electromagnetic calorimeter, where most of the pile-up energy will be deposited, it is expected to be able to distinguish between jets initiated by decays at the same position under different pile-up conditions.

5 High-p_T signatures from flavour

Flavour physics is often considered one of the most sensitive probes of new physics, which, depending on observable and model, can constrain new physics at scales of $1 - 10^5$ TeV. Many of the observables are associated with precision measurements at the intensity frontier. This is well documented in the flavour chapter of this report, Ref. [31]. Any small deviations in precision low energy measurements, could signal the presence of new particles in the TeV scale, whose effect, once integrated out, is to alter precision low energy observables. Thus, in tandem with low energy flavour observables, it is important to identify the high-p_T probes of flavour physics, relating direct tests with the indirect flavour probes.

Similar arguments hold for neutrino physics, where the generation of neutrino masses through the seesaw mechanism may generate a large variety of collider signatures, such as new resonances and cascade decays involving multiple leptons. In this section we first discuss the implication of neutrino mass models involving new heavy gauge bosons and sterile neutrinos, see Section 5.1. We then focus in Section 5.2 on constraints on models of Z' and leptoquarks related to B-decay flavour anomalies, and leptoquarks decaying to top and tau. Finally, in Section 5.3, we present a summary of the implications of these high-p_T prospects on the parameter space of various UV models addressing the aforementioned anomalies. Notice that part of the material included in this section is also contained in the flavour chapter of this report [31].

5.1 Neutrino masses

The potential Majorana nature of neutrinos as well as the origin of their tiny masses and large mixing angles remain some of the most pressing open issues in particle physics today. Models that address these mysteries, collective known as Seesaw models, hypothesise the presence of new particles that couple to SM fields via mixing/Yukawa couplings, SM gauge currents, and/or new gauge symmetries. The new predicted particles, often right-handed sterile neutrinos, can explain the generation of neutrino masses via a low-scale seesaw mechanism. Mixing between the active and sterile neutrinos is strongly constrained by precision measurements [358]. At the LHC, searches in purely leptonic final states have started probing masses below m_Z [359]. On the other hand, a plethora of rich physics can be studied in considerable detail at hadron colliders, and greatly complement low energy and oscillation probes of neutrinos [360,361]. Other complementary and promising searches for the low-scale seesaw neutrinos could be achievable also at future ep colliders studying lepton-flavour violating processes, *e.g.* $e^- p \to \mu^- W + j$. In this case, the leading production of heavy neutrinos depends on the mixing with the electron flavour, in contrast to production in pp collisions, where it is proportional to the total mixing. This allows us to infer the relative strength of the mixings, especially if a hierarchy is present. For more details, including comparison with ee and pp colliders, see Ref. [362].

In the following, a comprehensive summary of the discovery potential of Seesaw models at hadron colliders with collision energies of $\sqrt{s} = 14$ and 27 TeV is presented in Section 5.1.1. Heavy composite Majorana neutrinos are studied in Section 5.1.2 using same-sign leptons signatures, and using dilepton and jets signatures in Section 5.1.3.

5.1.1 Neutrino mass models at the HL- and HE-LHC

Contributors: T. Han, T. Li, X. Marcano, S. Pascoli, R. Ruiz, C. Weiland

We summarise the discovery potential of seesaw models at hadron colliders with collision energies of $\sqrt{s} = 14$ and 27 TeV. In particular, we will discuss models featuring heavy neutrinos, both pseudo-Dirac and Majorana as well as those with new gauge interaction, and models featuring scalar and fermion EW triplets. For a more comprehensive reviews on the sensitivity of colliders to neutrino mass models, see Ref.s [360, 361, 363–365] and references therein.

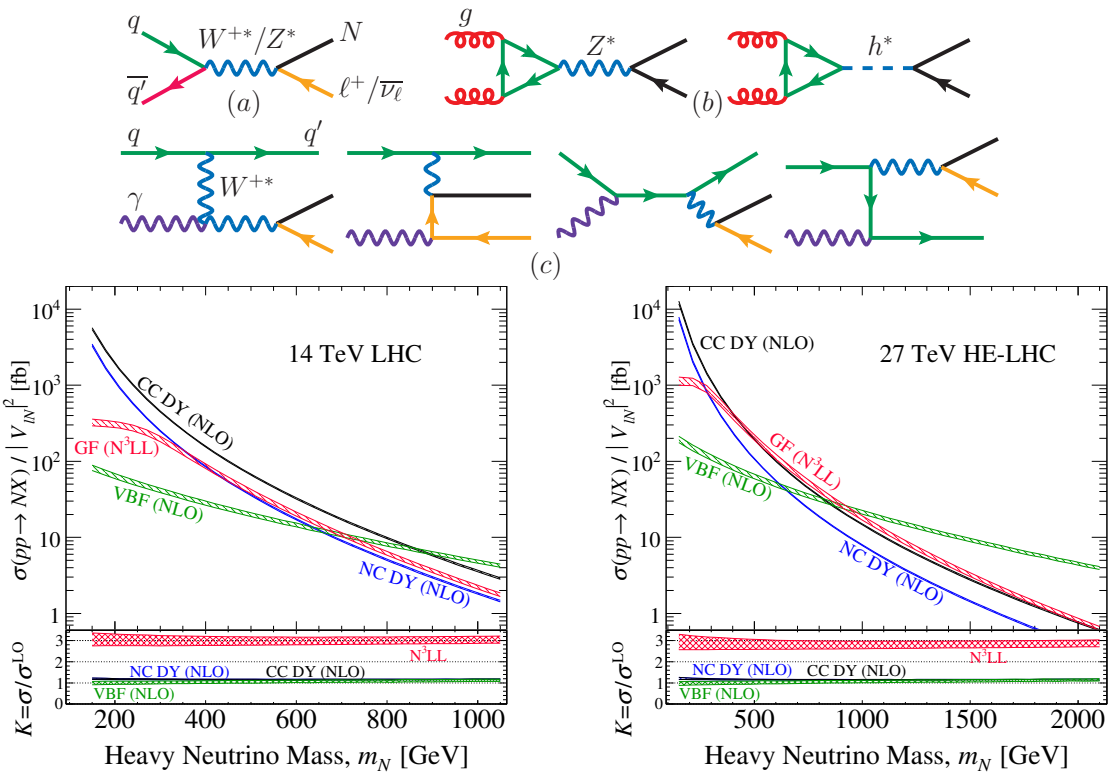

Fig. 5.1.1: Top: Born-level diagrams for heavy neutrino N production via (a) Drell-Yan, (b) gluon fusion, and (c) vector boson fusion; from Ref. [368]. Bottom: production cross sections, divided by active-heavy mixing $|V_{\ell N}|^2$, as a function of the heavy neutrino mass at $\sqrt{s} = 14$ TeV (left) and 27 TeV (right) [368, 369].

The Type I seesaw and Variants Discovery Potential at the HL- and HE-LHC

The Type I seesaw hypothesises the existence of fermionic gauge singlets with a Majorana mass term whose couplings to SM leptons generate light neutrino masses and mixing. In Ref.s [366, 367], it was proved that requiring all three light neutrinos to be massless is equivalent to the conservation of lepton number at all orders in perturbation theory. In other words, for low-scale seesaw models with only fermionic singlets, lepton number has to be nearly conserved and light neutrino masses are proportional to small lepton number violation (LNV) parameters in these models. For high-scale seesaws with only fermionic singlets, light neutrino masses are inversely proportional to large LNV mass scales, and again leads to approximate lepton number conservation at low energies. This in turn leads to the expectation that LNV processes should be suppressed in variants of the type I seesaw unless additional particles, whether they be fermions or scalars charged under the SM gauge couplings or new gauge interactions, are introduced to decouple the light neutrino mass generation from the heavy neutrino production. The updated discovery potential of heavy, SM singlet neutrinos at pp colliders is now summarised.

Heavy Neutrino Production through EW Bosons at Hadron Colliders

If kinematically accessible, heavy neutrinos N can generically be produced in hadron collisions through both neutral current and charged current processes, as shown in Fig. 5.1.1 (top). Following the prescriptions of Ref.s [368, 369], for $m_N > M_W$ and at various accuracies, the corresponding $\sqrt{s} = 14$ TeV heavy neutrino production cross sections are presented in Fig. 5.1.1 (bottom left). While the Drell-Yan (DY) process dominates at low masses, $W\gamma$ boson fusion (VBF) dominates for $m_N \gtrsim 900 - 1000$ GeV [368, 370], with gluon fusion (GF) remaining a sub-leading channel throughout [368, 371]. The situation is quite different at 27 TeV as shown in Fig. 5.1.1 (bottom right). Indeed, GF is the leading production mode for $m_N \gtrsim 450$ GeV until $m_N \approx 940$ GeV where VBF takes over.

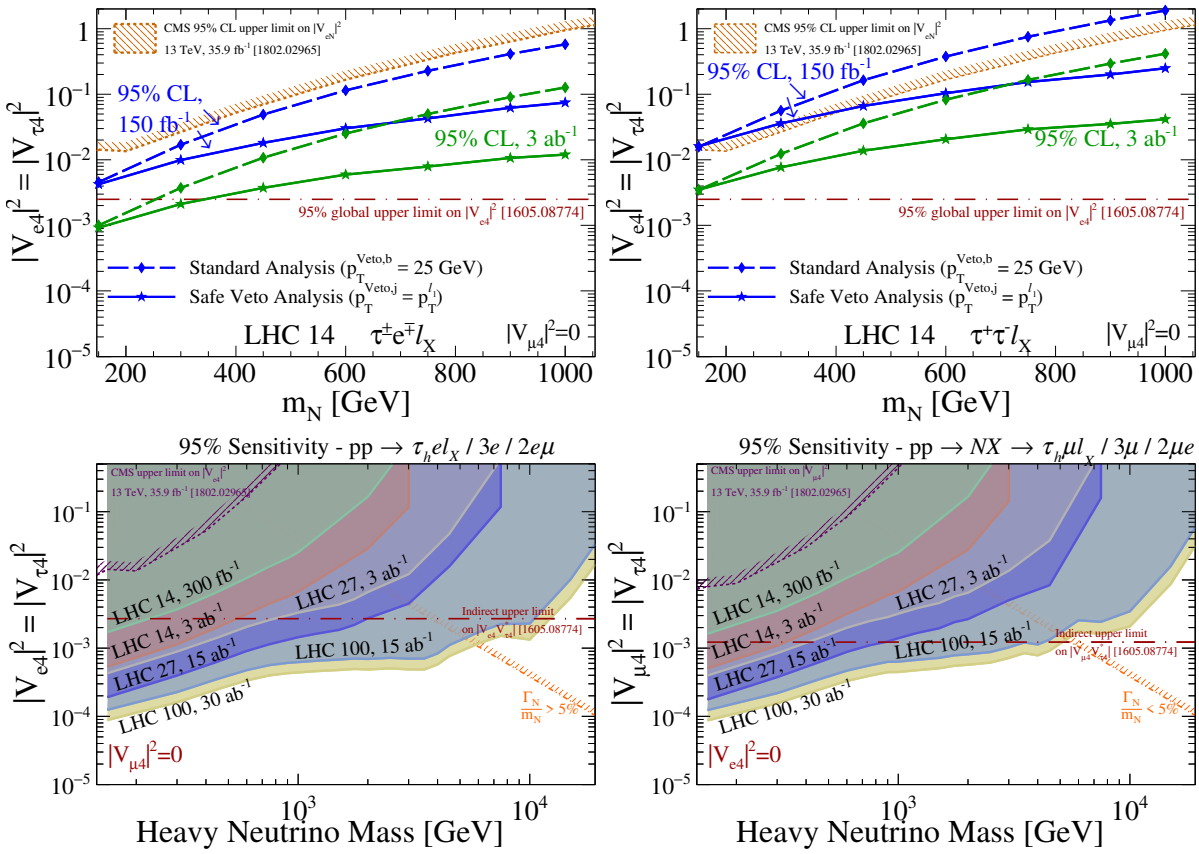

Fig. 5.1.2: Top: sensitivity to the active-heavy mixing $|V_{\ell N}|^2$ as a function of the heavy neutrino mass m_N in the trilepton final states (left) $\tau_h^\pm e^\mp \ell_X + \text{MET}$ and (right) $\tau_h^+ \tau_h^- \ell_X + \text{MET}$, assuming $|V_{e4}|^2 = |V_{\tau 4}|^2$ and $|V_{\mu 4}|^2 = 0$, at the $\sqrt{s} = 14$ TeV LHC. The dash-diamond line corresponds to the standard analysis with a b-jet veto while the solid-star line is the jet veto-based analysis [372, 373]. Bottom: for the benchmark mixing hypotheses (left) $|V_{e4}| = |V_{\tau 4}|$ with $|V_{\mu 4}| = 0$ and (right) $|V_{\mu 4}| = |V_{\tau 4}|$ with $|V_{e4}| = 0$, the projected sensitivity at $\sqrt{s} = 27$ TeV and 100 TeV using the trilepton analysis of Ref. [372].

For $m_N \approx 1$ TeV, the GF, DY, and VBF mechanisms all possess fiducial cross sections in excess of 10 fb.

Discovery Potential of Heavy Pseudo-Dirac Neutrinos in Low Scale Seesaws

The expected suppression of LNV processes in models that contain only fermionic gauge singlets motivates the study of lepton number conserving (LNC) processes. A first possibility to consider is the trilepton final state $\ell_i^\pm \ell_j^\mp \ell_k^\pm + \text{MET}$. The heavy neutrino N here is produced via both charged-current DY and VBF, and subsequently decays to only leptons, *i.e.*

$$pp \to \ell_N N + X \to \ell_N \ell_W W + X \to \ell_N \ell_W \ell_\nu \nu + X \,. \tag{5.1.1}$$

Notably, a new search strategy was recently proposed in Ref. [372, 373] based on a dynamical jet veto selection cut and found an increased sensitivity to active-heavy neutrino mixing by approximately an order of magnitude over the LHC's life. This is shown in Fig. 5.1.2 (top) specifically for the final states (L) $\tau_h^\pm e^\mp \ell_X + \text{MET}$ and (R) $\tau_h^+ \tau_h^- \ell_X + \text{MET}$, where τ_h represents a hadronically decaying τ and $\ell_X \in \{e, \mu, \tau_h\}$. With $3\,\text{ab}^{-1}$ and after taking into account global constraints on the active-heavy mixing [374] (dot-dashed line in Fig. 5.1.2 (top)), the HL-LHC is able to probe heavy neutrino masses up to 350 GeV and mixing down to $|V_{\ell N}|^2 \simeq 10^{-3}$ could be probed. For the benchmark mixing hypotheses (L) $|V_{e4}| = |V_{\tau 4}|$ with $|V_{\mu 4}| = 0$ and (R) $|V_{\mu 4}| = |V_{\tau 4}|$ with $|V_{e4}| = 0$, Fig. 5.1.2 (bottom) shows

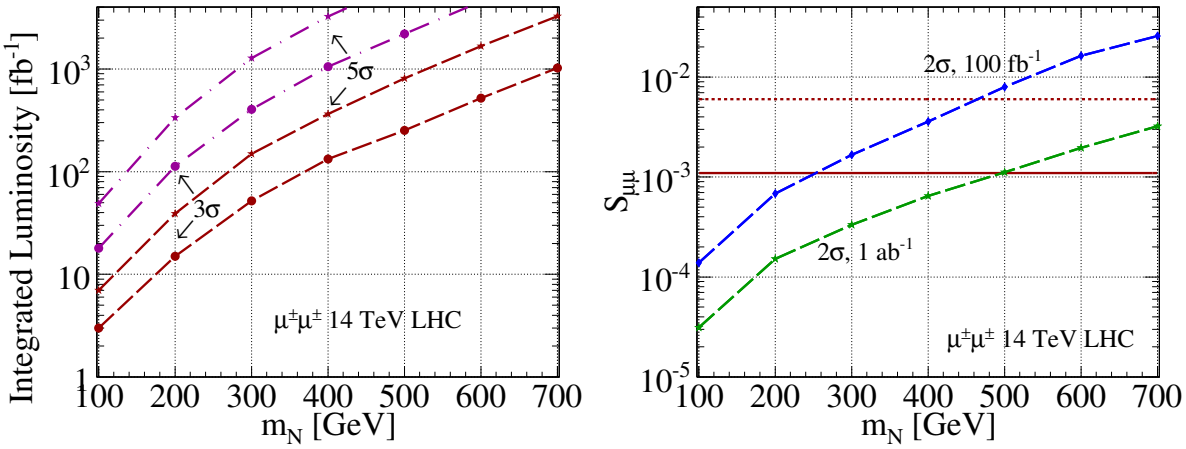

Fig. 5.1.3: Left: using the LNV final state $\mu^\pm\mu^\pm jj$, required luminosity for $3(5)\sigma$ evidence (discovery) as a function of heavy neutrino mass m_N assuming optimistic (brown) and pessimistic (purple) mixing scenarios [370]. Right: sensitivity to $N-\mu$ mixing [370] with the optimistic (pessimistic) mixing scenario is given by the horizontal dashed (full) line.

the projected sensitivity of this analysis at $\sqrt{s} = 27$ TeV and 100 TeV using the trilepton analysis of Ref. [372].

Another possibility is to search for lepton flavour violating (LFV) final states such as

$$q\,\overline{q'} \to N\,\ell_1^\pm \to \ell_1^\pm\,\ell_2^\mp\,W^\mp \to \ell_1^\pm\,\ell_2^\mp\,j\,j\,, \tag{5.1.2}$$

which was for example studied in the inverse seesaw (ISS), a low-scale variant of the type I, in Ref. [375]. Due to the strong experimental limits on $\mu \to e\gamma$ by MEG [376], the event rates involving taus are more promising than those for $e^\pm\mu^\mp jj$. Following Ref. [375], the number of $\tau^\pm\mu^\mp jj$ can be estimated using the μ_X-parametrisation [377] with the neutrino Yukawa coupling

$$Y_\nu = f \begin{pmatrix} -1 & 1 & 0 \\ 1 & 1 & 0.9 \\ 1 & 1 & 1 \end{pmatrix}. \tag{5.1.3}$$

as a representative example, and considering that only the lightest pseudo-Dirac pair is kinematically available. After $\mathcal{L} = 3(15)\ \mathrm{ab}^{-1}$, more than 100(500) LFV $\tau^\pm e^\mp jj$ events can be produced for heavy neutrino masses below 700 (1000) GeV, for pp collisions at $\sqrt{s} = 14(27)$ TeV.

Discovery Potential of Heavy Majorana Neutrinos in Phenomenological Type I Seesaw

In the presence of additional particles that can decouple the heavy neutrino production from the light neutrino mass generation, *e.g.*, new but far off-shell gauge bosons [378], the Majorana nature of the heavy neutrinos can leads to striking LNV collider signatures, such as the well-studied same-sign dilepton and jets process [379]

$$pp \to N\,\ell_1^\pm \to \ell_1^\pm\,\ell_2^\pm\,W^\mp \to \ell_1^\pm\,\ell_2^\pm + nj. \tag{5.1.4}$$

Assuming that a low-scale type I seesaw is responsible for the heavy neutrino production, Fig. 5.1.3 displays the discovery potential and active-heavy mixing sensitivity of the $\mu^\pm\mu^\pm$ channel [370]. Assuming the (pessimistic/conservative) mixing scenario of $S_{\mu\mu} = 1.1 \times 10^{-3}$ [370] the HL-LHC with $3\ \mathrm{ab}^{-1}$ is able to discover a heavy neutrino with a mass of $m_N \simeq 400$ GeV and is sensitive to masses up to 550 GeV at 3σ. Using only $1\ \mathrm{ab}^{-1}$, the HL-LHC can improve on the preexisting mixing constraints summarised in the pessimistic scenario for neutrino masses up to 500 GeV.

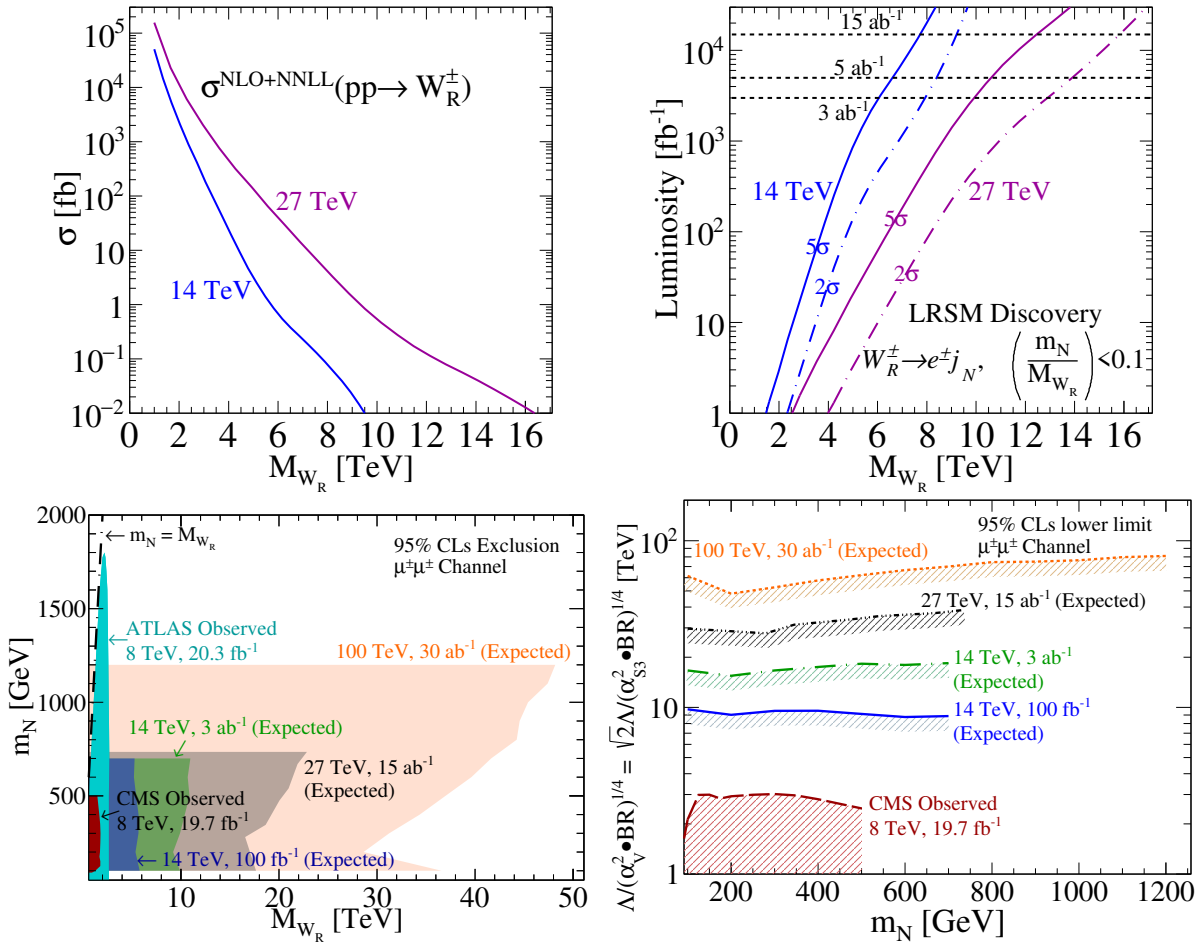

Fig. 5.1.4: Top: the total $pp \to W_R$ cross section at NLO+NNLL(Threshold) (left) and $5(2)\sigma$ discovery potential (sensitivity) via W_R decays to an electron and neutrino jet (j_N) (right), as a function of W_R mass and at $\sqrt{s} = 14$ and 27 TeV [380]. Bottom: observed and expected sensitivity to heavy Majorana neutrinos through the process $pp \to \mu^{\pm} N \to 2\mu^{\pm} + 2j$ and produced via non-resonant W_R (left) as well as dimension-six NEFT operators [378] (right).

Heavy Neutrinos and the Left-Right Symmetric Model at Colliders

The Left-Right Symmetric Model (LRSM) remains one of the best motivated high-energy completions of the SM. It addresses the origin of both tiny neutrino masses via a Type I+II seesaw hybrid mechanism as well as the SM's $V-A$ chiral structure through the spontaneous breakdown of an $SU(2)_L \otimes SU(2)_R$ symmetry, amongst other low-energy phenomena. At collider scales, the model predicts the presence of new heavy gauge bosons that are closely aligned with their gauge states $(W_R^{\pm},\ Z_R')$, heavy Majorana neutrinos (N), and a plethora of neutral and electrically charged scalars $(H_i^0,\ H_j^{\pm},\ H_k^{\pm\pm})$. Unlike $U(1)_{BL}$ neutrino mass models, the LRSM gauge couplings are fixed to the SM Weak coupling constant, up to (small) RG-running corrections. As a result, the Drell-Yan production mechanisms for W_R and Z_R result in large rates at hadron colliders. Following the procedure of Ref. [380], the $pp \to W_R^{\pm}$ cross section at NLO+NNLL(Threshold) is shown in Fig. 5.1.4 (top left) as a function of mass M_{W_R} at $\sqrt{s} = 14$ and 27 TeV. At $\sqrt{s} = 14(27)$ TeV, one sees that production cross sections for masses as large as $M_{W_R} \approx 5.5(9)$ TeV are in excess of 1 fb. For $M_{W_R} \approx 7.5(12.5)$ TeV, rates exceed 100 ab, and indicate $\mathcal{O}(10^2 - 10^3)$ events can be collected with $\mathcal{L} = 1 - 15\ \text{ab}^{-1}$ of data. Such computations up to NLO in QCD with parton shower matching, including for more generic coupling, are also publicly available following Ref.s [381, 382].

Of the many collider predictions the LRSM, one of its most promising discovery channels is

the production of heavy Majorana neutrinos from resonant W_R currents with N decaying via a lepton number-violating final state. At the partonic level, this is given by [379]

$$q_1\overline{q_2} \to W_R \to N\,\ell_i^{\pm} \to \ell_i^{\pm}\ell_j^{\pm}W_R^{\mp *} \to \ell_i^{\pm}\ell_j^{\pm}q_1'\overline{q_2'} \tag{5.1.5}$$

and has been extensively studied throughout the literature. For details; see Ref. [361] and references therein. Due to the ability to fully reconstruct Eq. (5.1.5), many properties of W_R and N can be extracted, including a complete determination of W_R chiral couplings to quarks independent of leptons [383]. Beyond the canonical $pp \to W_R \to N\ell \to 2\ell + 2j$ channel, it may be the case that the heavy neutrino is hierarchically lighter than the right-handed (RH) gauge bosons. Notably, for $(m_N/M_{W_R}) \lesssim 0.1$, N is sufficiently Lorentz boosted that its decay products, particularly the charged lepton, are too collimated to be resolved experimentally [380, 384]. Instead, one can consider the $(\ell_j^{\pm}q_1'\overline{q_2'})$-system as a single object, a *neutrino jet* [380, 381]. The hadronic process is then

$$pp \to W_R \to N\ell_i^{\pm} \to j_N\,\ell_i^{\pm}, \tag{5.1.6}$$

and inherits much of the desired properties of Eq. (5.1.5), such as the simultaneous presence of high-p_T charged leptons and lack of MET [380, 381], resulting in a very strong discovery potential. Assuming conservative detector efficiency (ε) and selection acceptance $(\mathcal{A})$ rates of $(\varepsilon, \mathcal{A}) \approx (0.33, 0.64)$ based on the realistic analysis of Ref. [380], and a branching fraction of $\mathcal{B}(W_R \to Ne \to eeq\overline{q'}) \approx 10\%$ for $(m_N/M_{W_R}) < 0.1$. Figure 5.1.4 (top right) shows the requisite integrated luminosity for $5(2)\sigma$ discovery of Eq. (5.1.6) at $\sqrt{s} = 14$ and 27 TeV. With $\mathcal{L} = 3(5)$ ab^{-1}, W_R as heavy as 6(6.5) TeV and 10(10.5) TeV, respectively, can be discovered at $\sqrt{s} = 14$ (27) TeV. With $\mathcal{L} = 15$ ab^{-1}, mass scales as heavy 16 TeV can be probed at the 2σ level at $\sqrt{s} = 27$ TeV.

For such heavy W_R and Z_R that may be kinematically outside the reach of the $\sqrt{s} = 14$ TeV LHC, one can still produce EW- and sub-TeV scale via off-shell W_R and Z_R bosons [378]. As a result, the $pp \to W_R^* \to N\ell \to 2\ell + 2j$ process occurs instead at a hard scale $Q \sim m_N$ and cannot be distinguished from the phenomenological Type I seesaw without a detailed analysis of the heavy neutrino's chiral couplings [378, 383]. However, this also means that searches for heavy N in the context of the phenomenological Type I can be recast/reinterpreted in the context of the LRSM. Subsequently, as shown in Fig. 5.1.4 (bottom left), W_R as heavy as $8-9$ TeV can be probed indirectly with $\mathcal{L} = 1$ ab^{-1} at $\sqrt{s} = 14$ TeV [378]. A similar argument can be applied to heavy neutrinos produced through dimension-six Heavy Neutrino Effective Field Theory (NEFT) operators, revealing sensitivity to mass scales up to $\Lambda \sim \mathcal{O}(10)$ TeV over the $\sqrt{s} = 14$ TeV LHC's lifetime [378], as shown in Fig. 5.1.4 (bottom right).

Type II Scalars Discovery Potential at the HL- and HE-LHC

The Type II seesaw hypothesises the existence of a new scalar $\mathrm{SU}(2)_L$ triplet that couples to SM leptons in order to reproduce the light neutrino mass spectrum and oscillation data. This is done by the spontaneous generation of a left handed Majorana mass for the light neutrinos. Moreover, the Type II scenario is notable for the absence of sterile neutrinos, demonstrating that light neutrino masses themselves do not imply the existence of additional fermions. The most appealing production mechanisms at hadron colliders of triplet Higgs bosons are the pair production of doubly charged Higgs and the associated production of doubly charged Higgs and singly charged Higgs,

$$pp \to Z^*/\gamma^* \to H^{++}H^{--}, \quad pp \to W^* \to H^{\pm\pm}H^{\mp}. \tag{5.1.7}$$

followed, in the most general situation, by lepton flavour- and lepton number-violating decays to SM charged leptons. In Fig. 5.1.5 (top left), we show the total cross section of the $pp \to H^{++}H^{--}$ and $pp \to H^{\pm\pm}H^{\mp}$ processes as a function of triplet mass (in the degenerate limit with $M_{H^{\pm}} = M_{H^{\pm\pm}}$), in collisions at $\sqrt{s} = 14$, 27, and 100 TeV.

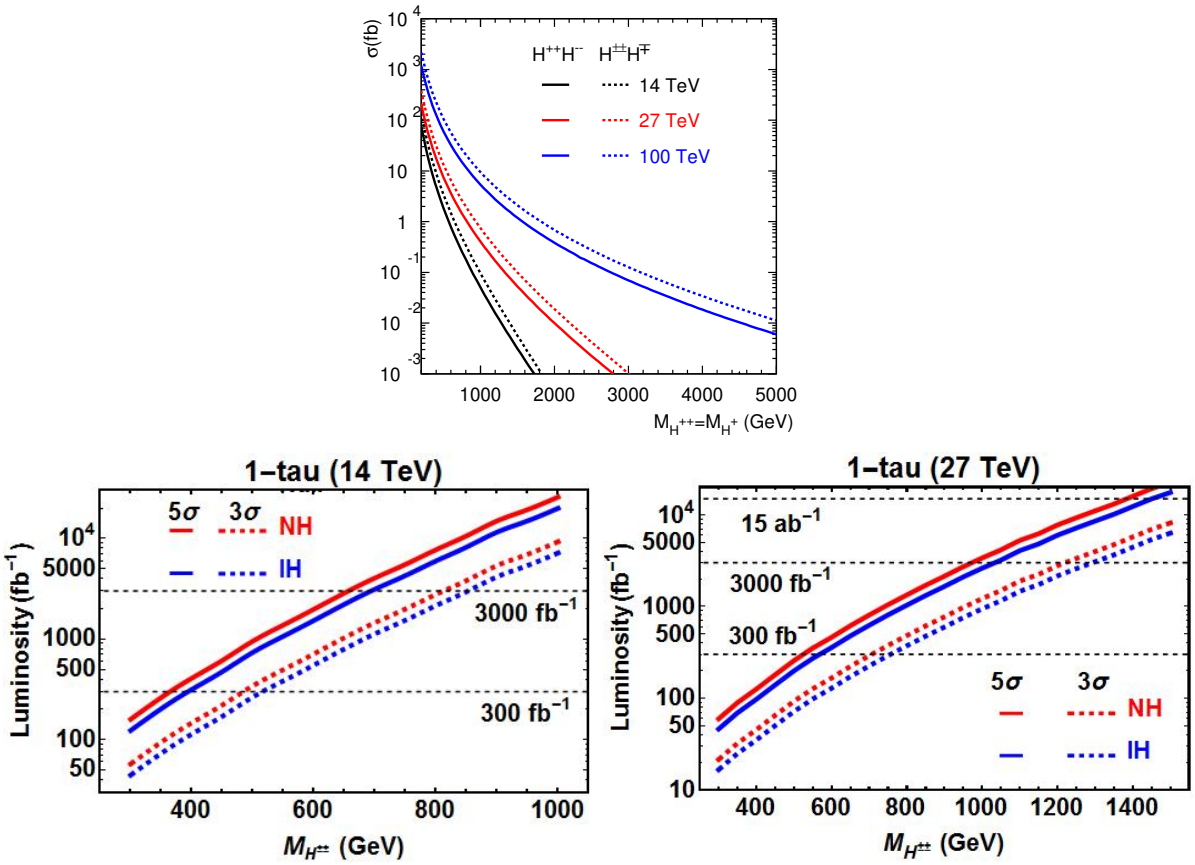

Fig. 5.1.5: Top: the total cross section for $pp \to H^{++}H^{--}$ and $H^{\pm\pm}H^{\mp}$ at $\sqrt{s} = 14$, 27, and 100 TeV. Bottom: requisite luminosity versus $M_{H^{\pm\pm}}$ for $5(3)\sigma$ discovery (evidence) for the process $pp \to H^{++}H^{--} \to \tau_h \ell^{\pm}\ell^{\mp}\ell^{\mp}$, where $\tau^{\pm} \to \pi^{\pm}\nu$, for the NH and IH at $\sqrt{s} = 14$ and 27 TeV.

In Type II scenarios, $H^{\pm\pm}$ decays to $\tau^{\pm}\tau^{\pm}$ and $\mu^{\pm}\mu^{\pm}$ pairs are comparable or greater than the $e^{\pm}e^{\pm}$ channel by two orders of magnitude. Moreover, the $\tau\mu$ channel is typically dominant in decays involving different lepton flavours [385, 386]. If such a seesaw is realised in nature, tau polarisations can help to determine the chiral property of triplet scalars: One can discriminate between different heavy scalar mediated neutrino mass mechanisms, such as those found in the Type II seesaw and Zee-Babu model, by studying the distributions of tau leptons' decay products [386, 387]. Due to the low τ_h identification efficiencies, future colliders with high energy and/or luminosity enables one to investigate and search for doubly charged Higgs decaying to τ_h pairs. Accounting for constraints from neutrino oscillation data on the doubly charged Higgs BRs, as well as tau polarisation effects [386], Fig. 5.1.5 (right) displays the 3σ and 5σ significance in the plane of integrated luminosity versus doubly charged Higgs mass for $pp \to H^{++}H^{--} \to \tau^{\pm}\ell^{\pm}\ell^{\mp}\ell^{\mp}$ at $\sqrt{s} = 14$, 27, and 100 TeV, respectively. For the one τ channel with $\tau^{\pm} \to \pi^{\pm(-)}\nu_{\tau}$, the sensitivity to doubly charged Higgs mass at HL-LHC can reach 655 GeV and 695 GeV for NH and IH respectively with a luminosity of 3 ab^{-1}. Higher masses, $1380 - 1930$ GeV for NH and $1450 - 2070$ GeV for IH, can be probed at 27 TeV with 15 $\mathrm{ab}^{-1}$and 100 TeV with 3 ab^{-1}.

Type III Leptons Discovery Potential at HL- and HE-LHC

Low-scale Type III Seesaws hypothesises the existence of heavy electrically charged $(E^{\pm})$ and neutral (N) leptons, which form a triplet under $\mathrm{SU}(2)_L$, that couple to both SM charged and neutral leptons through mixing/Yukawa couplings. Due to their gauge charges, triplet leptons also couple to EW gauge

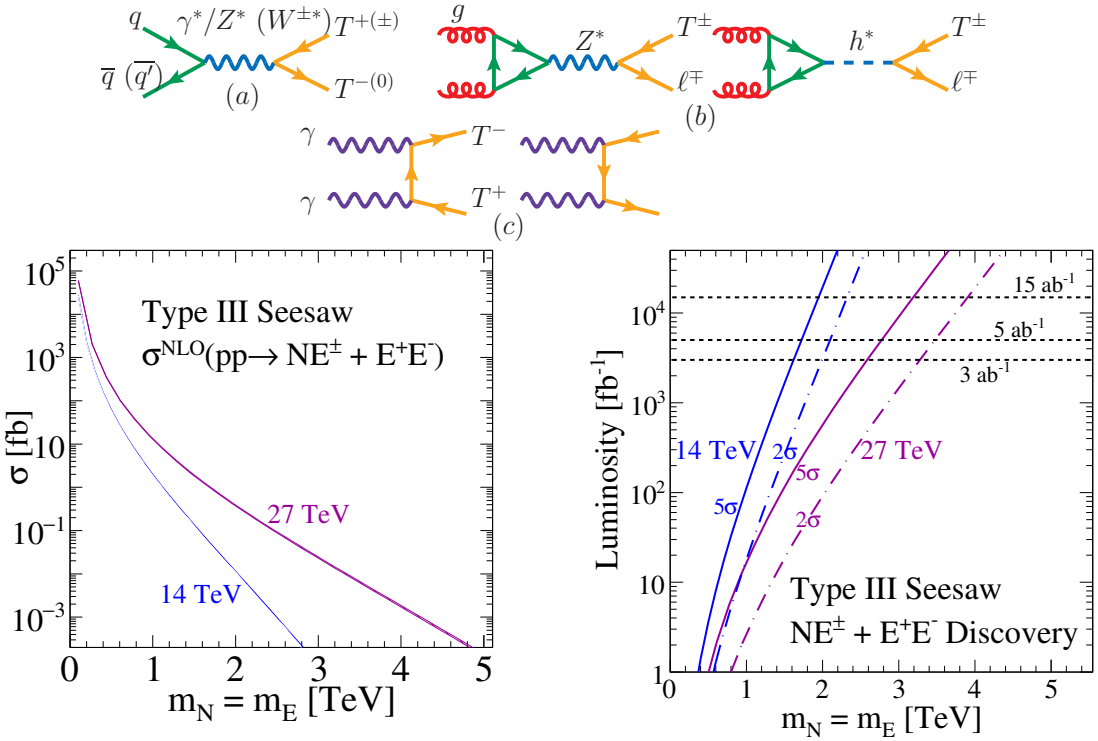

Fig. 5.1.6: Top: Born level production of Type III leptons via (a) Drell-Yan, (b) gluon fusion, and (c) photon fusion; from Ref. [361]. Bottom: at $\sqrt{s} = 14$ and 27 TeV and as a function of heavy triplet lepton mass, the summed inclusive production cross section [fb] of $pp \to NE^\pm + E^+E^-$, at NLO in QCD [388] (left), and the requisite integrated luminosity for $5(2)\sigma$ discovery (sensitivity) to $NE^\pm + E^+E^-$ based on the analyses of [389, 390] (right).

bosons appreciably and do not feature suppressed production cross section typical of seesaw scenarios with gauge singlet fermions. The presence of EW gauge couplings also implies that once a collider energy and mass are stipulated, the triplet lepton pair production cross section can be computed, up to small (and potentially negligible) mixing effects. Production mechanisms commonly found in the literature, and shown in Fig. 5.1.6 (top), include charged current and neutral current Drell-Yan, photon fusion, and gluon fusion if one considers heavy-light charged lepton associated production. A recent assessment of triplet production modes found [361] that despite the sizeable luminosities afforded to gluon fusion ($gg \to E^\pm \ell^\mp$), including its large QCD corrections [368], and photon fusion ($\gamma\gamma \to E^+E^-$), the Drell-Yan processes remain the dominant production channel of triplet leptons when kinematically accessible. In light of this, in Fig. 5.1.6 (bottom left), the summed cross sections for the Drell-Yan processes,

$$pp \to \gamma^*/Z^* \to E^+E^- \quad \text{and} \quad pp \to W^{\pm *} \to E^\pm N, \tag{5.1.8}$$

are shown at NLO in QCD, following Ref. [388], as a function of triplet masses (assuming $m_N = m_E$), at $\sqrt{s} = 14$ and 27 TeV. For $m_N, m_E \approx 1.2(1.8)$ TeV, the production rate reaches $\sigma(pp \to NE + EE) \approx 1$ fb at $\sqrt{s} = 14(27)$ TeV; and for heavier leptons with $m_N, m_E \approx 2.5(4.2)$ TeV, one sees that $\sigma(pp \to NE + EE) \approx 1$ ab.

Another consequence of the triplet leptons coupling to all EW bosons is the adherence to the Goldstone Equivalence Theorem. This implies that triplet leptons with masses well above the EW scale will preferentially decay to longitudinal polarised W and Z bosons as well as to the Higgs bosons. For decays of EW boson to jets or charged lepton pairs, triplet lepton can be full reconstructed from their final-state enabling their properties to be studied in detail. For fully reconstructible final-states,

$$NE^\pm \to \ell\ell' + WZ/Wh \quad \to \quad \ell\ell' + nj + mb, \tag{5.1.9}$$

$$E^+E^- \to \ell\ell' + ZZ/Zh/hh \quad \to \quad \ell\ell' \; + \; nj + mb, \tag{5.1.10}$$

which correspond approximately to the branching fractions $\mathcal{B}(NE) \approx 0.115$ and $\mathcal{B}(EE) \approx 0.116$, search strategies such as those considered in Ref.s [389, 390] can be enacted. Assuming a fixed detector acceptance and efficiency of $\mathcal{A} = 0.75$, which is in line to those obtained by Ref.s [389, 390], Fig. 5.1.6 (bottom right) shows as a function of triplet mass the requisite luminosity for a 5σ discovery (solid) and 2σ evidence (dash-dot) of triplet leptons at $\sqrt{s} = 14$ and 27 TeV. With $\mathcal{L} = 3 - 5$ ab^{-1}, the 14 TeV HL-LHC can discover states as heavy as $m_N, m_E = 1.6 - 1.8$ TeV. For the same amount of data, the 27 TeV HE-LHC can discover heavy leptons $m_N, m_E = 2.6 - 2.8$ TeV; with $\mathcal{L} = 15$ ab^{-1}, one can discover (probe) roughly $m_N, m_E = 3.2(3.8)$ TeV.

5.1.2 Like-sign dileptons with mirror type composite neutrinos at the HL-LHC

Contributors: M. Presilla, O. Panella, R. Leonardi

A composite scenario [391–394], where at a sufficiently high energy scale Λ (compositeness scale) the SM leptons and quarks show the effects of an internal substructure, has triggered considerable recent interest both from the theoretical [395–398] and experimental [399, 400] point of view. In particular recent studies [401] have concentrated in searching for heavy composite Majorana neutrinos at the LHC. The scenario discussed in such studies is one in which the excited neutrino (ν^*) is a Majorana particle. A recent CMS study has searched for a heavy composite Majorana neutrino (N). Using 2.6 fb^{-1} data of the 2015 Run II at $\sqrt{s} = 13$ TeV, heavy composite neutrino masses are excluded, at 95% C.L., up to $m_N = 4.35$ TeV and 4.60 (4.70) TeV for a value of $\Lambda = M_N$, from the $eeqq$ channel and the $\mu\mu qq$ channel, respectively [402, 403]. Here we focus on a mirror type assignment for the excited composite fermions. The neutrino mass term is built up from a Dirac mass, m_*, the mass of the charged lepton component of the $SU(2)$, right-handed doublet, and m_L the Majorana mass of the left-handed component (singlet) of the excited neutrino. The mass matrix is diagonalised leading to two Majorana mass eigenstates. The active neutrino field ν_R^* is thus a superposition of the two mass eigenstates with mixing coefficients which depend on the ratio m_L/m_*. We discuss the prospects of discovery of these physical states at the HL-LHC as compared with the previous searches of composite Majorana neutrinos at the LHC based on sequential type Majorana neutrinos.

We discuss a variant of the model analysed in Ref. [401, 403] taking up the scenario in which the excited fermions are organised with a mirror $SU(2)$ structure relative to the SM fermions, *i.e.* the right handed components form an $SU(2)$ doublet while the left handed components are singlets [283]. We construct a general Dirac-Majorana mass term and discuss its mass spectrum along with prospects of observing the resulting lepton number violating signatures at the HL-LHC [404].

In analogy with the usual procedure adopted in see-saw type extensions of the SM we may give a (lepton number violating) Majorana mass term to the left handed excited neutrino (ν_L^*) which is a singlet and does not actively participate to the gauge interactions in Eq. (5.1.14) –*sterile neutrino*–, while a (lepton number conserving) Dirac mass term m^* is associated to the right-handed component ν_R^* which belongs to the $SU(2)$ doublet and does participate in the gauge interactions – *active neutrino*-. We can thus write down the excited neutrino Dirac-Majorana mass term appearing in the Lagrangian density of the model as:

$$\mathcal{L}^{\text{D+M}} = -\frac{1}{2} m_L \, \bar{\nu}_L^* (\nu_L^*)^c - m_* \, \bar{\nu}_L^* \nu_R^* + \text{h.c.} \tag{5.1.11}$$

The Lagrangian mass term is easily diagonalised following standard procedures, obtaining two Majorana mass eigenstates, $\nu_{1,2}$, with (positive) mass eigenvalues given by:

$$m_{1,2} = \sqrt{m_*^2 + \left(\frac{m_L}{2}\right)^2} \mp \frac{m_L}{2} \tag{5.1.12}$$

Interacting states can be written as a mixing of the mass eigenstate according to the relation:

$$(\nu_L^*)^c = \; -i \cos\theta \, \nu_{1R} + \sin\theta \, \nu_{2R} \tag{5.1.13a}$$

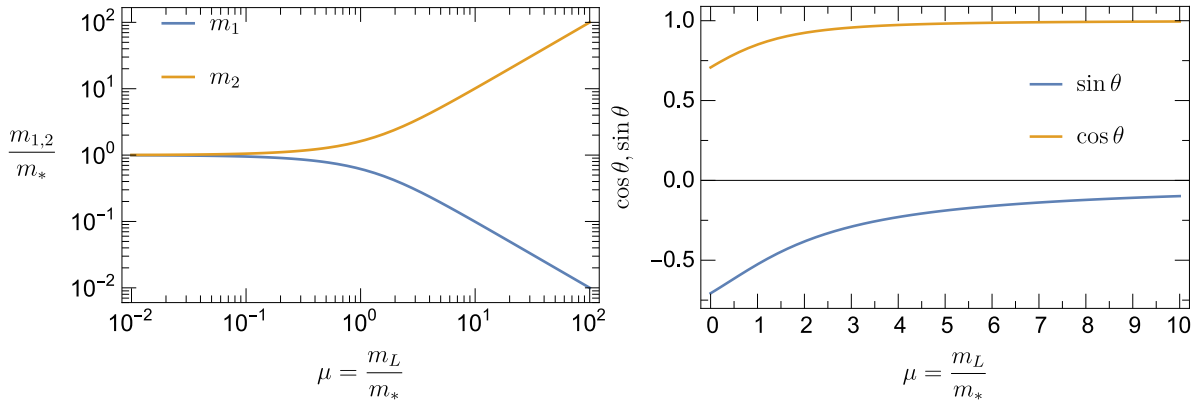

Fig. 5.1.7: Left: mass eigenstates $m_{1,2}$ (in units of m_*) from Eq. (5.1.12) as a function of the parameter $\mu = m_L/m_*$. Right: mixing coefficients $\cos\theta$ and $\sin\theta$ from Eq.s (5.1.13) as a function of the parameter $\mu = m_L/m_*$

$$\nu_R^* = \quad i\sin\theta\,\nu_{1R} + \cos\theta\,\nu_{2R} \tag{5.1.13b}$$

where the mixing angle θ is given in terms of the Dirac and Majorana masses: $\theta = -\frac{1}{2}\arctan\frac{2m_*}{m_L}$.

Now we take into account all the relevant effective couplings of these particles. In the mirror type model, we consider the first lepton family and assume that the excited neutrino and the excited electron are grouped into left handed singlets and a right-handed $SU(2)$ doublet [283]. The corresponding gauge mediated Lagrangian between the left-handed SM doublet L and the right-handed excited doublet R via the $SU(2)_L \times U(1)_Y$ gauge fields [405, 406], which should be of the magnetic type to warrant current conservation, can be written down:

$$\mathcal{L} = \frac{1}{2\Lambda}\,\bar{R}^*\sigma^{\mu\nu}\left(gf\frac{\boldsymbol{\tau}}{2}\cdot\boldsymbol{W}_{\mu\nu} + g'f'YB_{\mu\nu}\right)L + h.c.\,, \tag{5.1.14}$$

where $L^T = (\nu_L, \ell_L)$ is the ordinary $SU(2)_L$ lepton doublet, and $R^T = (\nu_R^*, \ell_R^*)$ is the excited right-handed doublet; g and g' are the $SU(2)_L$ and $U(1)_Y$ gauge couplings and $\boldsymbol{W}_{\mu\nu}$, $B_{\mu\nu}$ are the field strength for the $SU(2)_L$ and $U(1)_Y$ gauge fields; f and f' are dimensionless couplings. The relevant charged current (gauge) interaction of the excited (active) Majorana neutrino ν_R^* is easily derived from Eq. (5.1.14) and can be written out explicitly in terms of the Majorana mass eigenstates through Eq. (5.1.13b):

$$\mathcal{L}_{\rm G} = \frac{gf}{\sqrt{2}\Lambda}\,\left(-i\sin\theta\,\overline{\nu}_1 + \cos\theta\,\overline{\nu}_2\right)\,\sigma^{\mu\lambda}\,\ell_L\,\partial_\mu W_\lambda + h.c. \tag{5.1.15}$$

Contact interactions between ordinary fermions may arise by constituent exchange, if the fermions have common constituents, and/or by exchange of the binding quanta of the new unknown interaction whenever such binding quanta couple to the constituents of both particles [392, 406]. The dominant effect is expected to be given by the dimension 6 four-fermion interactions which scale with the inverse square of the compositeness scale Λ:

$$\mathcal{L}_{\rm CI} = \frac{g_*^2}{\Lambda^2}\frac{1}{2}j^\mu j_\mu \tag{5.1.16a}$$

$$j_\mu = \eta_L\bar{f}_L\gamma_\mu f_L + \eta'_L\bar{f}_L^*\gamma_\mu f_L^* + \eta''_L\bar{f}_L^*\gamma_\mu f_L + h.c. + (L\to R) \tag{5.1.16b}$$

where $g_*^2 = 4\pi$ and the η factors are usually set equal to unity. In this work the right-handed currents will be neglected for simplicity.

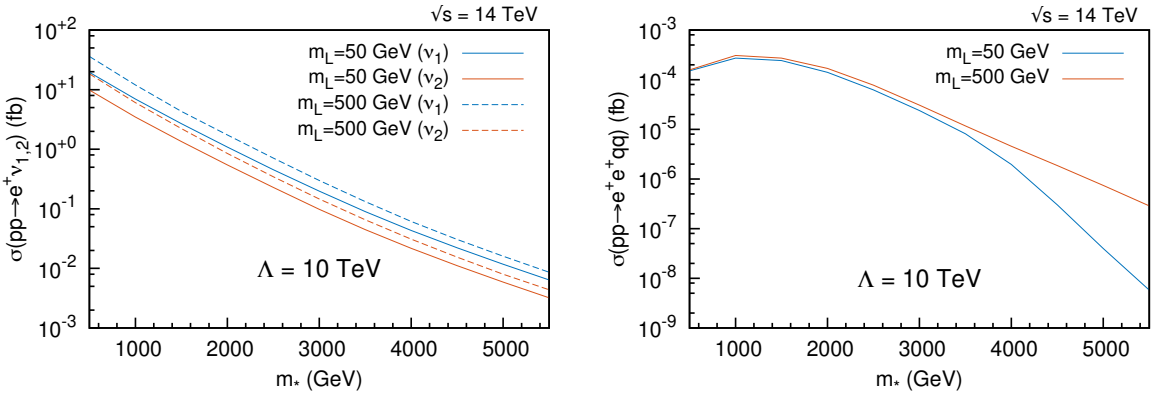

Fig. 5.1.8: Left: production cross section, at $\sqrt{s} = 14$ TeV, for the two mass eigen-states $pp \to e^+\nu_{1,2}$ for two different Majorana mass values, $m_L = 50, 500$ GeV. Right: cross section for the like-sign dileptons signature, $pp \to e^+e^+qq$ at the HL-LHC ($\sqrt{s} = 14$ TeV).

The single production $q\bar{q}' \to \nu^*\ell$ proceeds through flavour conserving but non-diagonal terms, in particular with currents like the third term in Eq. (5.1.16b) which couple excited states with ordinary fermions and the contact interactions in can be written out explicitly in terms of the Majorana mass eigenstates ν_i using Eq. (5.1.13b):

$$\mathcal{L}_{\rm CI} = \frac{g_*^2}{\Lambda^2}\,\bar{q}_L\gamma^\mu q'_L\,\left(-i\cos\theta\,\overline{\nu}_1 + \sin\theta\,\overline{\nu}_2\right)\,\gamma_\mu\ell_L\,. \tag{5.1.17}$$

The gauge interactions in Eq. (5.1.15) and the contact interactions in Eq. (5.1.17) have to be implemented in a MC generator. Here we have mostly used MADGRAPH [67], complementing the results with a validation obtained with the tree-level simulator CALCHEP [407].

In Fig. 5.1.8 is shown the behaviour of production cross section for the two mass eigenstates and for the whole process for different model scenarios. It is worth to notice that in the limit $m_L \to 0$ the cross-section of the like-sign dilepton process goes to zero.

We briefly discuss the potential for discovery at HL-LHC in the three-dimensional parameter space (Λ, m_L, m_*) using the fast simulation framework DELPHES [33] for studying the hypothetical response of the CMS Phase-2 detector. Standard model processes that could mimic the detection of a signal with lepton number violation in this rather clean signature are mainly the triple W boson production, $pp \to W^+W^+W^-$, and the top quark pair production $pp \to t\bar{t}$, the former being the dominant background source. Since the kinematic features of the final state reconstructed objects are similar to those of Ref. [401], we lower the background contribution by imposing two cuts on the leading lepton ($p_T(e_1) > 110$ GeV) and on the second-leading lepton ($p_T(e_2) > 35$ GeV). This particular signal region allows an efficiency in selecting signal around the 80%, while beating the background sources with efficiency of 0.00044% for the $t\bar{t}$ and of 0.0034% for the $W^+W^+W^-$.
We compute, at a c.o.m.energy of $\sqrt{s} = 14$ TeV and with an integrated luminosity of $\mathcal{L} = 3\ \mathrm{ab}^{-1}$, the statistical significance, as defined by the relation $S = \mathcal{L}\sigma_{\rm sig}\epsilon_{\rm sig}/\sqrt{\mathcal{L}\sigma_{\rm bkg}\epsilon_{\rm bkg}}$, where $\epsilon_{\rm sig}, \epsilon_{\rm bkg}$ are respectively the cumulative efficiencies of signal and background due to the event reconstruction. In Fig. 5.1.9 (left) we show the potential for discovery, in the plane (m_*, Λ), of the CMS Phase-2 detector for two different values of the Majorana mass $m_L = 50, 500$ GeV.

Another interesting feature of the present model is that the presence of two heavy neutrino mass eigenstates, which have also opposite CP eigenvalues, can lead to a charge asymmetry, *i.e.* to an asymmetry in the production rate of same-sign dilepton signal versus the opposite-sign dilepton signal [408]. In particular, the charge asymmetry $\mathcal{A} = (\sigma_{e^+e^-jj} - \sigma_{e^+e^+jj})/(\sigma_{e^+e^-jj} + \sigma_{e^+e^+jj})$ could be used to test the relative strength between the Dirac and Majorana nature of the heavy neutrinos at the HL-LHC.

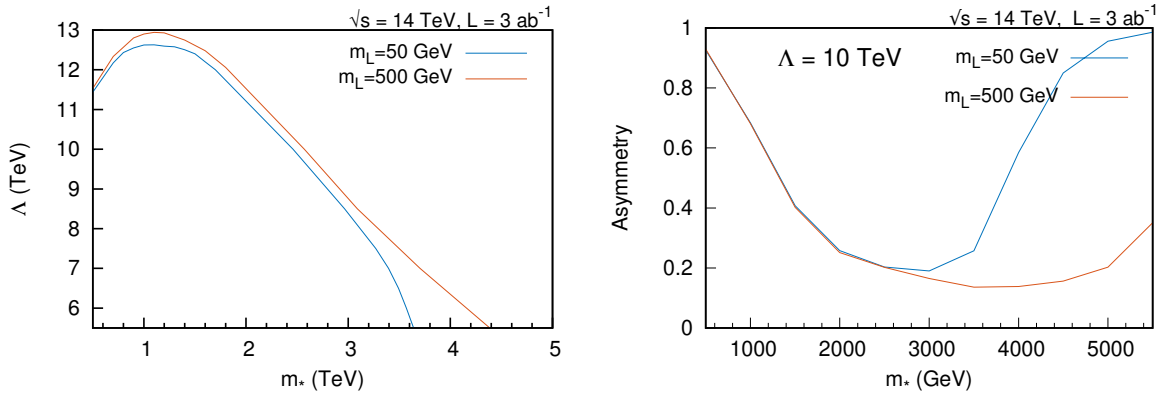

Fig. 5.1.9: Left: the 5σ contour levels curves, at $\sqrt{s} = 14$ TeV and $\mathcal{L} = 3\,\text{ab}^{-1}$, of the statistical significance ($S = 5$) in the parameter plane $[m^*, \Lambda]$, for two different values of the Majorana mass $m_L = 50, 500$ GeV. Right: the expected charge asymmetry at $\sqrt{s} = 14$ TeV and $\mathcal{L} = 3\,\text{ab}^{-1}$ of the same-sign and opposite sign channels for two different values of $m_L = 50, 500$ GeV as function of m_*.

We note that while the same-sign dilepton signature e^+e^+jj is effectively background free (see above), the opposite sign dilepton signature e^+e^-jj is expected to have a substantially larger SM background which however could be subtracted in order to extract the asymmetry $\mathcal{A}$ peculiar of the model features. Figure 5.1.9 (right) shows the charge asymmetry $\mathcal{A}$. In line with expectations that $\mathcal{A} \to 1$ when $\sigma_{e^+e^+jj}$ is suppressed we observe that as a function of m_* after the initial drop in the asymmetry, at fixed m_L, then at larger values of m_* the mass difference of the two eigenstates diminishes and so does the same-sign dilepton yield giving larger asymmetries close to 1 again.

In summary, we have presented a mechanism of lepton number violation within a mirror type compositeness scenario. The mirror model is realised when the left components of the excited states are singlets while the right components are active doublets which do participate to gauge transition interactions with SM fermions. We therefore introduce a *left*-handed Majorana neutrino singlet of mass m_L while the right-handed component belongs to a doublet and has a Dirac mass m_*. This situation is exactly specular to the one encountered in typical see-saw models where the sterile neutrino is the right handed component and the active one is the left handed component. diagonalisation of the mass matrix gives two Majorana mass eigenstates whose phenomenology at the HL-LHC is presented, providing the 5σ contour level curves of the statistical significance for a possible discover by a CMS Phase-2 like detector. We have also shown that the charge asymmetry $\mathcal{A}$ of the like sign dilepton signature is a useful observable for studying the model parameter space.

5.1.3 Search for heavy composite Majorana neutrinos at the HL- and the HE-LHC

Contributors: P. Azzi, C. Cecchi, L. Fanó, A. Gurrola, W. Johns, R. Leonardi, E. Manoni, M. Narain, O. Panella, M. Presilla, F. Romeo, S. Sagir, P. Sheldon, F. Simonetto, E. Usai, W. Zhang, CMS

Compositeness of ordinary fermions is one possible BSM scenario that may lead to a solution of the hierarchy problem or to the explanation of the proliferation of ordinary fermions. Elementary particles are thought to be bound states of some as–yet–unobserved fundamental constituents generically referred to as *preons*. Composite models also predict the existence of excited states of quarks and leptons, with masses lower than or equal to the compositeness scale Λ which interact with SM fermions via both magnetic type gauge couplings and contact interactions.

The heavy composite Majorana neutrino N_ℓ would be a particular case of such excited states. This can be produced in association with a lepton, in pp collisions, via quark–antiquark annihilation ($q\bar{q}' \to \ell N_\ell$). The production and decay processes can occur via both gauge and contact interactions.

The Lagrangian density for gauge mediated interactions is

$$\mathcal{L}_G = \frac{1}{2\Lambda}\overline{L_{\mathrm{R}}^*}\sigma^{\mu\nu}\left(gf\frac{\overrightarrow{\tau}}{2}\cdot\overrightarrow{W}_{\mu\nu} + g'f'YB_{\mu\nu}\right)L_{\mathrm{L}} + h.c., \tag{5.1.18}$$

where L_R^* and L_L are, respectively, the right-handed doublet of the excited fermions and the left-handed doublet of the SM, g and $g^{'}$ are the $SU(2)_L$ and $U(1)_Y$ gauge couplings, and f and f' are dimensionless couplings, which are expected to be of order unity [394] and henceforth simply assumed to be 1. The corresponding Lagrangian describing the four-fermion contact interactions by a dimension-6 effective operator can written as

$$\mathcal{L}_C = \frac{g_*^2}{\Lambda^2}\frac{1}{2}j^\mu j_\mu, \tag{5.1.19}$$

with

$$j_\mu = \eta_L\bar{\psi}_L\gamma_\mu\psi_L + \eta'_L\bar{\psi}_L^*\gamma_\mu\psi_L^* + \eta''_L\bar{\psi}_L^*\gamma_\mu\psi_L + h.c. + (L\to R), \tag{5.1.20}$$

where $g_*^2 = 4\pi$, the η factors that define the chiral structure are usually set equal to 1, and ψ and ψ^* are the SM and excited fermion fields [394].

The production process is dominated by the contact interaction mechanism for all values of the compositeness scale Λ and of the mass of the neutrino $M(N_\ell)$ relevant in this analysis, while for the decay the dominant interaction changes depending on Λ and $M(N_\ell)$ [401].

This study from CMS focuses on the final state signature $\ell\ell q\bar{q}^{'}$, where ℓ is either an electron or a muon [409]. For the HL-LHC sensitivity study, we use MC samples for the signal and the SM backgrounds. The MC samples for the signal are generated with CALCHEP V3.6 [407] using the NNPDF3.0 LO parton distribution functions [121]. The background samples considered are top quark pair production ($\mathrm{t\bar{t}}$), single top quark production (tW), Drell-Yan (DY) process, W+jets and diboson production (WW, WZ, ZZ), and are generated with MADGRAPH5_AMC@NLO [67] using the CTEQ6L1 PDF set [52]. For all of the MC samples the hadronisation of partons is simulated with PYTHIA 8 [68] and the expected response of the upgraded CMS detector is performed with the fast-simulation package DELPHES [33]. The contribution from additional pileup events has been included in the simulation as well.

In order to reduce the contamination from misreconstructed events, a kinematics-based selection is applied. The p_T of the leading lepton is required to be greater than 110 GeV, while the p_T of the subleading lepton must greater than 40 GeV. All lepton candidates are required to be in the pseudorapidity range $|\eta| < 2.4$. Restricting to the high-mass region given by $M(\ell,\ell) > 300$ GeV, where $M(\ell,\ell)$ is the dilepton invariant mass, allows reducing the DY background without affecting the signal acceptance. The large-radius jets are analysed using the PUPPI algorithm [410]. They are reconstructed with a distance parameter of $R = 0.8$ and they are required to have a minimum p_T of 200 GeV, to be within the region $|\eta| < 2.4$ and to be separated from leptons by a distance $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} > 0.8$. Requiring one or more large-radius jets is suitable regardless of whether N_ℓ decays through gauge or contact interactions. In fact, for gauge mediated decays of the heavy composite neutrino, the two quarks are expected to overlap and thus form a large-radius jet, while in the case of contact-mediated decays, the two quarks are well separated, but form two large-radius jets because of the overlap with final state radiation. The signal region is therefore defined by requiring two same-flavour isolated leptons (electrons or muons) and at least one large-radius jet.

A shape-based analysis is performed looking at the invariant mass distribution of the two leptons and the leading large-radius jet, $M(\ell\ell J)$. The expected discovery sensitivity of a heavy composite Majorana neutrino, produced in association with a lepton, and decaying into a same-flavour lepton and two jets, is shown in Fig. 5.1.10. The CMS Phase-2 detector will be able to find evidence for a composite neutrino with mass below $M(N_\ell) = 7.6$ TeV. The $M(\ell\ell J)$ distributions of signal and SM backgrounds are also used as input in the computation of an upper limit at the 95% C.L. on the cross section of the

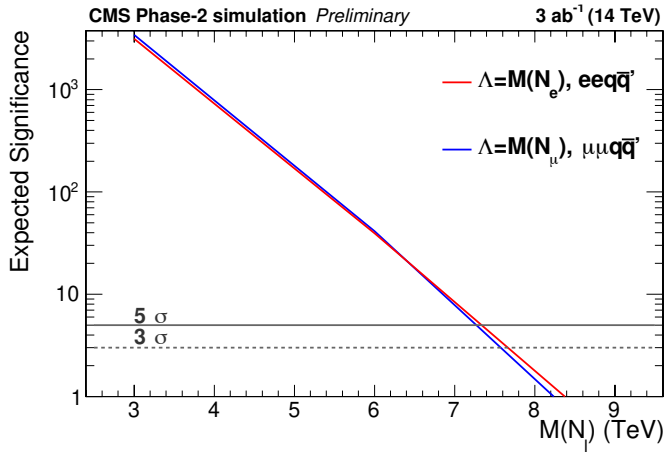

Fig. 5.1.10: Expected statistical significance for the HL-LHC projection of the $eeq\bar{q}'$ (red line) and $\mu\mu q\bar{q}'$ (blue line) channel for the case $\Lambda = M(N_\ell)$. The grey solid (dotted) line represents $5(3)\sigma$, respectively.

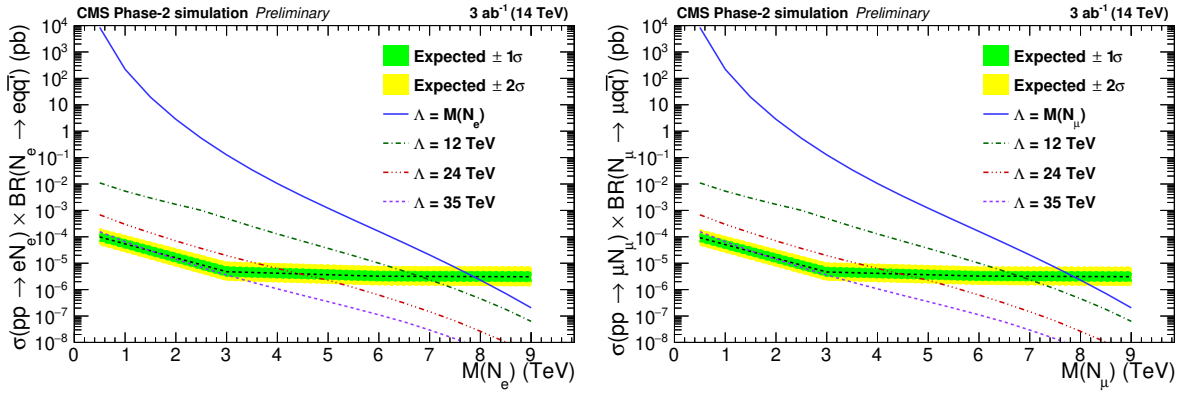

Fig. 5.1.11: Expected 95% C.L. upper limits for the HL-LHC projection (black dotted lines) on $\sigma(pp \to \ell N_\ell) \times \mathcal{B}(N_\ell \to \ell q\bar{q}')$, obtained in the analysis of the $eeq\bar{q}'$ (left) and the $\mu\mu q\bar{q}'$ (right) final states, as a function of the mass of the heavy composite Majorana neutrino. The corresponding green and yellow bands represent the expected variation of the limit to one and two standard deviation(s). The solid blue curve indicates the theoretical prediction of $\Lambda = M(N_l)$. The textured curves give the theoretical predictions for Λ values ranging from 12 to 35 TeV.

heavy composite Majorana neutrino produced in association with a lepton times its branching fraction to a same-flavour lepton and two quarks, $\sigma(pp \to \ell N_\ell) \times \mathcal{B}(N_\ell \to \ell q\bar{q}')$. A CL_s criterion [95] is used to set upper limits. Systematic uncertainties are included on the integrated luminosity (1%), pileup (2%), electron ID (0.5%), electron scale (0.5%), muon ID (0.5%), muon scale (0.5%), jet energy scale (1%), jet energy resolution (1%), the background prediction (0.3%), and Drell-Yan theory (4%), and are evaluated in accordance with the most recent recommendations described in Ref. [411].

The results are shown in Fig. 5.1.11 for the $eeq\bar{q}'$ and $\mu\mu q\bar{q}'$ channels. Figure 5.1.12 displays the corresponding upper limits on the $(\Lambda, M(N_\ell))$ plane. The HL-LHC running conditions and Phase-2 detector will significantly extend the region of parameter space that can be probed. While in Run-2 the mass of the heavy composite Majorana neutrino could be excluded up to 4.60 (4.70) TeV in the $eeq\bar{q}'$ ($\mu\mu q\bar{q}'$) channel [403], for the case of $\Lambda = M(N_\ell)$, for the HL-LHC we could potentially exclude a composite neutrino up to a mass of 8 TeV with the same assumption on the compositeness scale.

The sensitivity of the search is also considered for the High-Energy LHC at $\sqrt{s} = 27$ TeV.

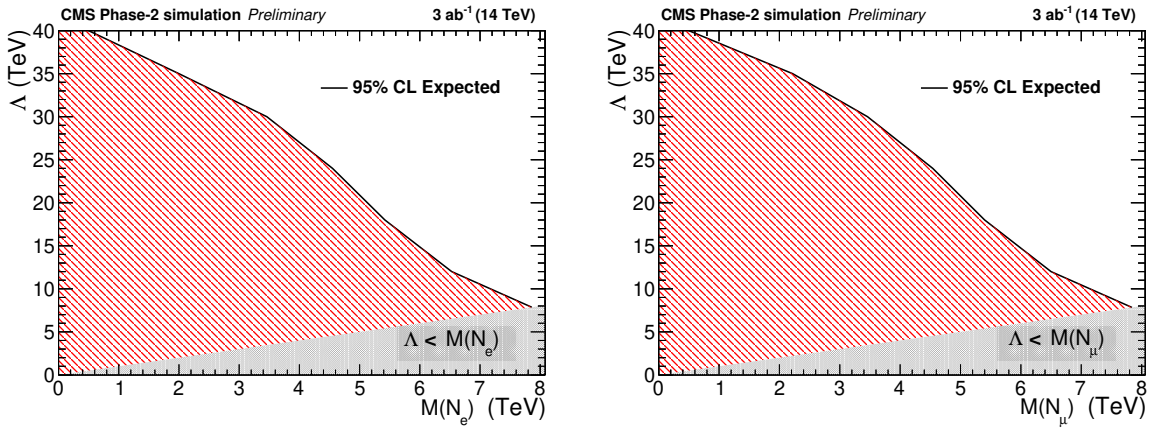

Fig. 5.1.12: Expected 95% C.L. lower limits (black lines) on the compositeness scale Λ, obtained in the analysis of the $eeq\bar{q}'$ (left) and the $\mu\mu q\bar{q}'$ (right) final states, as a function of the mass of the heavy composite Majorana neutrino. The gray zone corresponds to the phase space $\Lambda < M(N_\ell)$ not allowed by the model.

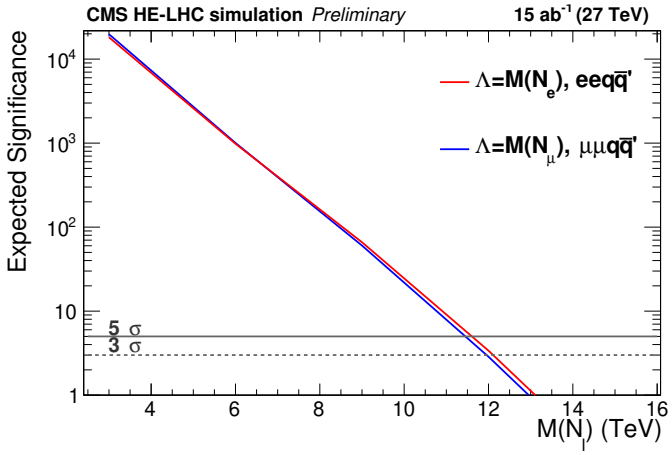

Fig. 5.1.13: Expected statistical significance for the HE-LHC projection of the $eeq\bar{q}'$ (red line) and the $\mu\mu q\bar{q}'$ (blue line) channel for the case $\Lambda = M(N_\ell)$. The gray solid (dotted) line represents $5(3)\sigma$, respectively.

Figure 5.1.13 shows that with the HE-LHC we could find evidence for a composite Majorana neutrino with mass below $M(N_\ell) = 12$ TeV, for $\Lambda = M(N_\ell)$. Figure 5.1.14 shows the results for several values of Λ. The projection of the exclusion limits is also presented in Fig. 5.1.15 for the $(\Lambda, M(N_\ell))$ plane. We conclude that, given the model condition $\Lambda = M(N_\ell)$, the HE-LHC could exclude a heavy composite Majorana neutrino with mass up to 12.5 TeV in both $eeq\bar{q}'$ and $\mu\mu q\bar{q}'$ channels.

5.2 Leptoquarks and Z'

Leptoquarks are hypothetical particles that carry both baryon and lepton quantum numbers. They are colour-triplets and carry fractional electric charge. The spin of a LQ state is either 0 (scalar LQ) or 1 (vector LQ). At the LHC, the pair-production of LQs is possible via gluon-gluon fusion and quark-antiquark annihilation and the production cross section only depends on the mass of the LQ. For scalar LQs, it is known at NLO in perturbative QCD [412]. The LQ may also be singly produced, in association with a lepton, but the cross section is model dependent. New massive vector bosons, Z', are a common feature of NP models. Typically they are assumed to couple in a flavour independent fashion. However, it is possible to build models where these couplings are generation dependent and, after moving to the mass basis, become inter-generational. Constraints on such couplings are weaker for the third generation.

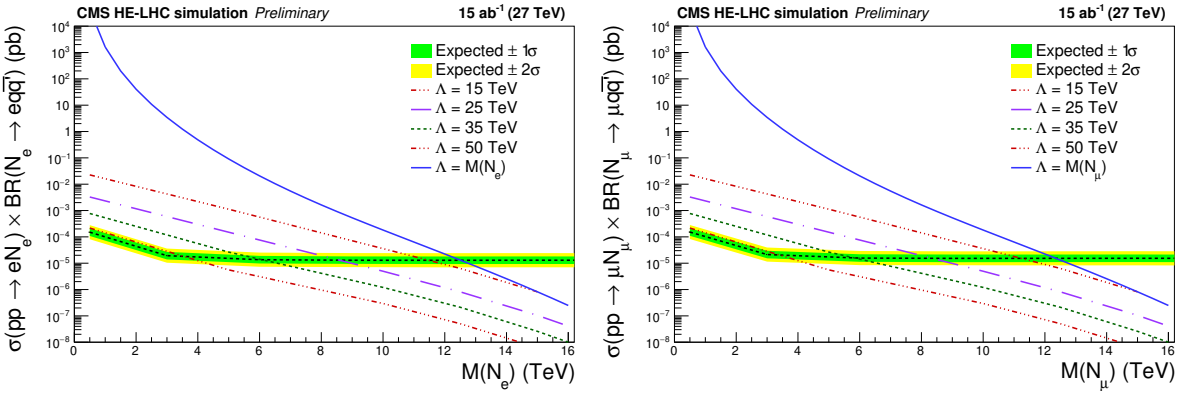

Fig. 5.1.14: Expected 95% C.L. upper limits for the HE-LHC projection of the $eeq\bar{q}'$ channel (left) and the $\mu\mu q\bar{q}'$ channel (right).

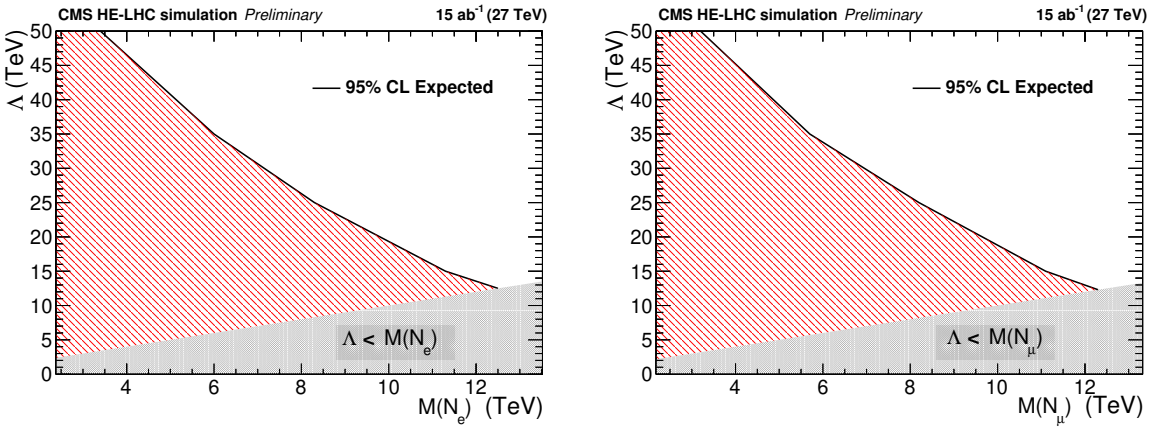

Fig. 5.1.15: Expected 95% C.L. lower limits (black lines) on the compositeness scale Λ, obtained in the analysis of the $eeq\bar{q}'$ (left) and the $\mu\mu q\bar{q}'$ (right) final states, as a function of the mass of the heavy composite Majorana neutrino for the HE-LHC projection. The grey zones are not allowed by the model.

Such models have been invoked to explain several B-physics anomalies.

In this section the reach of the HL-LHC for LQs in the $t + \tau$ and $t + \mu$ channel is discussed in Section 5.2.1. The reach of HL- and HE-LHC for models capable of explaining the B-physics anomalies is addressed in Section 5.2.2. HL-LHC searches for LQs in $b+\tau$ final states is discussed in Section 5.2.3, while the HE-LHC capability is considered in Section 5.2.4.

5.2.1 Leptoquark searches in t+τ and t+μ decays at HL-LHC

Contributors: J. Haller, R. Kogler, A. Reimers, CMS

The reach of searches for pair production of LQs with decays to $t + \mu$ and $t + \tau$ at CMS is studied for the HL-LHC with target integrated luminosities of $\mathcal{L}_{\text{int}}^{\text{target}} = 300\ \text{fb}^{-1}$ and $3\ \text{ab}^{-1}$ [413]. The studies are based on projecting signal and background event yields to HL-LHC conditions from published CMS results of the t+μ [414] and t+τ [415] LQ decay channels which use data from proton-proton collisions at $\sqrt{s} = 13$ TeV corresponding to $\mathcal{L}_{\text{int}} = 35.9\ \text{fb}^{-1}$ recorded in 2016. While the analysis strategies are kept unchanged with respect to the ones in Ref.s [414, 415], different total integrated luminosities, the higher c.o.m. energy of 14 TeV, and different scenarios of systematic uncertainties are considered. In the first scenario (denoted "w/ YR18 syst. uncert."), the relative experimental systematic uncertainties are scaled by a factor of $1/\sqrt{f}$, with $f = \mathcal{L}_{\text{int}}^{\text{target}}/35.9\ \text{fb}^{-1}$, until they reach a defined lower limit based

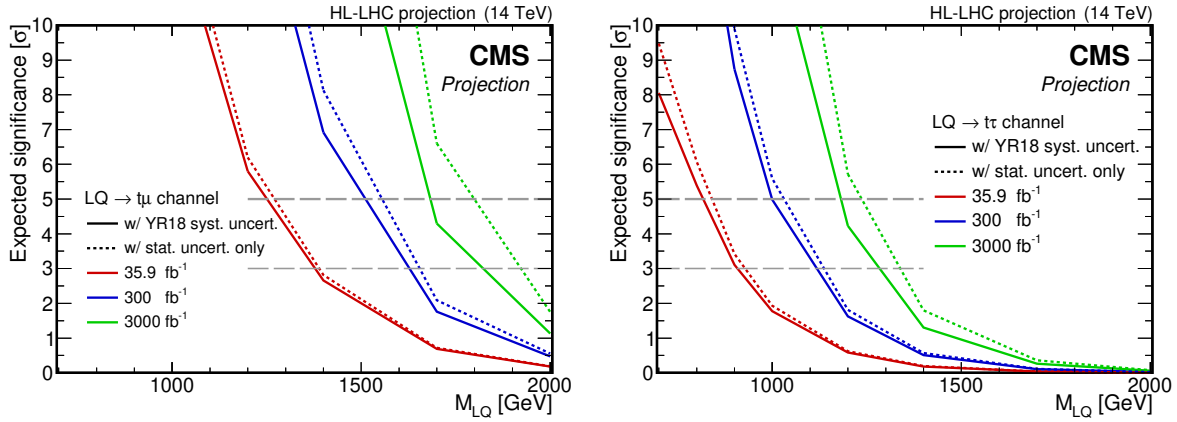

Fig. 5.2.1: Expected significances for an LQ decaying exclusively to top quarks and muons (left) or τ leptons (right).

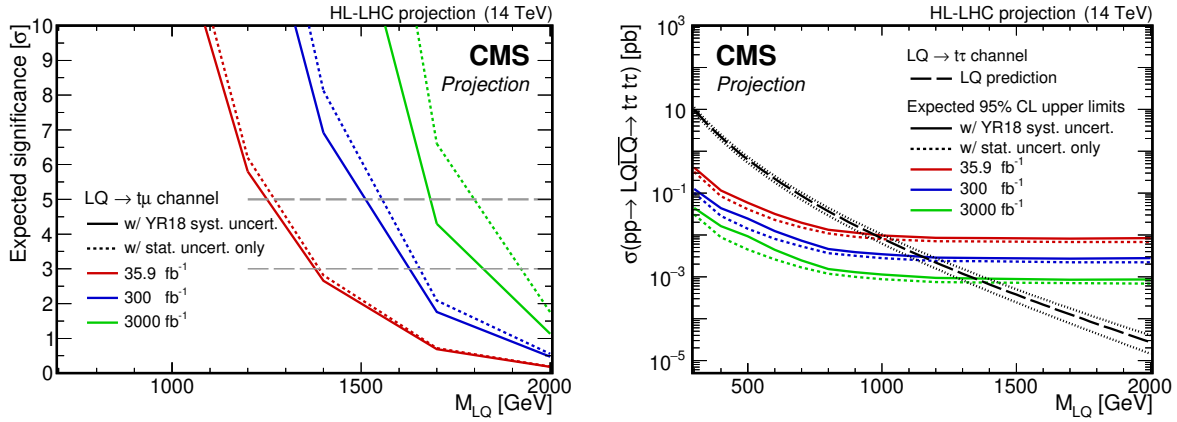

Fig. 5.2.2: Expected upper limits on the LQ pair production cross section at the 95% C.L. for an LQ decaying exclusively to top quarks and muons (left) or τ leptons (right).

on estimates of the achievable accuracy with the upgraded detector [8] as described in Section 1.2. The relative theoretical systematic uncertainties are halved. In the second scenario (denoted "w/ stat. uncert. only"), no systematic uncertainties are considered. The relative statistical uncertainties in both scenarios are scaled by $1/\sqrt{f}$.

Figure 5.2.1 presents the expected signal significances of the analyses as a function of the LQ mass for different assumed integrated luminosities in the "w/ YR18 syst. uncert." and "w/ stat. uncert. only" scenarios. Increasing the target integrated luminosity to $\mathcal{L}_{\text{int}}^{\text{target}} = 3\,\text{ab}^{-1}$ greatly increases the discovery potential of both analyses. The LQ mass corresponding to a discovery at 5σ significance with a dataset corresponding to $3\,\text{ab}^{-1}$increases by more than 500 GeV compared to the situation at $\mathcal{L}_{\text{int}}^{\text{target}} = 35.9\,\text{fb}^{-1}$, from about 1200 GeV to roughly 1700 GeV, in the LQ $\to t\mu$ decay channel. For LQs decaying exclusively to top quarks and τ leptons, a gain of 400 GeV is expected, pushing the LQ mass in reach for a 5σ discovery from 800 GeV to 1200 GeV.

In Fig. 5.2.2, the expected projected exclusion limits on the LQ pair production cross section are shown. Leptoquarks decaying only to top quarks and muons are expected to be excluded below masses of 1900 GeV for $3\,\text{ab}^{-1}$, which is a gain of 500 GeV compared to the limit of 1420 GeV obtained in the published analysis of the 2016 dataset [414]. The mass exclusion limit for LQs decaying exclusively to top quarks and τ leptons are expected to be increased by 500 GeV, from 900 GeV to approximately 1400 GeV.

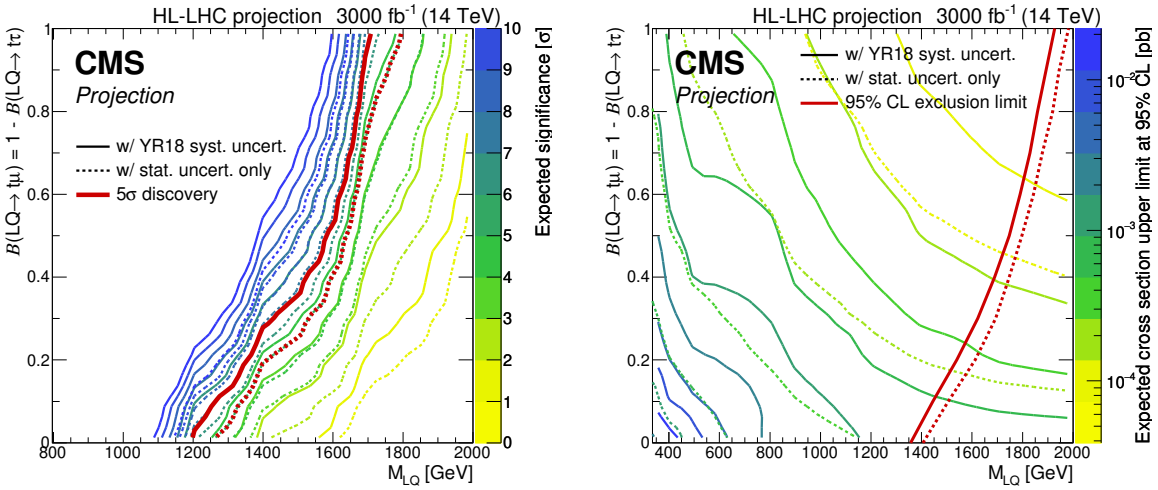

Fig. 5.2.3: Expected significances (left) and expected upper limits on the LQ pair-production cross section at the 95% C.L. (right) as a function of the LQ mass and the branching fraction. Colour-coded lines represent lines of a constant expected significance or cross section limit, respectively. The red lines indicate the 5σ discovery level (left) and the mass exclusion limit (right).

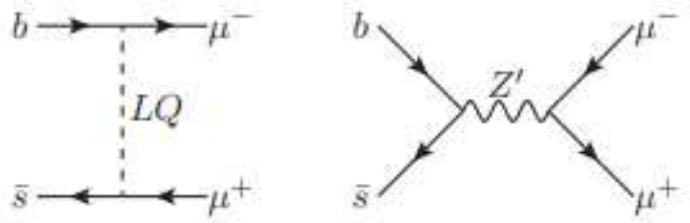

Fig. 5.2.4: Feynman diagrams of two simplified models for mediating an effective operator that explains discrepancies in $B \to K^{(*)}\mu^+\mu^-$ decays as compared to SM predictions. The diagram on the left hand side shows mediation by a scalar LQ, whereas the right-hand side shows mediation by a flavour dependent Z'.

Figure 5.2.3 shows the expected signal significances and upper exclusion limits on the pair production cross section of scalar LQs allowed to decay to top quarks and muons or τ leptons at the 95% C.L. as a function of the LQ mass and a variable branching fraction $\mathcal{B}(\text{LQ} \to t\mu) = 1 - \mathcal{B}(\text{LQ} \to t\tau)$ for an integrated luminosity of 3 ab^{-1}in the two different scenarios. For all values of $\mathcal{B}$, LQ masses up to approximately 1200 GeV and 1400 GeV are expected to be in reach for a discovery at the 5σ level and a 95% C.L. exclusion, respectively.

5.2.2 Z' and leptoquarks for B decay anomalies at HL- and HE-LHC

Contributors: B. Allanach, T. Tevong You

Recent measurements of R_K^* and other b observables indicate that the $\bar{b}P_L s\bar{\mu}P_L\mu$ vertex may be receiving BSM corrections. Here, we examine simplified models that may predict such corrections at the tree-level: Z' models and leptoquark models depicted in Fig. 5.2.4.

The 'naïve' Z' model contains the Lagrangian pieces

$$\mathcal{L}_{Z'}^{\text{min.}} \supset \left(g_L^{sb} Z'_\rho \bar{s}\gamma^\rho P_L b + \text{h.c.}\right) + g_L^{\mu\mu} Z'_\rho \bar{\mu}\gamma^\rho P_L \mu\,, \tag{5.2.1}$$

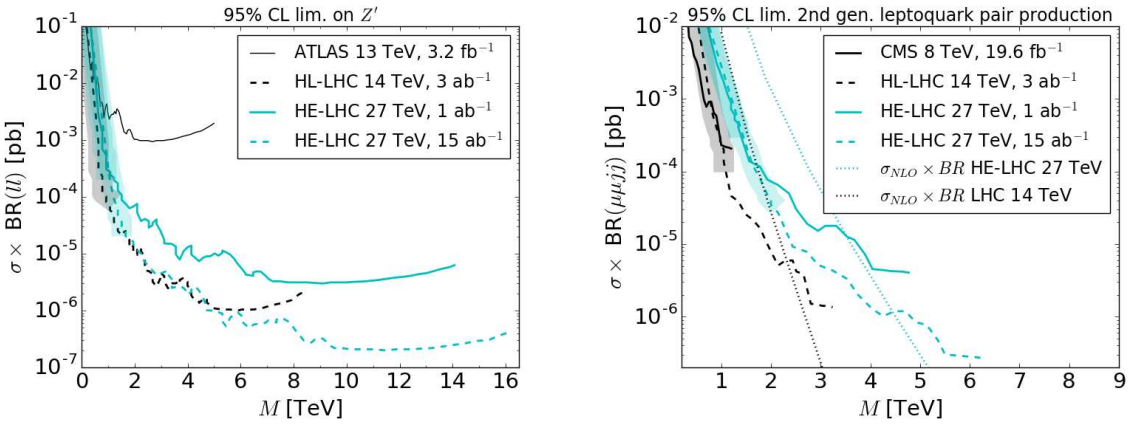

Fig. 5.2.5: Current bounds and projected sensitivities to the naïve Z' model. Left: bounds from a 3.2 fb^{-1} ATLAS Z' search in the $\mu^+\mu^-$ channel [419]. Right: bounds from a 19.6 fb^{-1} search for the process $gg \to \bar{S}_3 S_3 \to (\mu^- j)(\mu^+ j)$, these bounds were then used [420] to extrapolate to the HE-LHC and HL-LHC, and the predicted NLO production cross-sections for the production of the $S_3\bar{S}_3$ pairs.

whereas the more realistic '$33\mu\mu$' Z' model contains more couplings ($SU(2)_L$ and flavour copies):

$$\begin{aligned}\mathcal{L}^{33\mu\mu}_{Z'} \supset\, & g^q_L Z'_\rho \Big[\bar{t}\gamma^\rho P_L t + |V_{tb}|^2 \bar{b}\gamma^\rho P_L b + |V_{td}|^2 \bar{d}\gamma^\rho P_L d + |V_{ts}|^2 \bar{s}\gamma^\rho P_L s \\ & + \left(V_{tb}V^*_{ts}\bar{b}\gamma^\rho P_L s + V^*_{ts}V_{td}\bar{d}\gamma^\rho P_L s + V_{tb}V^*_{td}\bar{b}\gamma^\rho P_L d + \text{h.c.}\right) \\ & + g^{\mu\mu}_L \left(\bar{\mu}\gamma^\rho P_L \mu + \sum_{i,j} \bar{\nu}_i U_{i\mu}\gamma^\rho P_L U^*_{\mu j}\nu_j\right)\Big], \end{aligned} \tag{5.2.2}$$

where U denotes the PMNS matrix involved in lepton mixing. In a fit to 'clean' $b-$observables including $R_{K^{(*)}}$ Ref. [416], we have that, in the naïve Z' model,

$$|g^{sb}_L g^{\mu\mu}_L| = (1.0 \pm 0.25)\left(\frac{M_{Z'}}{31\text{ TeV}}\right)^2, \tag{5.2.3}$$

which we use to constrain the couplings and masses of the Z', (the $33\mu\mu$ model's Z' couplings to $\bar{s}b$ and $\mu^+\mu^-$ can also be matched to Eq. (5.2.1)).

There are particular combinations of quantum numbers allowed for the LQs [416–418], depending upon their spin. For the scalar case this is the triplet LQ S_3, with quantum numbers $(\bar{3}, 3, \frac{1}{3})$ under $SU(3)_c \times SU(2)_L \times U(1)_Y$ and mass M, whose Yukawa couplings to the third family left-handed quark and second family left-handed lepton doublets Q_3 and L_2 are of the form

$$y_{b\mu} Q_3 L_2 S_3 + y_{s\mu} Q_2 L_2 S_3 \text{h.c.}\,. \tag{5.2.4}$$

Its effect on the clean $b-$observables result in a constraint

$$|y_{sb} y_{b\mu}| = (1.00 \pm 0.25)\left(\frac{M}{31\text{ TeV}}\right)^2, \tag{5.2.5}$$

from the fit [416].

In Fig. 5.2.5, we display the projected sensitivities on the naïve Z' and scalar leptoquark models of the HE-LHC and HL-LHC, extrapolated from a 3.2 fb^{-1} ATLAS Z' resonance search in the $\mu^+\mu^-$ model as a function of Z' mass. The extrapolation is performed under the following approximations: changes in efficiency with respect to changing $\sqrt{s}$ or other changes to the operating environment are neglected, and

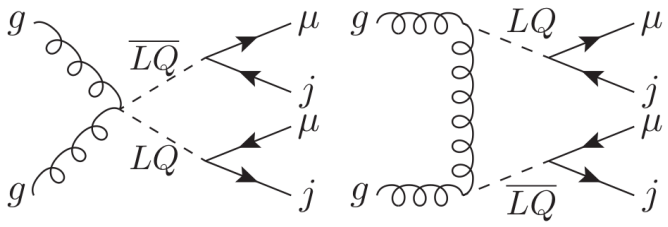

Fig. 5.2.6: Example processes contributing to $S_3\bar{S}_3$ production and subsequent decay at the LHC.

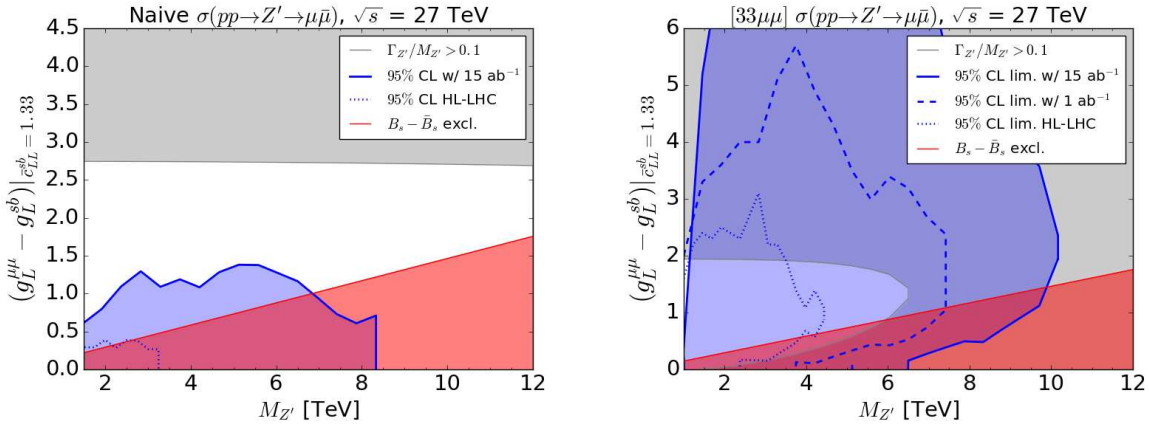

Fig. 5.2.7: Current bounds and projected sensitivities to Z' models explaining $R_{K^{(*)}}$. Each point in the plane has had the couplings adjusted to be consistent with the central value of Eq. (5.2.3). The red region is excluded from $B_s - \bar{B}_s$ mixing measurements, the blue region shows the expected 95% C.L. sensitive region and the greyed region is at width $\Gamma > 0.1 M_{Z'}$, meaning that the extrapolation used to calculate sensitivities (which uses the narrow width approximation) is inaccurate. The blue region shows the region of sensitivity. The vertical axis shows the difference between the muonic and the quark Z' coupling, initially intended to show when one is large compared to the other. However, the $B_s - \bar{B}_s$ mixing constraint implies that $g_L^{sb} \ll g_L^{\mu\mu}$ and so the vertical axis is equal to $g_L^{\mu\mu}$, to a good approximation.

the *narrow width* approximation is used. At strong coupling, the narrow width approximation becomes bad. In the right-hand plot, the sensitivity coming from the process $gg \to \bar{S}_3 S_3 \to \mu^+ j \mu^- j$ depicted in Fig. 5.2.6 is shown. The sensitivities are phrased in terms of production cross-section times BRs of final states on the vertical axis. In the LQ model, the production cross-section depends only upon the mass M of the LQ: its coupling is given by the QCD gauge coupling. We see that HL-LHC(HE-LHC) is sensitive to LQs of mass up to 2.5 (4.2) TeV for this topology. The $B_s - \bar{B}_s$ mixing constraint implies $\left|y_{b\mu} y^*_{s\mu}\right| < M/(26\ \text{TeV})$ for the S_3 LQ case. Combining this with Eq. (5.2.5) yields a bound $M < 40$ TeV[7] [416]. Thus, the HL-LHC and HE-LHC could probe a non-negligible fraction of the viable LQ parameter space.

For the Z' models, the production cross-section depends sensitively upon the coupling g_L^{bs}. If the coupling is large, Z's with masses up to 18 TeV can explain $R_K^{(*)}$ and still be compatible with bounds originating from $B_s - \bar{B}_s$ mixing measurements ($|g_L^{sb}| \leq M_{Z'}/148$ TeV) [416]. We display the relevant sensitivities and bounds upon flavourful Z' models in Fig. 5.2.7 as a function of coupling and mass. From the left hand panel, we see that the HL-LHC only probes a small fraction of the viable naïve Z' parameter space. However, when we examine more realistic model (the $33\mu\mu$ model) in the right-hand

[7] One can also consider singlet or triplet vector LQs whose joint constraints imply $M < 20, 40$ TeV, respectively, but whose sensitivities are equal to those of the S_3.

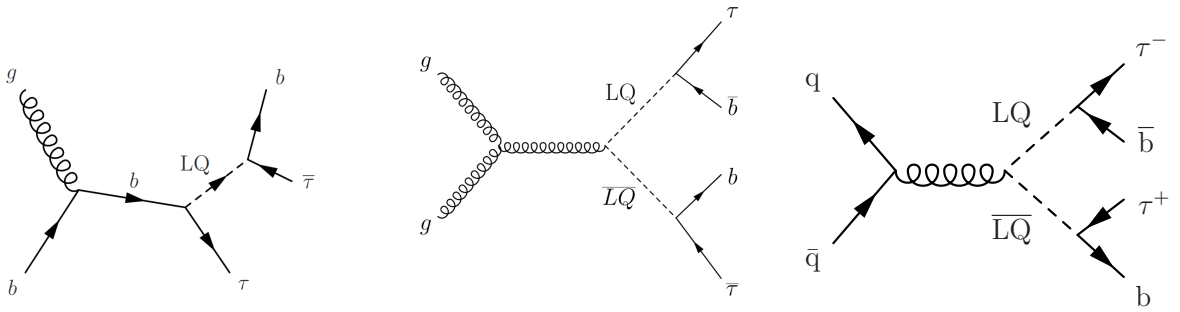

Fig. 5.2.8: Leading order Feynman diagrams for the production of a third-generation LQ in the single production s-channel (left) and the pair production channel via gluon fusion (centre) and quark fusion (right).

panel, we see that a large fraction of parameter space where the narrow width approximation applies is covered. These conclusions become stronger when one examines the sensitivity of the HE-LHC, as the solid lines display: the viable region of the $33\mu\mu$ model with narrow width approximation is completely covered, for example.

We note that the results presented herein represent only a rough estimation and further more detailed studies are desirable. In particular, the narrow width approximation in the case of the LQs is likely to be a rough approximation because one is really producing a pair of LQs. Our approximations effectively assume that they are produced at threshold. At higher luminosities or energies, the efficiency for identifying isolated muons will change, as well as the efficiencies for identifying jets. This could be better estimated by performing Monte-Carlo event generation studies together with a detector simulation rather than extrapolating current limits from the LHC.

5.2.3 Search for leptoquarks decaying to τ and b at HL-LHC

Contributors: Y. Takahashi, P. Matorras, CMS

Third-generation scalar LQs have recently received considerable interest from the theory community, as the existence of leptoquarks with large couplings can explain the anomaly in the $\overline{\mathrm{B}} \to \mathrm{D}\tau\overline{\nu}$ and $\overline{\mathrm{B}} \to \mathrm{D}^{*}\tau\overline{\nu}$ decay rates reported by the BaBar [421, 422], Belle [423–428], and LHCb [429] Collaborations.

This analysis from CMS [430] presents future discovery and exclusion prospects for singly and pair produced third-generation scalar LQs, each decaying to τ_h and a bottom quark. Here, τ_h denotes a hadronically decaying τ lepton. The relevant Feynman diagrams of the signal processes at leading order (LO) are shown in Fig. 5.2.8.

The analysis uses DELPHES [33] event samples of simulated pp collisions at a c.o.m. energy of 14 TeV, corresponding to integrated luminosities of 300 $\mathrm{fb}^{-1}$and 3 ab^{-1}. The matrix elements of LQ signals for both single and pair LQ production are generated at LO using version 2.6.0 of MADGRAPH5_aMC@NLO [67] for $m_{LQ} = 500$, 1000, 1500, and 2000 GeV. The branching fraction β of the LQ to a charged lepton and a quark, in this case LQ$\to \tau b$, is assumed to be $\beta = 1$. The unknown Yukawa coupling λ of the LQ to a τ lepton and a bottom quark is set to $\lambda = 1$. The width Γ is calculated using $\Gamma = m_{LQ}\lambda^2/(16\pi)$ [431], and is less than 10% of the LQ mass for most of the considered search range. The signal samples are normalised to the cross section calculated at LO, multiplied by a K factor to account for higher order contributions [432].

Similar event selections are used in both the singly and pair produced LQ searches, except for the requirement on the number of jets. In both channels, two reconstructed τ_h with opposite-sign charge are required, each with transverse momentum $p_{T,\tau} > 50$ GeV and a maximum pseudorapidity $|\eta_\tau| < 2.3$. In the search for single production, the presence of at least one reconstructed jet with $p_T > 50$ GeV is required, while at least two are required in the search for pair production. Jets are reconstructed with FASTJET [35], using the anti-k_{T} algorithm [34], with a distance parameter of 0.4.

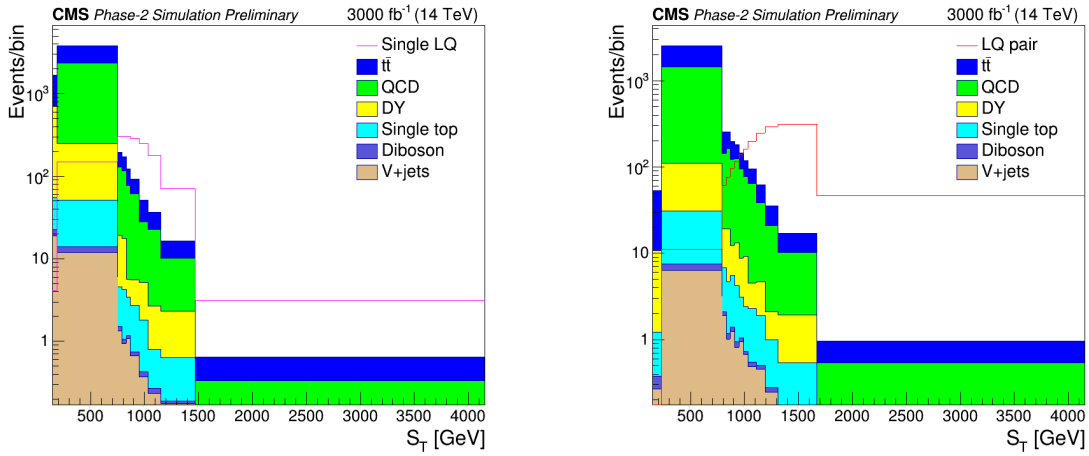

Fig. 5.2.9: Left: scalar sum of the p_T of the two selected τ leptons and the highest-p_T jet in the single LQ selection region. Right: scalar sum of the p_T of the two selected τ leptons and the two highest-p_T jets in the LQ pair search region. The considered backgrounds are shown as stacked histograms, while empty histograms for signals for the single LQ and LQ pair channels (for $m_{LQ} = 1000$ GeV) are overlaid to illustrate the sensitivity. Both signal and background are normalised to a luminosity of 3 ab^{-1}.

To reduce background due to Drell-Yan (particularly Z$\rightarrow \tau\tau$) events, the invariant mass of the two selected τ_h, $m_{\tau\tau}$, is required to be > 95 GeV. In addition, at least one of the previously selected jets is required to be b-tagged to reduce QCD multijet backgrounds. Finally, an event is rejected if it contains an identified and isolated electron (muon), with $p_T > 10$ GeV, $|\eta| < 2.4$ (2.5). The acceptance of the signal events is 4.9% (11%) for single (pair) production, where the branching ratio of two τ leptons decaying hadronically is included in the numerator of the acceptance.

Signal extraction is based on a binned maximum likelihood fit to the distribution of the scalar p_T sum S_T, which is defined as the sum of the transverse momenta of the two τ_h and either the highest-p_T jet in the case of single LQ production, or the two highest-p_T jets in the case of LQ pair production. These distributions are shown in Fig. 5.2.9 for the HL-LHC 3 ab^{-1} scenario.

Systematic uncertainties are calculated by scaling the current experimental uncertainties. For uncertainties limited by statistics, including the uncertainty on the DY (3.3%) and QCD (3.3%) cross sections, a scale factor of $1/\sqrt{\mathcal{L}}$ is applied, for an integrated luminosity ratio $\mathcal{L}$. For uncertainties coming from theoretical calculations, a scale factor of $1/2$ is applied with respect to current uncertainties, as is the case for the uncertainties on the cross section for top (2.8%) or diboson (3%) events. Other experimental systematic uncertainties are scaled by the square root of the integrated luminosity ratio until the uncertainty reaches a minimum value, including uncertainties on the integrated luminosity (1%), τ identification (5%) and b-tagging/misidentification (1%/5%).

Figure 5.2.10 shows an upper limit at 95% C.L. on the cross section times branching fraction β as a function of m_{LQ} by using the asymptotic CLs modified frequentist criterion [94, 95, 257, 433]. Upper limits are calculated considering two different scenarios. The first one, hereafter abbreviated as "stat. only" considers only statistical uncertainties, to observe how the results are affected by the increase of the integrated luminosity. The second scenario, hereafter abbreviated as "stat.+syst.," also includes the estimate of the systematic uncertainties at the HL-LHC. For the single LQ production search, the theoretical prediction for the cross section assumes $\lambda = 1$ and $\beta = 1$.

Comparing the limits with theoretical predictions assuming unit Yukawa coupling $\lambda = 1$, third-generation scalar leptoquarks are expected to be excluded at 95% C.L. for LQ masses below 730 (1250) GeV for a luminosity of 300 fb^{-1}, and below 1130 (1520) GeV for 3 ab^{-1} in the single (pair) production channel, considering both statistical and systematic uncertainties.

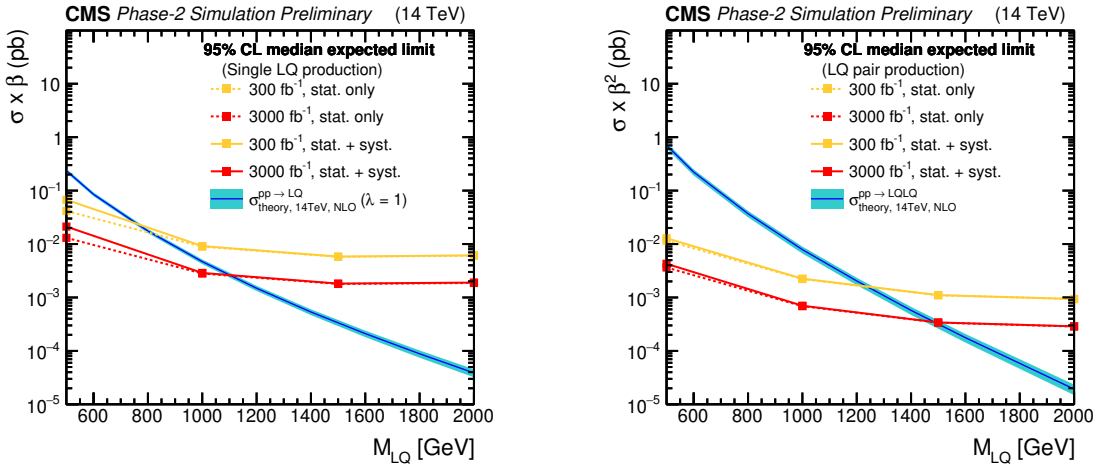

Fig. 5.2.10: Expected limits at 95% C.L. on the product of the cross section σ and the branching fraction β, as a function of the LQ mass, for the two high luminosity projections, 300 fb^{-1} (red) and 3 ab^{-1} (orange), for both the stat. only (dashed lines) and the stat.+syst. scenarios (solid lines). This is shown in conjunction with the theoretical predictions at NLO [432] in cyan. Projections are calculated for both the single LQ (left) and LQ pair production (right).

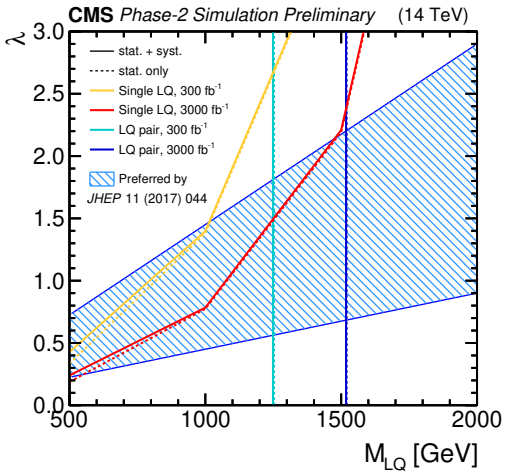

Fig. 5.2.11: Expected exclusion limits at 95% C.L. on the Yukawa coupling λ at the LQ-lepton-quark vertex, as a function of the LQ mass. A unit branching fraction β of the LQ to a τ lepton and a bottom quark is assumed. Future projections for 300 fb^{-1} and 3 ab^{-1} are shown for both the stat. only and stat.+syst. scenarios, shown as dashed and filled lines respectively, and for both the single LQ and LQ pair production, where the latter corresponds to the vertical line (since it does not depend on λ). The left hand side of the lines represents the exclusion region for each of the projections, whereas the region with diagonal blue hatching shows the parameter space preferred by one of the models proposed to explain anomalies observed in B physics [434].

Since the single-LQ signal cross section scales with λ^2, it is straightforward to recast the results presented in Fig. 5.2.10 in terms of expected upper limits on m_{LQ} as a function of λ, as shown in Fig. 5.2.11. The blue band shows the parameter space (95% C.L.) for the scalar LQ preferred by the B physics anomalies: $\lambda = (0.95 \pm 0.50) m_{LQ}(\mathrm{TeV})$ [434]. For the 300 (3000) fb^{-1} luminosity scenario, the leptoquark pair production channel is more sensitive if $\lambda < 2.7$ (2.3), while the single leptoquark production is dominant otherwise.

Using the predicted cross section [432] of the signal, it is also possible to estimate the maximal

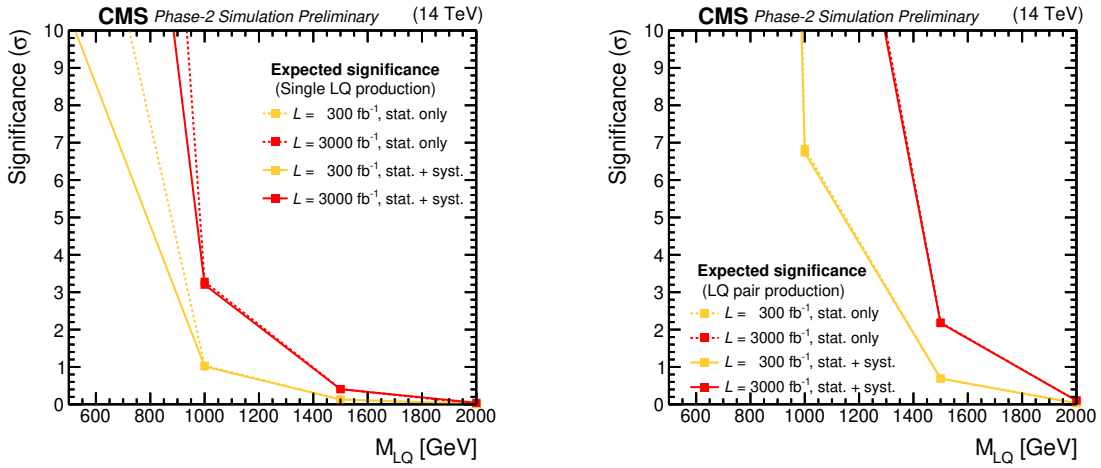

Fig. 5.2.12: Expected local significance of a signal-like excess as a function of the LQ mass, for the two high luminosity projections, 300 fb^{-1} (red) and 3 ab^{-1} (orange), assuming the theoretical prediction for the LQ cross section at NLO [432], calculated with $\lambda = 1$ and $\beta = 1$. Projections are calculated for both single LQ (left) and LQ pair production (right).

LQ mass expected to be in reach for a 5σ discovery. Figure 5.2.12 shows the expected local significance of a signal-like excess as a function of the LQ mass hypothesis.

In summary, this study shows that future LQ searches under higher luminosity conditions are promising, as they are expected to greatly increase the reach of the search. They also show that the pair production channel is expected to be the most sensitive. A significance of 5σ is within reach for LQ masses below 800 (1200) GeV for the single (pair) production channels in the 300 fb^{-1} scenario and 1000 (1500) GeV for the 3 ab^{-1} scenario.

5.2.4 HE-LHC sensitivity study for leptoquarks decaying to $\tau + b$

Contributors: A. Greljo and L. Mittnacht

We analysed the sensitivity of the 27 TeV pp collider with 15 ab^{-1} of integrated luminosity to probe pair production of the scalar and vector leptoquarks decaying to $(b\tau)$ final state. We investigated events containing either one electron or muon, one hadronically decaying tau lepton, and at least two jets. The signal events and the dominant background events $(t\bar{t})$ were generated with MADGRAPH5_aMC@NLO at leading-order. PYTHIA 6 was used to shower and hadronise events and DELPHES 3 was used to simulate the detector response. The scalar leptoquark (r_{23}) and the vector leptoquark (U_1) UFO model files were taken from Ref. [432].

To verify the procedure, we simulated the $t\bar{t}$ background and the scalar leptoquark signal at 13 TeV and compared to the predicted shapes in the S_T distribution from the existing CMS analysis [435]. After we verified the 13 TeV analysis, we simulated the signal and the dominant background events at 27 TeV. From these samples, we selected all events satisfying the particle content requirements and applied the lower cut in the S_T variable. The cut threshold was chosen to maximise $s/\sqrt{b}$ while requiring at least 2 expected signal events at an integrated luminosity of 15 ab^{-1}. In the case of the vector leptoquark we considered the Yang-Mills ($\kappa = 1$) and the minimal coupling ($\kappa = 0$) scenarios [432]. From the simulations of the scalar and vector leptoquark events, we found the ratio of the cross-sections, and assuming similar kinematics, we estimated the sensitivity also for the vector leptoquark U_1.

As shown in Fig. 5.2.13, the HE-LHC collider will be able to probe pair produced third generation scalar leptoquark (decaying exclusively to $b\tau$ final state) up to mass of $\sim$ 4 TeV and vector leptoquark up to $\sim$ 4.5 TeV and $\sim$ 5.2 TeV for the minimal coupling and Yang-Mills scenarios, respectively.

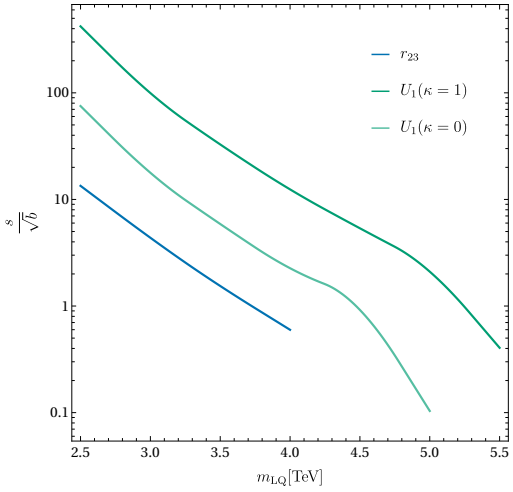

Fig. 5.2.13: Expected sensitivity for pair production of scalar (r_{23}) and vector (U_1) leptoquark at 27 TeV pp collider with an integrated luminosity of 15 ab^{-1}.

While this result is obtained by a rather crude analysis, it shows the impressive reach of the future high-energy pp-collider. In particular, the HE-LHC will cut deep into the relevant perturbative parameter space for $b \to c\tau\nu$ anomaly. As a final comment, this is a rather conservative estimate of the sensitivity to leptoquark models solving $R(D^*)$ anomaly, since a dedicated single leptoquark production search is expected to yield even stronger bounds [432, 434].

5.3 High p_T implications of flavour anomalies

Contributors: A. Celis, A. Greljo, L. Mittnacht, M. Nardecchia, T. You

Precision measurements of flavour transitions at low energies, such as flavour changing B, D and K decays, are sensitive probes of hypothetical dynamics at high energy scales. These can provide the first evidence of new BSM phenomena, even before direct discovery of new particles at high energy colliders. Indeed, the current anomalies observed in B-meson decays, the charge current one in $b \to c\tau\nu$ transitions, and neutral current one in $b \to s\ell^+\ell^-$, may be the first hint of new dynamics which is still waiting to be discovered at high-p_T. When considering models that can accommodate the anomalies, it is crucial to analyse the constraints derived from high-p_T searches at the LHC, since these can often rule out significant regions of model parameter space. Below we review these constraints, and assess the impact of the HL- and HE-LHC upgrades.

5.3.1 EFT analysis

If the dominant NP effects give rise to dimension-six SMEFT operators, the low-energy flavour measurements are sensitive to C/Λ^2, with C the dimensionless NP Wilson coefficient and Λ the NP scale. The size of the Wilson coefficient is model dependent, and thus so is the NP scale required to explain the $R_{D^{(*)}}$ and $R_{K^{(*)}}$ anomalies. Perturbative unitarity sets an upper bound on the energy scale below which new dynamics need to appear [436]. The conservative bounds on the scale of unitarity violation are $\Lambda_U = 9.2$ TeV and 84 TeV for $R_{D^{(*)}}$ and $R_{K^{(*)}}$, respectively, obtained when the flavour structure of NP operators is exactly aligned with what is needed to explain the anomalies. More realistic frameworks for flavour structure, such as MFV, $U(2)$ flavour models, or partial compositeness, give rise to NP effective operators with largest effects for the third generation. This results in stronger unitarity bounds, $\Lambda_U = 1.9$ TeV and 17 TeV for $R_{D^{(*)}}$ and $R_{K^{(*)}}$, respectively. These results mean that: *(i)* the mediators responsible for the $b \to c\tau\nu$ charged current anomalies are expected to be in the energy range of the LHC, *(ii)* the mediators responsible for the $b \to s\ell\ell$ neutral current anomalies could well be above the energy range of the LHC. However, in realistic flavour models also these mediators typically fall within

the (HE-)LHC reach.

If the neutrinos in $b \to c\tau\nu$ are part of a left-handed doublet, the NP responsible for $R_{D^{(*)}}$ anomaly generically implies a sizeable signal in $pp \to \tau^+\tau^-$ production at high-p_T. For realistic flavour structures, in which $b \to c$ transition is $\mathcal{O}(V_{cb})$ suppressed compared to $b \to b$, one expects rather large $bb \to \tau\tau$ NP amplitude. Schematically, $\Delta R_{D^{(*)}} \sim C_{bb\tau\tau}(1 + \lambda_{bs}/V_{cb})$, where $C_{bb\tau\tau}$ is the size of effective dim-6 interactions controlling $bb \to \tau\tau$, and λ_{bs} is a dimensionless parameter controlling the size of flavour violation. Recasting ATLAS 13 TeV, 3.2 fb^{-1} search for $\tau^+\tau^-$ [437], Ref. [438] showed that $\lambda_{bs} = 0$ scenario is already in slight tension with data. For $\lambda_{bs} \sim 5$, which is moderately large, but still compatible with FCNC constraints, HL (or even HE) upgrade of the LHC would be needed to cover the relevant parameter space implied by the anomaly (see Ref. [434]). For large λ_{bs} the limits from $pp \to \tau^+\tau^-$ become comparable with direct the limits on $pp \to \tau\nu$ from the bottom-charm fusion. The limits on the EFT coefficients from $pp \to \tau\nu$ were derived in Ref. [439], and the future LHC projections are promising. The main virtue of this channel is that the same four-fermion interaction is compared in $b \to c\tau\nu$ at low energies and $bc \to \tau\nu$ at high-p_T. Since the effective NP scale in $R(D^{(*)})$ anomaly is low, the above EFT analyses are only indicative. For more quantitative statements we review below bounds on explicit models.

The hints of NP in $R_{K^{(*)}}$ require a $(bs)(\ell\ell)$ interaction. Correlated effects in high-p_T tails of $pp \to \mu^+\mu^-(e^+e^-)$ distributions are expected, if the numerators (denominators) of LFU ratios $R_{K^{(*)}}$ are affected. Reference [440] recast the 13 TeV 36.1 fb^{-1} ATLAS search [441] (see also Ref. [442]), to set limits on a number of semi-leptonic four-fermion operators, and derive projections for HL-LHC (see Ref. [440]). These show that direct limits on the $(bs)(\ell\ell)$ operator from the tails of distributions will never be competitive with those implied by the rare B-decays [440,443]. On the other hand, flavour conserving operators, $(qq)(\ell\ell)$, are efficiently constrained by the high p_T tails of the distributions. The flavour structure of an underlining NP could thus be probed by constraining ratios $\lambda^q_{bs} = C_{bs}/C_{qq}$ with C_{bs} fixed by the $R_{K^{(*)}}$ anomaly. For example, in models with MFV flavour structure, so that $\lambda^{u,d}_{bs} \sim V_{cb}$, the present high-$p_T$ dilepton data is already in slight tension with the anomaly [440]. Instead, if couplings to valence quarks are suppressed, *e.g.*, if NP dominantly couples to the 3rd family SM fermions, then $\lambda^b_{bs} \sim V_{cb}$. Such NP will hardly be probed even at the HL-LHC, and it is possible that NP responsible for the neutral current anomaly might stay undetected in the high-p_T tails at HL-LHC and even at HE-LHC. Future data will cover a significant part of viable parameter space, though not completely, so that discovery is possible, but not guaranteed.

5.3.2 *Constraints on simplified models for $b \to c\tau\nu$*

Since the $b \to c\tau\nu$ decay is a tree-level process in the SM that receives no drastic suppression, models that can explain these anomalies necessarily require a mediator that contributes at tree-level:

- *SM-like W'*: A SM-like W' boson, coupling to left-handed fermions, would explain the approximately equal enhancements observed in $R(D)$ and $R(D^*)$. A possible realisation is a colour-neutral real $SU(2)_L$ triplet of massive vector bosons [444]. However, typical models encounter problems with current LHC data since they result in large contributions to $pp \to \tau^+\tau^-$ cross-section, mediated by the neutral partner of the W' [438,444,445]. For $M_{W'} \gtrsim 500$ GeV, solving the $R(D^{(*)})$ anomaly within the vector triplet model while being consistent with $\tau^+\tau^-$ resonance searches at the LHC is only possible if the related Z' has a large total decay width [438]. Focusing on the W', Ref. [446] analysed the production of this mediator via gg and gc fusion, decaying to $\tau\nu_\tau$. Reference [446] concluded that a dedicated search using that a b-jet is present in the final state would be effective in reducing the SM background compared to an inclusive analysis that relies on τ-tagging and $E_T^{\rm miss}$. Nonetheless, relevant limits will be set by an inclusive search in the future [439].

- *Right-handed W':* Ref.s [447,448] recently proposed that W' could mediate a right-handed interac-

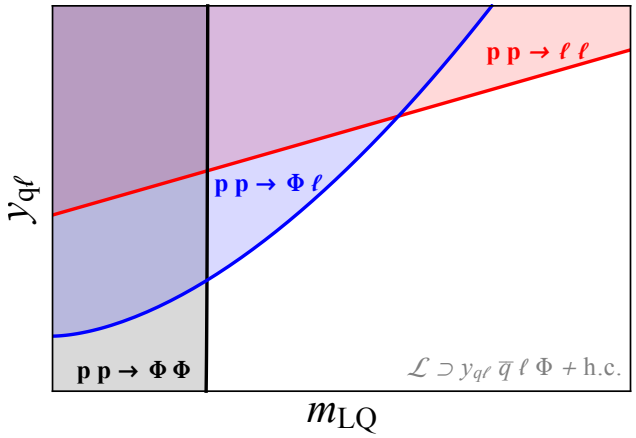

Fig. 5.3.1: Schematic of the LHC bounds on LQ showing complementarity in constraining the (m_{LQ}, y_{q_ℓ}) parameters. The three cases are: pair production $\sigma \propto y^0_{q_\ell}$, single production $\sigma \propto y^2_{q_\ell}$ and Drell-Yan $\sigma \propto y^4_{q_\ell}$ (from Ref. [432]).

tion, with a light sterile right-handed neutrino carrying the missing energy in the B decay. In this case, it is possible to completely uncorrelate FCNC constraints from $R(D^{(*)})$. The most constraining process in this case is instead $pp \to \tau\nu$. Reference [439] performed a recast of the latest ATLAS and CMS searches at 13 TeV and about 36 fb^{-1} to constrain most of the relevant parameter space for the anomaly.

• *Charged Higgs $H^\pm$:* Models that introduce a charged Higgs, for instance a two-Higgs-doublet model, also contain additional neutral scalars. Their masses are constrained by EW precision measurements to be close to that of the charged Higgs. Accommodating the $R(D^{(*)})$ anomalies with a charged Higgs typically implies large new physics contributions to $pp \to \tau^+\tau^-$ via the neutral scalar exchanges, so that current LHC data can challenge this option [438]. Note that a charged Higgs also presents an important tension between the current measurement of $R(D^*)$ and the measured lifetime of the B_c meson [449–452].

• *Leptoquarks:* The observed anomalies in charged and neutral currents appear in semileptonic decays of the B-mesons. This implies that the putative NP has to couple to both quarks and leptons at the fundamental level. A natural BSM option is to consider mediators that couple simultaneously quarks and leptons at the tree level. Such states are commonly referred as leptoquarks. Decay and production mechanisms of the LQ are directly linked to the physics required to explain the anomalous data.

– **Leptoquark decays:** the fit to the $R(D^*)$ observables suggest a rather light leptoquark (at the TeV scale) that couples predominately to the third generation fermions of the SM. A series of constraints from flavour physics, in particular the absence of BSM effects in kaon and charm mixing observables, reinforces this picture.
– **Leptoquark production mechanism:** The size of the couplings required to explain the anomaly is typically very large, roughly $y_{q\ell} \approx m_{LQ}/$ (1 TeV). Depending of the actual sizes of the leptoquark couplings and its mass we can distinguish three regimes that are relevant for the phenomenology at the LHC:

  1. LQ pair production due to strong interactions,
  2. Single LQ production plus lepton via a single insertion of the LQ coupling, and
  3. Non-resonant production of di-lepton through t-channel exchange of the leptoquark.

  Interestingly all three regimes provide complementary bounds in the (m_{LQ}, y_{q_ℓ}) plane, see Fig. 5.3.1.

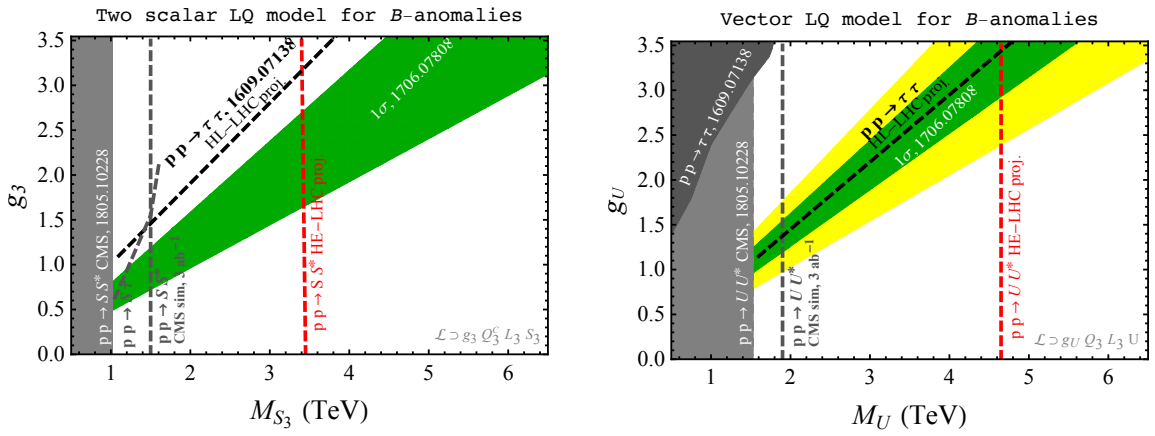

Fig. 5.3.2: Present constraints and HE and HL-LHC reach in the LQ mass versus coupling plane for the scalar leptoquark S_3 (left), and vector leptoquark U_1 (right). The grey and dark grey solid regions are the current exclusions. The grey and black dashed lines are the projected reach for HL-LHC (pair production prospects are based on Section 5.2.3). The red dashed lines are the projected reach at HL-LHC (see Section 5.2.4). The green and yellow bands are the 1σ and 2σ preferred regions from the fit to B physics anomalies. The second coupling required to fit the anomaly does not enter in the leading high-p_T diagrams but is relevant for fixing the preferred region shown in green, for more details see Ref. [434].

Several simplified models with a leptoquark as a mediator were shown to be consistent with the low-energy data. A vector leptoquark with $SU(3)_c \times SU(2)_L \times U(1)_Y$ SM quantum numbers $U_\mu \sim (\mathbf{3}, \mathbf{1}, 2/3)$ was identified as the only single mediator model which can simultaneously fit the two anomalies (see *e.g.* Ref. [434] for a recent fit including leading RGE effects). In order to substantially cover the relevant parameter space, one needs future HL- (HE-) LHC, see Fig. 5.3.2 (right) (see also Ref. [434] for details on the present LHC constraints). A similar statement applies to an alternative model featuring two scalar leptoquarks, S_1, S_3 [453], with the projected reach at CLIC and HL-LHC shown in Fig. 5.3.2 (left) (see Ref. [454] shows details on present LHC constraints).

Leptoquarks states are emerging as the most convincing mediators for the explanations of the flavour anomalies. It is then important to explore all the possible signatures at the the HL- and HE-LHC. The experimental program should focus not only on final states containing quarks and leptons of the third generation, but also on the whole list of decay channels including the off-diagonal ones ($b\mu$, $s\tau$, ...). The completeness of this approach would shed light on the flavour structure of the putative New Physics.

Another aspect to be emphasised concerning leptoquark models for the anomalies is the fact of the possible presence of extra fields required to complete the UV Lagrangian. The accompanying particles would leave more important signatures at high p_T than the leptoquark, this is particularly true for vector leptoquark extensions (see, for example, Ref. [455, 456]).

As a final remark, it is important to remember that the anomalies are not yet experimentally established. Among others, this also means that the statements on whether or not the high p_T LHC constraints rule out certain $R(D^{(*)})$ explanations assumes that the actual values of $R(D^{(*)})$ are given by their current global averages. If future measurements decrease the global average, the high $p_T$constraints can in some cases be greatly relaxed and HL- and/or HE-LHC may be essential for these, at present tightly constrained, cases.

5.3.3 Constraints on simplified models for $b \to sll$

The $b \to sll$ transition is both loop and CKM suppressed in the SM. The explanations of the $b \to sll$ anomalies can thus have both tree level and loop level mediators. Loop-level explanations typically

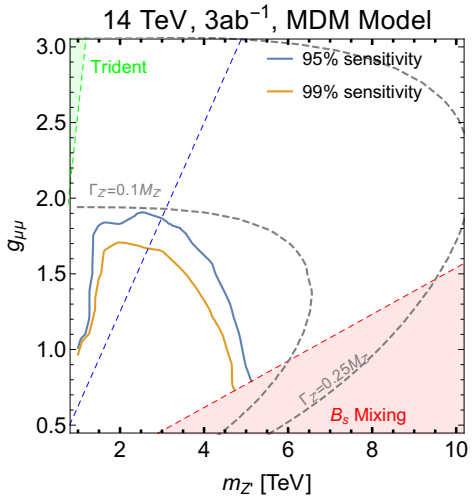

Fig. 5.3.3: HL-LHC 95% (blue) and 99% (orange) C.L. sensitivity contours to Z' in the "mixed-down" model for $g_{\mu\mu}$ vs Z' mass in TeV. The dashed grey contours give the Z' width as a fraction of mass. The green and red regions are excluded by trident neutrino production and B_s mixing, respectively. The dashed blue line is the stronger B_s mixing constraint from Ref. [457]. See also Section 5.2.2.

involve lighter particles. Tree-level mediators can also be light, if sufficiently weakly coupled. However, they can also be much heavier—possibly beyond the reach of the LHC.

• *Tree-level mediators:*
For $b \to sll$ anomaly there are two possible tree-level UV-completions, the Z' vector boson and leptoquarks, either scalar or vector. For leptoquarks, Fig. 5.2.5 (right) shows the current 95% C.L. limits from 8 TeV CMS with 19.6 fb^{-1} in the $\mu\mu jj$ final state (solid black line), as well as the HL-LHC (dashed black line) and 1 (10) ab^{-1} HE-LHC extrapolated limits (solid (dashed) cyan line). Dotted lines give the cross-sections times BR at the corresponding collider energy for pair production of scalar leptoquarks, calculated at NLO using the code of Ref. [412]. We see that the sensitivity to a leptoquark with only the minimal $b-\mu$ and $s-\mu$ couplings reaches around 2.5 and 4.5 TeV at the HL-LHC and HE-LHC, respectively. This pessimistic estimate is a lower bound that will typically be improved in realistic models with additional flavour couplings. Moreover, the reach can be extended by single production searches [420], albeit in a more model-dependent way than pair production. The cross section predictions for vector leptoquark are more model-dependent and are not shown in Fig. 5.2.5 (right). For $\mathcal{O}(1)$ couplings the corresponding limits are typically stronger than for scalar leptoquarks.

For the Z' mediator the minimal couplings in the mass eigenstate basis are obtained by unitary transformations from the gauge eigenstate basis, which necessarily induces other couplings. Reference [458] defined the "mixed-up" model (MUM) and "mixed-down" model (MDM) such that the minimal couplings are obtained via CKM rotations in either the up or down sectors respectively. For MUM there is no sensitivity at the HL-LHC. The predicted sensitivity at the HL-LHC for the MDM is shown in Fig. 5.3.3 as functions of Z' muon coupling $g_{\mu\mu}$ and the Z' mass, setting the Z' coupling to b and s quarks such that it solves the $b \to s\ell\ell$ anomaly. The solid blue (orange) contours give the 95% and 99% C.L. sensitivity. The red and green regions are excluded by B_s mixing [459] and neutrino trident production [460, 461], respectively. The more stringent B_s mixing constraint from Ref. [457] is denoted by the dashed blue line; see, however, Ref. [462] for further discussion regarding the implications of this bound. The dashed grey contours denote the width as a fraction of the mass. We see that the HL-LHC will only be sensitive to Z'' with narrow width, up to masses of 5 TeV.

At the HE-LHC, the reach for 10 ab^{-1} is shown in Fig. 5.3.4 for the MUM and MDM on the left and right, respectively. In this case the sensitivity may reach a Z' with wider widths up to 0.25 and 0.5 of its mass, while the mass extends out to 10 to 12 TeV. We stress that this is a pessimistic estimate of

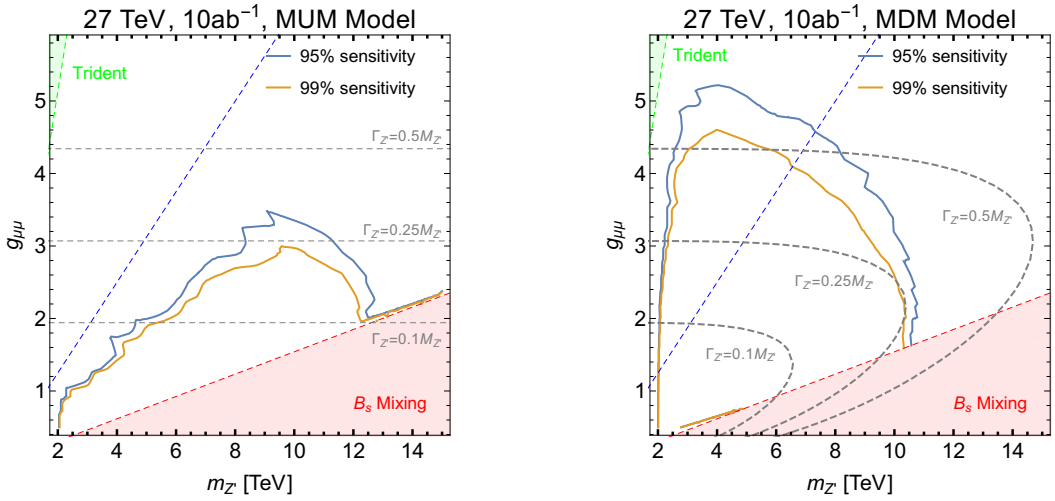

Fig. 5.3.4: HE-LHC 95% (blue) and 99% (orange) C.L. sensitivity contours to Z' in the "mixed-up" (left) and "mixed-down" (right) model in the parameter space of $g_{\mu\mu}$ vs Z' mass in TeV. The dashed grey contours are the width as a fraction of mass. The green and red regions are excluded by trident neutrino production and B_s mixing. The dashed blue line is the stronger B_s mixing constraint from Ref. [457]. See also Section 5.2.2.

the projected sensitivity, particular to the two minimal models; more realistic scenarios will typically be easier to discover.

• *Explanations at the one-loop level:*
It is possible to accommodate the $b \to s\ell^+\ell^-$ anomalies even if mediators only enter at one-loop. One possibility are the mediators coupling to right-handed top quarks and to muons [463–467]. Given the loop and CKM suppression of the NP contribution to the $b \to s\ell^+\ell^-$ amplitude, these models can explain the $b \to s\ell^+\ell^-$ anomalies for a light mediator, with mass around $\mathcal{O}(1)$ TeV or lighter. Constraints from the LHC and future projections for the HL-LHC were derived in Ref. [467] by recasting di-muon resonance, $pp \to t\bar{t}t\bar{t}$ and SUSY searches. Two scenarios were considered: *i)* a scalar LQ $R_2(3, 2, 7/6)$ combined with a vector LQ $\widetilde{U}_{1\alpha}(3, 1, 5/3)$, *ii)* a vector boson Z' in the singlet representation of the SM gauge group. Reference [466] also analysed the HL-LHC projections for the Z'. The constraints from the LHC already rule out part of the relevant parameter space and the HL-LHC will be able to cover much of the remaining regions. Dedicated searches in the $pp \to t\bar{t}t\bar{t}$ channel and a dedicated search for $t\mu$ resonances in $t\bar{t}\mu^+\mu^-$ final state can improve the sensitivity to these models [467].

6 Other BSM signatures

New physics models aimed at extending the SM either to overcome some of its theoretical puzzles, like the EW, flavour and strong CP "hierarchies", or by the need of explaining new phenomena, such as neutrino masses, Dark Matter, and baryogenesis, often predict signatures that are very different from the common SUSY ones, due to the absence of large missing transverse energy. These signatures are instead usually characterised by on-shell resonances, singly or doubly produced, depending on their quantum numbers, that decay into visible SM particles.

The lack so far of hints of new physics at the LHC, has typically required an increased level of complication in models addressing the aforementioned puzzles. Many of these complicated, though well motivated scenarios, are not always the best reference to clearly and simply evaluate the potential of a future collider. Often, as in the case of SUSY, considering simplified models inspired by more motivated, but involved constructions, constitutes the best choice to provide target experimental signatures. These targets are perfectly suited to evaluate the potential of future collider upgrades or new future colliders, and to compare them. Moreover, one can also try to answer questions such as what is the sensitivity to discriminate models given a discovery.

Usual standard scenarios include singly-produced resonances, with integer spin, decaying to two SM fermions or bosons, and pair-produced heavy fermion resonances, decaying to SM bosons and fermions. Most of these cases will be covered in this section, where the main "metric" to evaluate collider performances is the reach in the mass of these resonances, or the reach in covering a mass vs. coupling parameter space. The experimental signatures can be rather clean, like in the case of dilepton resonances, where the reach is usually limited by statistical uncertainties, or they can instead be affected by large SM backgrounds, especially in the hadronic channels, where the reach is typically limited by systematic uncertainties.

This section presents several results considering a broad variety of signatures and new physics scenarios. Of course the list is far from complete in terms of its coverage of possible BSM scenarios. However, it provides a clear and wide enough picture of the potential of the HL- and HE-LHC in terms of reach on heavy states, and coverage of their parameter space.

Finally, notwithstanding that the presented results contain a very detailed study of future prospects, that should serve as a reference for future studies, the global message of this section is that the HL-LHC will be able to extend the present LHC mass reach on heavy objects typically by $\sim 20 - 50\%$. Furthermore, HL-LHC will also be able to constrain, and potentially discover, new physics that is presently unconstrained. Concerning the HE-LHC, the conclusion is often a doubled mass reach, beyond HL-LHC, on heavy objects.

The results are presented considering a categorisation in terms of the spin of the studied resonances, which usually reflects in the final states considered. We therefore present sections containing spin 0 and 2 (Section 6.1), spin 1 (Section 6.2) and spin 1/2 resonances (Section 6.3). Additional prospect analyses that are more signature-based and could enter in more than one of the first three sections, have been collected in the last Section 6.4.

6.1 Spin 0 and 2 resonances

We present here several results concerning the production and decay of spin 0 and 2 particles decaying into several different SM final states. These range from resonant double Higgs production through a spin-2 KK graviton, to heavy scalar singlets that could mix with the Higgs, making the interplay with Higgs coupling measurements a crucial ingredient, from light pseudoscalar and axion-like particles to colour octet scalars.

6.1.1 *Resonant double Higgs production in the 4b final state at the HL-LHC*

Contributors: S. Willocq and A. Miller, ATLAS

The projection study in Ref. [468], summarised here, uses the search for high-mass spin-2 KK gravitons decaying into two Higgs bosons, HH, as a benchmark, with each of the Higgs bosons decaying to $b\bar{b}$, thereby yielding a final state with two highly boosted $b\bar{b}$ systems, which are reconstructed as two large-radius jets. The following strategy is followed to obtain sensitivity estimates at the HL-LHC: (i) signal and background mass distributions for the pair of candidate Higgs bosons in the event are taken from the most recent ATLAS data analysis at $\sqrt{s} = 13$ TeV [274] and scaled to 3 ab^{-1}; (ii) simulated signal and background mass distributions are used to derive mass-dependent scaling functions to extrapolate the distributions from $\sqrt{s} = 13$ TeV to 14 TeV; (iii) simulated signal and background mass distributions are used for further scaling of the distributions to reproduce the impact of additional selection criteria not included in Run-2 searches.

The dominant background for the 13 TeV data analysis stems from multijet production. This background source is estimated directly from data in that analysis and represents about 80%, 90%, and 95% of the total background in the signal region for events with 2, 3, and 4 b-tags (the classification of events based on the number of b-tags is described below). The remaining source of background originates almost completely from $t\bar{t}$ production. The shape of the dijet mass distribution for $t\bar{t}$ events is taken from MC samples. The normalisation of the $t\bar{t}$ background in Ref. [274] is extracted from a fit to the leading large-R jet mass distribution in the 13 TeV data. Samples of simulated multijet background events are generated to derive scaling functions to be applied to the background predictions from the 13 TeV data analysis. These samples are generated at both $\sqrt{s} = 13$ TeV and $\sqrt{s} = 14$ TeV. Two different sets of MC samples are used to study the impact of differences in jet flavour composition on the multijet background scaling functions. The first set of events corresponds to the $2 \to 2$ processes $pp \to jj$ (with $j = g$ or q) generated with PYTHIA 8 with truth jet p_T in the range between 400 and 2500 GeV. The second set of events corresponds to the $2 \to 4$ processes $pp \to bbbb$ generated with MADGRAPH5_aMC@NLO requiring b-quarks to have p_T above 100 GeV and the events are required to have at least one b-quark with p_T above 200 GeV.

Large-radius jets are used in the analysis. They are built from generated particles with the anti-k_t algorithm operating with a radius parameter $R = 1.0$. Previous studies indicate that the trimming effectively removes the impact of pileup up to $\mu = 300$ [469]. Small-radius jets are built from generated charged particles with the anti-k_t algorithm and a radius of $R = 0.2$. Only charged particles with $p_T > 0.5$ GeV are used in the clustering to emulate the track jets used in the 13 TeV data analysis.

The event selection applied to the truth-level analysis proceeds similarly to that used for the 13 TeV data analysis. Three regions in the plane formed by the leading large-R jet mass and the subleading large-R jet mass are used in the analysis. The signal region is defined by the requirement $X_{HH} < 1.6$, with X_{HH} defined as

$$X_{HH} = \sqrt{\left(\frac{m_{\mathrm{J}}^{\mathrm{lead}} - 125\ \mathrm{GeV}}{0.1\, m_{\mathrm{J}}^{\mathrm{lead}}}\right)^2 + \left(\frac{m_{\mathrm{J}}^{\mathrm{subl}} - 120\ \mathrm{GeV}}{0.1\, m_{\mathrm{J}}^{\mathrm{subl}}}\right)^2}, \tag{6.1.1}$$

where m_J is the large-R jet mass. The choices made to define the control and sideband regions are driven by the need to select events that are kinematically similar to those in the signal region while providing sufficiently large samples to derive the background estimate from the sideband region and validate it in the control region.

For the 13 TeV data analysis, the dominant multijet background is estimated with a data-driven approach which utilises events with a smaller number of b-tags in the sideband region. The events used for this estimation are required to have the same track-jet topology as in the event categories in which they are used to model the background. Events with 1 b-tag are used to model the background in the 2-tag category. Likewise, events with 2 b-tags are used to model the background in the 3- and 4-tag

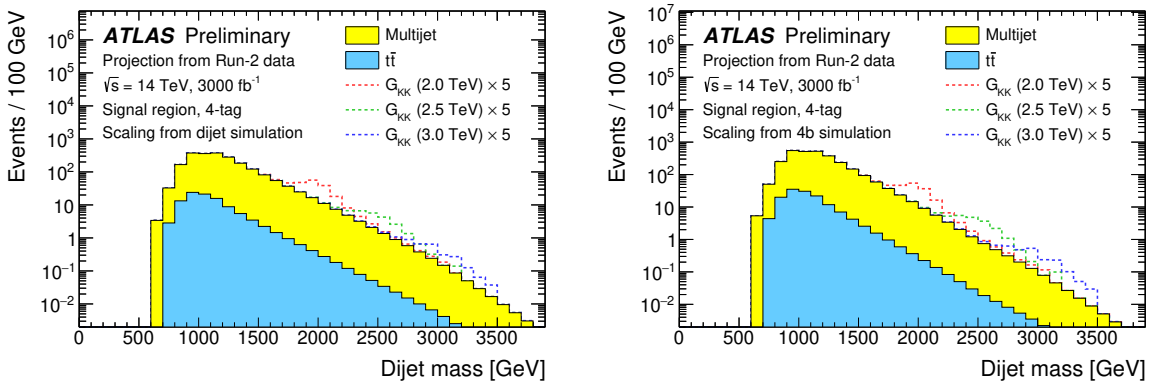

Fig. 6.1.1: Dijet mass distributions from the truth-level analysis for 4-tag events in the signal region for the expected background and signals at the HL-LHC. The multijet background is scaled using either the dijet (left) or the $4b$ multijet (right) MC samples. The event yields for signal events at G_{KK} masses of 2.0, 2.5, and 3.0 TeV are scaled up for visibility.

categories. Various checks performed show that either multijet simulation can be used reliably to predict the shape of the dijet mass distributions. However, differences in the flavour content of the large-R jets in the dijet and $4b$ multijet MC samples do affect the predicted background yields in the following study and the two samples are used to extract a range of projections at the HL-LHC.

As mentioned above, the projection for the HL-LHC proceeds in three steps. At first, the dijet mass distributions for signal and both multijet and $t\bar{t}$ background events from the 13 TeV data analysis in Run-2 are scaled from 36.1 fb^{-1} to 3 ab^{-1}. The background distributions are further scaled with mass-dependent functions to extrapolate from $\sqrt{s} = 13$ TeV to 14 TeV. These functions take into account both increases in cross section and changes in detector performance from the Run-2 ATLAS detector to the future upgraded detector at the HL-LHC. Further mass-dependent scaling is applied to all signal and background distributions to reflect improvements in the reconstruction of highly boosted jets, as obtained by using variable-radius track jets [470] instead of fixed-radius ($R = 0.2$) track jets, or in the background suppression by applying a requirement on the maximum number of charged particles associated with each large-R jet.

The first improvement relative to the 13 TeV data analysis arises from the use of variable-radius track jets. This circumvents the problem that $R = 0.2$ track jets from the $H \to b\bar{b}$ decay start merging for Higgs boson p_T values larger than approximately $2m_H/R = 1250$ GeV. The second improvement relative to the 13 TeV data analysis is the requirement of a maximum number of charged particles associated with large-R jets to exploit differences between quark- and gluon-initiated jets, the latter being an important component of the multijet background. The impact of pileup at $\mu = 200$ has been studied for charged particle tracks with $p_T > 1$ GeV associated with the primary vertex. In the case of $t\bar{t}$ events, the average number of tracks associated with the primary vertex increases by about 15% due to pileup. Further pileup suppression is possible with additional requirements on the longitudinal impact parameter or track-vertex association probability. Both leading and subleading large-R jets are required to have fewer than 20 charged particles with $p_T > 1$ GeV and $\Delta R < 0.6$ with respect to the jet axis.

The dijet mass distributions at $\sqrt{s} = 14$ TeV with 3 ab^{-1}resulting from the scaling procedure described above, including variable-radius track jets and the requirement on the maximum number of charged particles per large-R jet, are shown in Fig. 6.1.1 for 4-tag events in the signal region using either the dijet (left) or the $4b$ multijet (right) MC samples. Systematic uncertainties are scaled down by factors of two or more (where applicable) relative to the values from the 13 TeV data analysis to account for the increased precision available with 3 ab^{-1}at the HL-LHC.

Upper limits on $\sigma \times \mathcal{B}$ at $\sqrt{s} = 14$ TeV range from 1.44 fb (1.82 fb) at a mass of 1.0 TeV to

Model	$\sqrt{s} = 13$ TeV, 36.1 fb^{-1} as in Ref. [274]	$\sqrt{s} = 14$ TeV, 3 ab^{-1} dijet scaling	$\sqrt{s} = 14$ TeV, 3 ab^{-1} $4b$ scaling
$k/\overline{M}_{\mathrm{Pl}} = 0.5$	no limit	2.15 TeV	2.00 TeV
$k/\overline{M}_{\mathrm{Pl}} = 1.0$	1.36 TeV	2.95 TeV	2.75 TeV

Table 6.1.1: Expected 95% C.L. lower limits on G_{KK} mass for the 13 TeV data analysis and the extrapolation to the HL-LHC for $k/\overline{M}_{\mathrm{Pl}} = 0.5$ and 1.0 in the bulk RS model. Different extrapolations are provided based on modelling of the changes in multijet background using either the dijet or the $4b$ multijet MC samples.

0.025 fb (0.040 fb) at a mass of 3.0 TeV when dijet ($4b$) scaling and the variable-radius track jets with a maximum requirement on the number of charged particles are applied. The benefit from the use of variable-radius track jets becomes significant at the highest resonance masses considered here, with an improvement in the upper limits of at least 24% (depending on the choice of scaling) at 3.0 TeV. The additional requirement on the maximum number of charged particles further improves the upper limits by factors of about 20% and 45% at masses of 2.0 and 3.0 TeV, respectively. Systematic uncertainties have a modest impact on the limits with an effect of at most 20% at 1.0 TeV and decreasing to $\sim 5\%$ at high mass. The lower mass limits on KK gravitons are summarised in Table 6.1.1, evaluated at the 95% C.L., using either the dijet MC samples or the $4b$ multijet MC samples to model the changes in the multijet background relative to the background predictions from the 13 TeV data analysis.

6.1.2 VBF production of resonances decaying to HH in the 4b final state at HL-LHC

Contributors: A. Carvalho, J. Komaragiri, D. Majumder, L. Panwar, CMS

Several BSM scenarios predict the existence of resonances decaying to a pair of Higgs bosons, H [3, 4, 471], such as warped extra dimensional (WED) models [472], which have a spin-0 radion [473–475] and a spin-2 first Kaluza–Klein (KK) excitation of the graviton [476–478]. Others, such as the two-Higgs doublet models [479] (particularly, the MSSM [480]) and the Georgi-Machacek model [481] also contain spin-0 resonances. These resonances may have a sizeable branching fraction to a Higgs pair.

Searches for a new particle X in the HH decay channel have been performed by the ATLAS [482–484] and CMS [485–489] Collaborations in proton-proton (pp) collisions at $\sqrt{s} = 7$ and 8 TeV. The ATLAS Collaboration has set limits on the production of a KK bulk graviton decaying to HH in the final state with a pair of b quark and antiquark, $b\bar{b}b\bar{b}$, using pp collision data at $\sqrt{s} = 13$ TeV [274, 490, 491]. The CMS Collaboration has also set limits on the production of a KK bulk graviton and a radion, decaying to HH, in the $b\bar{b}b\bar{b}$ final state, using pp collision data at $\sqrt{s} = 13$ TeV, corresponding to an integrated luminosity of 35.9 fb^{-1} [492, 493]. At present, the searches from ATLAS and CMS set a limit on the production cross sections and the branching fractions $\sigma(pp \to X)\mathcal{B}(X \to HH \to b\bar{b}b\bar{b})$ for masses of X, m_X up to 3 TeV.

The searches were confined to the s-channel production of a narrow resonance X from the SM quark-antiquark or gluon-gluon interactions. The WED models that were used in the interpretations of the results have extra spatial dimension compactified between two branes (called the bulk) via an exponential metric κl, where κ is the warp factor and l the coordinate of the extra spatial dimension [494]. The reduced Planck scale, $\overline{M_{\mathrm{Pl}}} \equiv M_{\mathrm{Pl}}/8\pi$, M_{Pl} being the Planck scale and the ultraviolet cutoff of the theory $\Lambda_{\mathrm{R}} \equiv \sqrt{6}e^{-\kappa l}\overline{M_{\mathrm{Pl}}}$ [473] are fundamental scales in these models. A radion of mass below 1.4 TeV is excluded, assuming $\Lambda_{\mathrm{R}} = 3$ TeV, while the cross section limit for a bulk graviton decaying to $HH \to b\bar{b}b\bar{b}$ is between 1.4 and 4 fb for masses between 1.4 and 3.0 TeV, at 95% C.L. [492, 493].

The search for these resonances in other production modes, such as VBF, as depicted in Fig. 6.1.2, has not yet been explored. While the s-channel production cross section of a bulk graviton, assuming

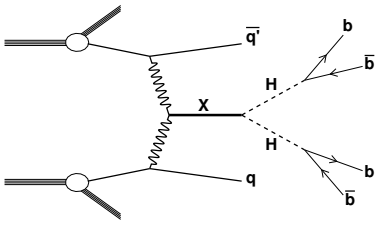

Fig. 6.1.2: Diagrammatic representation of the vector boson fusion production of a resonance X decaying to a pair of Higgs bosons H, with both Higgs bosons decaying to $b\bar{b}$ pairs.

$\kappa/\overline{M_{\rm Pl}} = 0.5$, is in the range $0.05 - 5$ fb for masses between 1.5 and 3 TeV, the VBF production mode is expected to have a cross section an order of magnitude smaller [495]. The absence of a signal from the s-channel process may point to highly suppressed couplings of X with the SM quarks and gluons, making VBF the dominant production process in pp collisions.

Here we explore the prospects for the search for a massive resonance produced through VBF and decaying to HH at the HL-LHC with the upgraded CMS detector. For a very massive resonance, highly Lorentz-boosted Higgs bosons are more efficiently reconstructed as a single large-area jet (Higgs jet). In addition, a signal event will also have two energetic jets at large pseudorapidity η. This study from the CMS Collaboration is reported in detail in Ref. [496]

A simulation of the upgraded Phase 2 CMS detector was used for this study. Signal events for bulk gravitons were simulated at leading order using MADGRAPH5_aMC@NLO 2.4.2 [67] for masses in the range 1.5 to 3 TeV and for a fixed width of 1% of the mass. The NNPDF3.0 leading order PDFs [121], taken from the LHAPDF6 PDF set [497–500], with the four-flavour scheme, were used. The main background is given by multijet events, and has been simulated using PYTHIA 8.212 [68], for events containing two hard partons, with the invariant mass of the two partons required to be greater than 1 TeV.

For both the signal and the background processes, the showering and hadronisation of partons was simulated with PYTHIA 8. The pileup events contribute to the overall event activity in the detector, the effect of which was included in the simulations assuming a pileup distribution averaging to 200. All generated samples were processed through a GEANT4-based [53, 54] simulation of the upgraded CMS detector.

The two leading-p_T large-radius anti-$k_{\rm T}$ jets with a distance parameter of 0.8 (AK8) in the event, J_1 and J_2, are required to have $p_T > 300$ GeV and $|\eta| < 3.0$. To identify the two leading-p_T AK8 jets with the boosted $H \to b\bar{b}$ candidates from the $X \to HH$ decay (H tagging), these jets are groomed [501] to remove soft and wide-angle radiation using the modified mass drop algorithm [502, 503], with the soft radiation fraction parameter z set to 0.1 and the angular exponent parameter β set to 0, also known as the soft-drop algorithm [504, 505]. By undoing the last stage of the jet clustering, one gets two subjets each for J_1 and J_2. The invariant mass of the two subjets is the soft-drop mass of each AK8 jet, which has a distribution with a peak near the Higgs boson mass $m_H = 125$ GeV [506, 507], and a width of about 10%. The soft-drop mass window selection was optimised using a figure of merit of $S/\sqrt{B}$ and required to be in the range $90 - 140$ GeV for both leading jets.

The N-subjettiness ratio $\tau_{21} \equiv \tau_2/\tau_1$ [508] has a value much smaller than unity for a jet with two subjets. For signal selection, J_1 and J_2 are required to have $\tau_{21} < 0.6$ following an optimisation of the above figure of merit.

The H tagging of J_1 and J_2 further requires identifying their subjet pairs to be b tagged with a

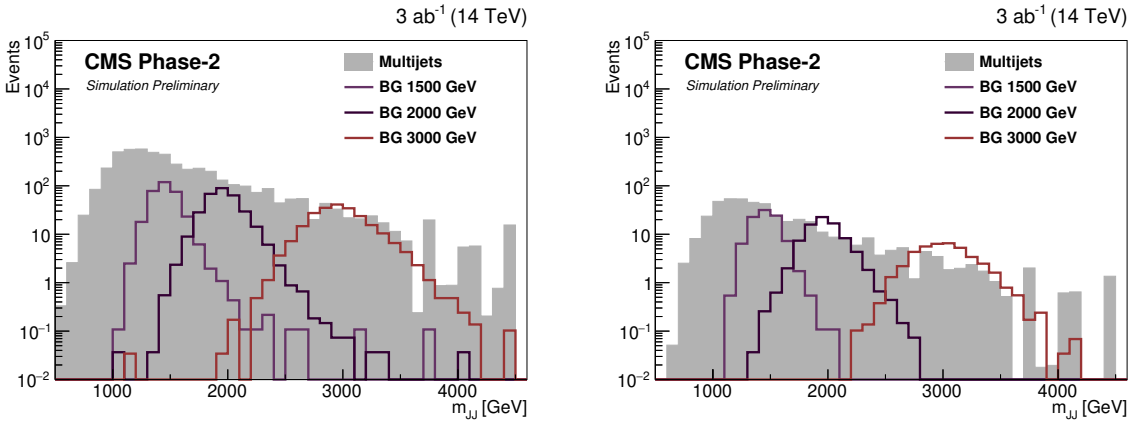

Fig. 6.1.3: Estimated multijet background and the signal m_{JJ} distributions for bulk gravitons (BG) of masses 1.5, 2, and 3 TeV, assuming a signal cross section of 1 fb. The distributions on the left are for the $3b$ and those on the right are for the $4b$ subjet b-tagged categories and for an average pileup of 200.

Process	$3b$ category		$4b$ category	
	Events	Efficiency (%)	Events	Efficiency (%)
Multijets	4755	1.6×10^{-3}	438	1.5×10^{-4}
BG (m_X =1.5 TeV)	326	11	95.2	3.2
BG (m_X =2 TeV)	316	11	81.2	2.7
BG (m_X =3 TeV)	231	7.7	41.4	1.4

Table 6.1.2: Event yields and efficiencies for the signal and multijet background for an average pileup of 200. The product of the cross sections and branching fractions of the signals $\sigma(pp \to X\text{jj} \to HH\text{jj})$ is assumed to be 1 fb. Owing to the large sample sizes of the simulated events, the statistical uncertainties are small.

probability of about 49% to contain at least one b hadron, and a corresponding probability of about 1% of having no b or c hadrons. Events are classified into two categories: those having exactly three out of the four b-tagged subjets ($3b$ category), and those that have all four subjets b-tagged ($4b$ category).

Events are required to have at least two AK4 jets j_1 and j_2, which are separated from the H jets by $\Delta R > 1.2$, with $p_T > 50$ GeV and $|\eta| < 5$. To pass the VBF selections, these jets must lie in opposite η regions of the detector, and a pseudorapidity difference $|\Delta\eta(j_1, j_2)| > 5$. The invariant mass m_{jj} reconstructed using these AK4 jets is required to pass $m_{jj} > 300$ GeV.

The bulk graviton invariant mass m_{JJ} is reconstructed from the 4-momenta of the two Higgs jets in events passing the above mentioned full selection criteria. The main multijet background is smoothly falling, above which the signal is searched for as a localised excess of events for a narrow resonance X.

It is expected that the multijet background component in a true search at the HL-LHC will rely on the data for a precise estimate. Methods such as those described in Ref. [492] are known to provide an accurate prediction of the multijet background m_{JJ} shape as well as the yield.

The simulated multijet background sample consists of ~ 4 million events none of which survive the full selection. To estimate the background, the subjet b-tagging efficiency is determined using a loose set of selection criteria which require events to have J_1 and J_2 passing only the soft-drop mass and τ_{21} requirements. The b-tagging efficiency is obtained for the different subjet flavours and as a function of p_T and η.

Multijet events passing all selection criteria except the subjet b tagging are then reweighted according to the subjet efficiencies to obtain the probability of the event to pass the three of four subjet b-tagging categories. The m_{JJ} distributions for the multijet background after the full selection are then

obtained from the weighted events in these two categories.

From the analysis of current LHC data at $\sqrt{s} = 13$ TeV, it was found that the multijet backgrounds measured in data are a factor of 0.7 smaller than estimated in simulation. Accordingly, the multijet background yield from simulation has been corrected by this factor, assuming this to hold also for the simulations of the multijet processes at $\sqrt{s} = 14$ TeV . The m_{JJ} of the backgrounds thus obtained and the signals are shown in Fig. 6.1.3, while the event yields after full selection are given in Table 6.1.2.

The efficiency of events to pass the VBF jet selection depends strongly on pileup due to the combinatorial backgrounds from pileup jets, which affects both the signal and the background selection. Moreover, the VBF selection efficiency for multijets grows faster than the signal efficiency with pileup, since the latter has true VBF jets which already pass the selection in the absence of pileup. Hence, in the present search, the requirement of additional VBF jets does not result in any appreciable gain in the signal sensitivity. It is anticipated that developments in the rejection of pileup jets in the high η region will eventually help suppress the multijets background and improve the signal sensitivity further.

The expected significance of the signal, assuming a production cross section of 1 fb is estimated. Several systematic uncertainties are considered. The uncertainty in the jet energy scale amounts to 1%. The uncertainty in the subjet b-tagging efficiency difference between the data and simulations is taken to be 1%. An uncertainty of 1% is assigned to the integrated luminosity measurement. These uncertainties are based on the projected values for the full data set at the HL-LHC.

In addition, several measurement uncertainties are considered based on the 2016 search for a resonance decaying to a pair of boosted Higgs bosons [492], which are scaled down by a factor of 0.5 for the HL-LHC study. The H jet selection uncertainties include the uncertainties in the H jet mass scale and resolution (1%), the uncertainty in the data to simulation difference in the selection on τ_{21} (13%), and the uncertainty in the showering and hadronisation model for the H jet (3.5%). The uncertainties in the signal acceptance because of the parton distribution functions (1%) and the simulation of the pileup (1%) are also taken into account

The expected signal significance of a bulk graviton of mass 2000 GeV, produced through vector boson fusion, with an assumed production cross section of 1 fb and decaying into a pair of Higgs bosons, each of which decays to a $b\bar{b}$ pair is found to be 2.6σ for an integrated luminosity of 3 ab^{-1}.

6.1.3 Heavy Higgs bosons in models with vector-like fermions at the HL- and HE-LHC

Contributors: R. Dermisek, E. Lunghi, S. Shin

Among the simplest extensions of the SM are models with extended Higgs sector and models with additional vectorlike matter. Although many search strategies for individual new particles were designed, there are large regions of the parameter space that HL- or HE-LHC will not be sensitive to as a result of either small production rates or large SM backgrounds. However, combined signatures of both extra sectors can lead to many new opportunities to search for heavy Higgs bosons and vectorlike matter simultaneously [509].

For example, in a type-II two Higgs doublet model, the production cross section of the 1 TeV heavy CP-even Higgs boson can be as sizeable as $\sim$ 2 pb (10 pb) at 13 TeV (27 TeV) c.o.m. energy, depending on the values of $\tan\beta$. However, in the decoupling limit, where $H \to ZZ,\ WW$ are suppressed or not present, the dominant decay modes are $t\bar{t}$, hh, $b\bar{b}$ and $\tau^+\tau^-$ which suffer from large SM backgrounds or small branching fractions in some regions of $\tan\beta$. On the other hand, vectorlike leptons typically have very clean signatures but their production rates are very small. Nevertheless, since vectorlike leptons can appear in decay chains of heavy Higgs bosons, the combined signature can feature both the sizeable production rate and clean final states.

We consider a type-II two Higgs doublet model augmented by vectorlike pairs of new quarks ($SU(2)$ doublets $Q_{L,R}$ and SU(2) singlets $U_{L,R}$ and $D_{L,R}$) and vectorlike pairs of new leptons ($SU(2)$ doublets $L_{L,R}$, $SU(2)$ singlets $E_{L,R}$ and SM singlets $N_{L,R}$) [510]. The Q_L, U_R, D_R, L_L and E_R

Table 6.1.3: Quantum numbers of SM leptons and quarks (ℓ_L^i, e_R^i, q_L^i, u_R^i, d_R^i for $i = 1, 2, 3$), extra vectorlike leptons and quarks and the two Higgs doublets. The electric charge is given by $Q = T_3 + Y$, where T_3 is the weak isospin, which is $+1/2$ for the first component of a doublet and $-1/2$ for the second component.

have the same hypercharges as quarks and leptons in the SM, as summarised in Table 6.1.3. We further assume that the new leptons mix only with one family of SM leptons in order to simply avoid strong constraints from the experiments searching for lepton flavour violation and we consider the mixing with the second family as an example [509–518] (the discovery potential in the case of mixing with the first family would be comparable [516] and in the case of mixing with the third family it would be significantly weaker [516, 519]). This can be achieved by requiring that the individual lepton number is an approximate symmetry (violated only by light neutrino masses). Similarly, we assume that the new quarks mix only with the third family of SM quarks. We consider the most general renormalisable Lagrangian consistent with these assumptions.

Details of the lepton sector of the model were worked out in Ref. [510]. After spontaneous symmetry breaking, $\left\langle H_u^0 \right\rangle = v_u$ and $\left\langle H_d^0 \right\rangle = v_d$ with $\sqrt{v_u^2 + v_d^2} = v = 174$ GeV (we also define $\tan\beta \equiv v_u/v_d$), the model can be summarised by mass matrices in the charged lepton sector, with left-handed fields $(\bar{\mu}_L, \bar{L_L^-}, \bar{E}_L)$ on the left and right-handed fields $(\mu_R, L_R^-, E_R)^T$ on the right [512],

$$M_e = \begin{pmatrix} y_\mu v_d & 0 & \lambda_E v_d \\ \lambda_L v_d & M_L & \lambda v_d \\ 0 & \bar{\lambda} v_d & M_E \end{pmatrix}, \tag{6.1.2}$$

and in the neutral lepton sector, with left-handed fields $(\bar{\nu}_\mu, \bar{L}_L^0, \bar{N}_L)$ on the left and right-handed fields $(\nu_R = 0, L_R^0, N_R)^T$ on the right [510],

$$M_\nu = \begin{pmatrix} 0 & 0 & \kappa_N v_u \\ 0 & M_L & \kappa v_u \\ 0 & \bar{\kappa} v_u & M_N \end{pmatrix}. \tag{6.1.3}$$

The superscripts on vectorlike fields represent the charged and the neutral components (we inserted $\nu_R = 0$ for the right-handed neutrino which is absent in our framework in order to keep the mass matrix 3×3 in complete analogy with the charged sector). The usual SM Yukawa coupling of the muon is denoted by y_μ, the Yukawa couplings to H_d are denoted by various λs, the Yukawa couplings to H_u are denoted by various κs, and finally the explicit mass terms for vectorlike leptons are given by $M_{L,E,N}$. Note that explicit mass terms between SM and vectorlike fields (*i.e.* $\bar{\mu}_L L_R$ and $\bar{E}_L \mu_R$) can be rotated away. These mass matrices can be diagonalised by bi-unitary transformations and we label the two new charged and neutral mass eigenstates by e_4, e_5 and ν_4, ν_5 respectively:

$$U_L^\dagger M_e U_R = \text{diag}\left(m_\mu, m_{e_4}, m_{e_5}\right), \tag{6.1.4}$$

$$V_L^\dagger M_\nu V_R = \text{diag}\left(0, m_{\nu_4}, m_{\nu_5}\right). \tag{6.1.5}$$

Since $SU(2)$ singlets mix with $SU(2)$ doublets, the couplings of all involved particles to the Z, W and Higgs bosons are in general modified. The flavour conserving couplings receive corrections and flavour changing couplings between the muon (or muon neutrino) and heavy leptons are generated. The relevant formulas for these couplings in terms of diagonalisation matrices defined above can be found

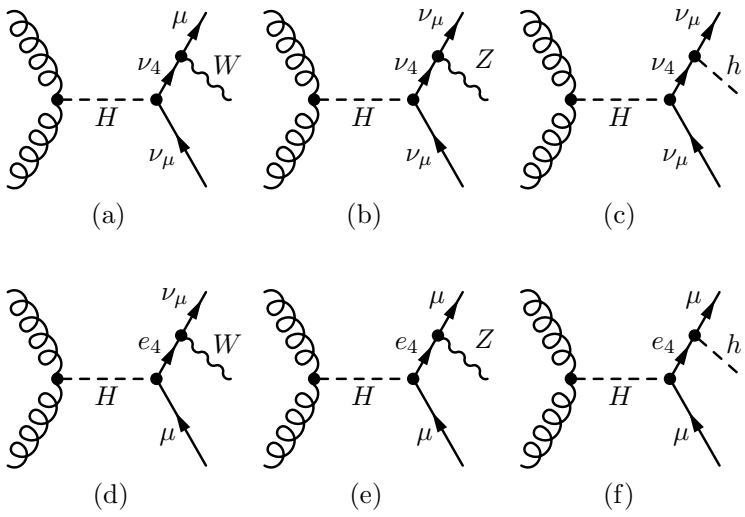

Fig. 6.1.4: Heavy Higgs boson cascade decays through vectorlike leptons.

in Ref.s [510, 512]. In the limit of small mixing, approximate analytic expressions for diagonalisation matrices can be obtained which are often useful for the understanding of numerical results. These are also given in Ref.s [510, 512]. Details of the quark sector of the model can be found in Ref. [520]. The mass matrix in the up and down quark sectors closely follow those for the neutrino and the charged leptons above.

The generated flavour changing couplings between heavy and light leptons lead to new decay modes of heavy CP-even (or CP-odd) Higgs boson: $H \to \nu_4 \nu_\mu$ and $H \to e_4 \mu$, where e_4 and ν_4 are the lightest new charged and neutral leptons. The BRs for these decay modes can be very large when the mass of the heavy Higgs boson is below the $t\bar{t}$ threshold and the light Higgs boson (h) is SM-like so that $H \to ZZ,\ WW$ are suppressed or not present. In this case, flavour changing decays $H \to \nu_4 \nu_\mu$ or $H \to e_4 \mu$ compete only with $H \to b\bar{b}$, and for sufficiently heavy H, also with $H \to hh$. Subsequent decay modes of e_4 and ν_4, $e_4 \to W\nu_\mu$, $e_4 \to Z\mu$, $e_4 \to h\mu$ and $\nu_4 \to W\mu$, $\nu_4 \to Z\nu_\mu$, $\nu_4 \to h\nu_\mu$ lead to the following 6 decay chains of the heavy Higgs boson:

$$H \to \nu_4 \nu_\mu \to W\mu\nu_\mu,\ Z\nu_\mu\nu_\mu,\ h\nu_\mu\nu_\mu\,, \tag{6.1.6}$$

$$H \to e_4 \mu \to W\nu_\mu\mu,\ Z\mu\mu,\ h\mu\mu\,, \tag{6.1.7}$$

which are also depicted in Fig. 6.1.4. In addition, H could also decay into pairs of vectorlike leptons. This is however limited to smaller ranges for masses in which these decays are kinematically open. Moreover, the final states are the same as in pair production of vectorlike leptons. We will not consider these possibilities here. Finally, although we focus on the second family of SM leptons in final states, the modification for a different family of leptons or quarks is straightforward.

In Ref. [509], it was found that in a large range of the parameter space BRs for the decay modes (6.1.6) and (6.1.7) can be sizeable or even dominant while satisfying constraints from searches for heavy Higgs bosons, pair production of vectorlike leptons [516] obtained from searches for anomalous production of multilepton events, and constraints from precision EW observables [283]. Since the Higgs production cross section can be very large, for example the cross section for a 200 GeV Higgs boson at 13 TeV (27 TeV) LHC for $\tan\beta = 1$ is 18 pb (67 pb) [521–523], the final states above can be produced in large numbers. Thus searching for these processes could lead to the simultaneous discovery of a new Higgs boson and a new lepton. Some of the decay modes in Fig. 6.1.4 also allow for full reconstruction of the masses of both new particles in the decay chain.

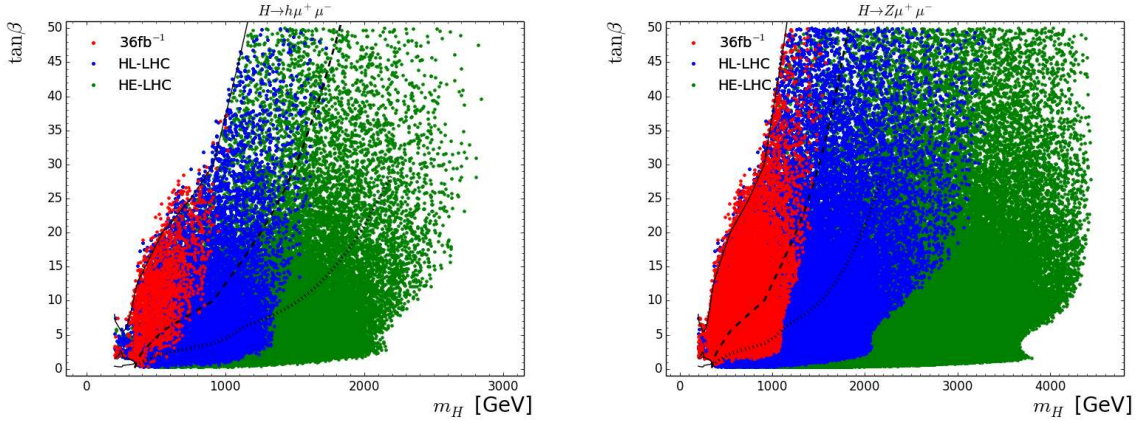

Fig. 6.1.5: Experimental sensitivities for $H \to e_4^\pm \mu^\mp \to h\mu^+\mu^-$ (left) $H \to e_4^\pm \mu^\mp \to Z\mu^+\mu^-$ (right). Red, blue and green points are the regions of the $[m_H, \tan\beta]$ plane which are accessible with LHC with 36 fb^{-1}, at the HL-LHC, and at the HE-LHC, respectively. Black solid, dashed and dotted lines represent the corresponding reaches of $H \to \tau\tau$ searches.

The final states of the processes (6.1.6) and (6.1.7) are the same as final states of $pp \to WW, ZZ, Zh$ production or $H \to WW, ZZ$ decays with one of the gauge bosons decaying into second generation of leptons. Since searching for leptons in final states is typically advantageous, our processes contribute to a variety of existing searches. Even searches for processes with fairly large cross sections can be significantly affected. For example, the contribution of $pp \to H \to \nu_4\nu_\mu \to W\mu\nu_\mu$ to $pp \to WW$ can be close to current limits while satisfying the constraints from $H \to WW$. This has been studied in Ref. [510] in the two Higgs doublet model we consider here, and also in a more model independent way in Ref. [517].

The discussion of the main features of each of the heavy Higgs decay modes, of existing experimental searches to which these new process contribute, and of possible new searches can be found in Ref. [509]. The processes with small SM backgrounds are the best place to look for this scenario. Examples include $H \to h\nu_\mu\nu_\mu$ and $H \to h\mu\mu$ with $h \to \gamma\gamma$.

We now discuss the parameter regions of heavy Higgses and vectorlike leptons which can be accessed by dedicated searches for the modes we propose with current LHC (36 fb^{-1}), HL- and HE-LHC. Among the processes depicted in Fig. 6.1.4, we choose $H \to e_4^\pm \mu^\mp \to h\mu^+\mu^-$ and $H \to e_4^\pm \mu^\mp \to Z\mu^+\mu^-$ as representative examples. These are interesting because they result in additional resonances. The first process was analysed in Ref. [518] for $m_H \leq 340$ GeV. The key selection criterion is an *off-Z* cut ($|m_{\mu^+\mu^-} - M_Z| > 15$ GeV) which exploits the fact that the invariant mass of the two muons in the final state is distributed mostly outside of the Z boson resonance region. This cut removes to a large extent background events from Z + (heavy flavoured) jets with $Z \to \mu^+\mu^-$ and raises enormously the signal significance [518]. In order to maximise the signal cross section, we focus on $h \to b\bar{b}$ (which we studied in detail in Ref. [518]) and $Z \to b\bar{b}$.

To obtain the expected sensitivities, we estimate the number of background events for the HL-LHC by rescaling the results of Ref. [518] (which are based on the search for a heavy resonance decaying to hZ at ATLAS [524]) by the ratio of luminosities. We further estimate that the backgrounds at the HE-LHC increase by a factor 3.6×5 with respect to those at the HL-LHC, where 3.6 is the ratio of the background cross sections calculated with MADGRAPH 5 and 5 comes from the ratio of integrated luminosities (15 ab^{-1}/3 ab^{-1}).

We take a flat signal acceptance of about 30% for $m_H \leq 800$ GeV based on the analysis presented in Ref. [518] for $m_H = 450, 550, 650, 750$ GeV and $m_{e_4} = 250$ GeV. For $m_H \geq 800$ GeV the dimuon invariant mass is much harder and concentrated above the Z resonance; in this region we assume

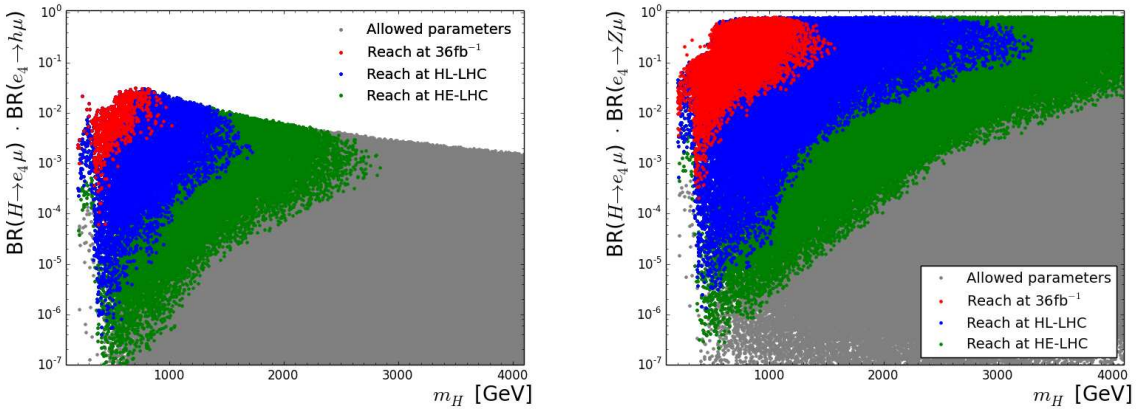

Fig. 6.1.6: Possible values of the BRs $\mathcal{B}(H \to e_4\mu) \times \mathcal{B}(e_4 \to h\mu)$ (left) and $\mathcal{B}(H \to e_4\mu) \times \mathcal{B}(e_4 \to Z\mu)$ (right) as a function of m_H. Note that $\mathcal{B}(H \to e_4\mu)$ includes both $H \to e_4^+\mu$ and $H \to e_4^-\mu^+$ decay modes. See the caption in Fig. 6.1.5 for further details.

an acceptance of about 50%. Furthermore, we consider a flat 50% detector efficiency throughout this analysis.

These estimates of background events, signal acceptances, and detector efficiencies, allow us to calculate the corresponding experimental sensitivities using the condition:

$$N_s^{95} \leq \sigma_H \cdot \mathcal{B}(H \to e_4\mu) \cdot \mathcal{B}(e_4 \to h\mu,\, Z\mu) \cdot A \cdot \epsilon \cdot \mathcal{L}\,, \tag{6.1.8}$$

where σ_H is the $pp \to H$ production cross section, A is the signal acceptance, ϵ is the experimental efficiency, and $\mathcal{L}$ is the integrated luminosity. N_s^{95} is the 95% C.L. upper limit on the expected number of events calculated from the background estimations described above using a modified frequentist construction (CLs) [95] based on a Poisson distribution.

Among the conventional searches of neutral heavy Higgs bosons, $H \to \tau^+\tau^-$ [525] currently provides the strongest constraints on our model, especially for large $\tan\beta$ region; we expect that future analysis improvements may boost the impact of $H \to b\bar{b}$ and $H \to t\bar{t}$. Searches for $H \to WW$ and $H \to ZZ$ are not constraining because these decays are heavily suppressed in the alignment limit in which tree–level couplings of heavy Higgs and weak gauge bosons vanish. Nevertheless, the processes $H \to e_4\ell(\nu_4\nu_\ell) \to \nu_\ell\ell W$ and $H \to e_4\ell \to \ell^+\ell^- Z$ are indirectly constrained by searches for $H \to WW$ and $H \to ZZ$ albeit with different kinematic topologies [509, 510, 517]. The decay $H \to \gamma\gamma$ currently constraints our model at small $\tan\beta \lesssim 1.5$ (at the HL-LHC values of $\tan\beta$ for which we expect constraints raises to about 3.5). Here we focus on $H \to \tau^+\tau^-$ as a competitive search avenue for a heavy neutral Higgs boson.

Let us comment on the extraction of the experimental sensitivities to $H \to \tau\tau$ mentioned above. We assume that there is no change in cut acceptances and detector efficiencies for $H \to \tau\tau$ (for a given m_H) for the HL-LHC and the HE-LHC,[8] implying that $S/\sqrt{B}$ controls to a good approximation the change in sensitivity. With this assumptions, the sensitivity at the HL-LHC increases simply by the square-root of the ratio of the integrated luminosities, *i.e.*, $\sqrt{3000./36.} = 9.13$. For the HE-LHC, we can obtain the sensitivities by further assuming that the background production cross sections ($\sigma_{\text{bkg.}}$) increase by the ratio of Higgs production cross sections for $\tan\beta = 1$, *i.e.*,

$$\sigma_{\text{bkg.}}^{13\text{ TeV}}/\sigma_{\text{bkg.}}^{27\text{ TeV}} = \sigma(pp \to H)_{\tan\beta=1}^{27\text{ TeV}}/\sigma(pp \to H)_{\tan\beta=1}^{13\text{ TeV}}\,, \tag{6.1.9}$$

[8] This is reasonable because the kinematics of H decay products depends almost exclusively on m_H.

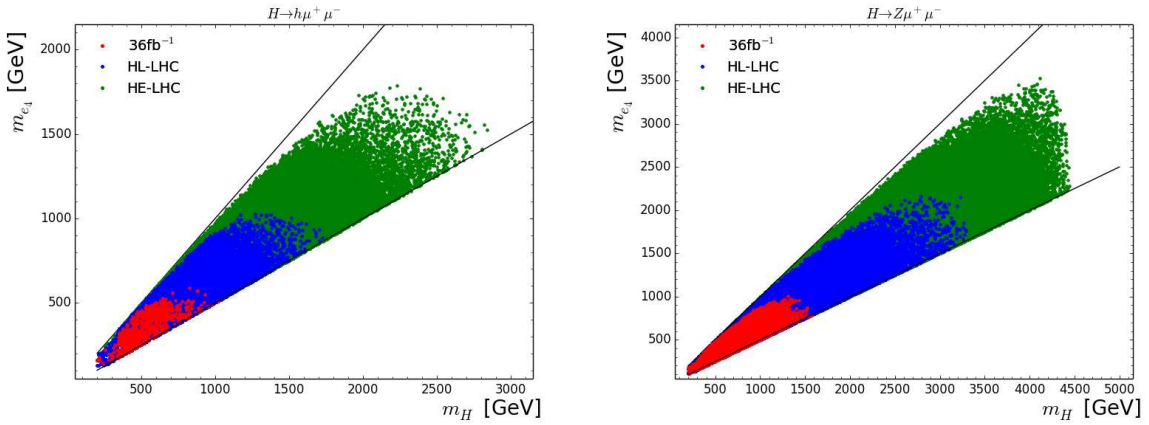

Fig. 6.1.7: Experimental sensitivities for $H \to e_4^\pm \mu^\mp \to h\mu^+\mu^-$ (left) and $H \to e_4^\pm \mu^\mp \to Z\mu^+\mu^-$ (right) in the $[m_H, m_{e_4}]$ plane. Note that we require $m_H > m_{e_4}$ to allow the decay channel, and that we loose sensitivity for $m_H > 2m_{e_4}$, where the $H \to e_4 e_4$ BR dominates. See the caption in Fig. 6.1.5 for further details.

and that the background cut acceptances remain constant. Then, the sensitivity increases as follows:

$$\begin{aligned}\frac{\mathrm{S}^{27\,\mathrm{TeV},\,15\,\mathrm{ab}^{-1}}}{\sqrt{\mathrm{B}^{27\,\mathrm{TeV},\,15\,\mathrm{ab}^{-1}}}} &= \frac{\mathrm{S}^{13\,\mathrm{TeV},\,36\,\mathrm{fb}^{-1}}}{\sqrt{\mathrm{B}^{13\,\mathrm{TeV},\,36\,\mathrm{fb}^{-1}}}} \cdot \frac{\sigma(pp \to H \to \tau^+\tau^-)^{27\,\mathrm{TeV}}}{\sigma(pp \to H \to \tau^+\tau^-)^{13\,\mathrm{TeV}}} \cdot \sqrt{\frac{\sigma_{\mathrm{bkg.}}^{13\,\mathrm{TeV}}}{\sigma_{\mathrm{bkg.}}^{27\,\mathrm{TeV}}} \cdot \frac{\mathcal{L}^{15\,\mathrm{ab}^{-1}}}{\mathcal{L}^{36\,\mathrm{fb}^{-1}}}} \\ &= \frac{\mathrm{S}^{13\,\mathrm{TeV},\,36\,\mathrm{fb}^{-1}}}{\sqrt{\mathrm{B}^{13\,\mathrm{TeV},\,36\,\mathrm{fb}^{-1}}}} \cdot \frac{\sigma(pp \to H \to \tau^+\tau^-)^{27\,\mathrm{TeV}}}{\sigma(pp \to H \to \tau^+\tau^-)^{13\,\mathrm{TeV}}} \cdot 20.4 \cdot \sqrt{\frac{\sigma(pp \to H)^{13\,\mathrm{TeV}}_{\tan\beta=1}}{\sigma(pp \to H)^{27\,\mathrm{TeV}}_{\tan\beta=1}}}\,,\end{aligned} \tag{6.1.10}$$

where $\mathrm{S}^{27\,\mathrm{TeV},\,15\,\mathrm{ab}^{-1}}$ ($\mathrm{S}^{13\,\mathrm{TeV},\,36\,\mathrm{fb}^{-1}}$) and $\mathrm{B}^{27\,\mathrm{TeV},\,15\,\mathrm{ab}^{-1}}$ ($\mathrm{B}^{13\,\mathrm{TeV},\,36\,\mathrm{fb}^{-1}}$) are the number of signal and background events for $H \to \tau^+\tau^-$ at the HE-LHC (at the LHC with 36 fb^{-1}). Note that the estimated sensitivity in Eq. (6.1.10) does not include experimental systematic uncertainties, that would somewhat weaken the reach of $H \to \tau\tau$.

Our main results are presented in Fig.s 6.1.5, 6.1.6 and 6.1.7, where we show the experimental sensitivities for $H \to e_4^\pm \mu^\mp \to h\mu^+\mu^-$ (left) $H \to e_4^\pm \mu^\mp \to Z\mu^+\mu^-$ (right) obtained from re-analysing current data with integrated luminosity 36 fb^{-1} (red), our estimates for the HL-LHC (blue), and HE-LHC (green). For comparison, in Fig. 6.1.5, the reach of $H \to \tau^+\tau^-$ searches in conventional type-II two Higgs doublet model with the current data, at the HL-LHC, and the HE-LHC are shown as black solid, dashed, and dotted lines, respectively. The scatter points satisfy constraints from EWPT, Drell-Yan pair production of vectorlike leptons [516], heavy Higgs searches in the $H \to \tau^+\tau^-$ [525] and $H \to \gamma\gamma$ [526, 527] channels. The range of parameters that we scan over is:

$$M_{L,N} \in [100, 5000]\ \mathrm{GeV}\,, \tag{6.1.11}$$

$$\lambda_L, \lambda_E, \lambda, \bar{\lambda} \in [-1, 1]\,, \tag{6.1.12}$$

$$\kappa_N = \kappa = \bar{\kappa} = 0\,, \tag{6.1.13}$$

$$\tan\beta \in [0.3, 50]\,. \tag{6.1.14}$$

From the inspections of Fig. 6.1.5, we see that searches for heavy Higgs cascade decays into vectorlike leptons considerably extend the reach beyond that of $H \to \tau^+\tau^-$. Searches for $H \to h\mu^+\mu^-$ are sensitive to m_H up to 1.7 TeV (2.9 TeV) and m_{e_4} up to 1 TeV (1.8 TeV) at the HL-LHC (HE-LHC). The decay mode $H \to Z\mu^+\mu^-$ is even more promising and extends the sensitivity to m_H up to 3.3 TeV (4.5 TeV) and m_{e_4} up to 2.2 TeV (3.5 TeV) at the HL-LHC (HE-LHC).

6.1.4 *Heavy singlet scalars at HL- and HE-LHC*

Contributors: D. Buttazzo, F. Sala, A. Tesi

The existence of extended Higgs sectors is predicted in several motivated extensions of the SM. In particular, extra Higgses that are singlets under the SM gauge group arise in some of the most natural BSM constructions, like the next-to-MSSM (NMSSM, see Ref. [528] for a review), as well as in Twin [529] and Composite [530, 531] Higgs models (TH and CH models). Independently of the hierarchy problem of the Fermi scale, extra singlets constitute a minimal possibility to realise a first-order EW phase transition [532–534], which is a necessary condition to achieve EW baryogenesis. These considerations constitute a strong case for the experimental hunt of extra singlet-like scalar particles. It is the purpose of this Section, which summarises and updates the work of Ref.s [535, 536], to review the experimental status of the searches for such scalars, and to determine the reach of the HL- and HE-LHC. To keep this contribution brief, we focus on the case where the extra singlet is heavier than the Higgs boson.

Framework. We add to the SM a real scalar field ϕ, so that the most general renormalisable Lagrangian reads

$$\mathcal{L} = \mathcal{L}_{\rm SM} + \frac{1}{2}(\partial S)^2 - \mu_S^2 S^2 - a_{HS}|H|^2 S - \lambda_{HS}|H|^2 S^2 - a_S S^3 - \lambda_S S^4 \,, \tag{6.1.15}$$

where H is the SM Higgs doublet. Unless a Z_2 symmetry is enforced ($a_{HS} = a_S = 0$), and is not spontaneously broken, the singlet mixes with the SM Higgs as

$$\phi = -s_\gamma\, h_0 + c_\gamma\, s_0, \qquad h = s_\gamma\, s_0 + c_\gamma\, h_0 \,, \tag{6.1.16}$$

where h_0 and s_0 are the neutral CP-even degrees of freedom contained in H and S, h and ϕ are the resulting mass eigenstates, and s_γ, c_γ are the sine and cosine of their mixing angle γ. The signal strengths μ of h and ϕ into SM particles, defined as cross-section times BR, read

$$\mu_h = c_\gamma^2\, \mu_{\rm SM}, \quad \mu_{\phi\to VV,ff} = s_\gamma^2\, \mu_{\rm SM}(m_\phi)\cdot(1-\mathcal{B}(\phi\to hh)), \quad \mu_{\phi\to hh} = s_\gamma^2\, \sigma_{\rm SM}(m_\phi)\cdot\mathcal{B}(\phi\to hh), \tag{6.1.17}$$

where $\sigma_{\rm SM}$ is the production cross-section of a SM Higgs boson, and $\mu_{\rm SM}$ is its signal strength into the pair of SM particles of interest.

Constraints from Higgs couplings. The couplings of the SM-like Higgs boson h to other SM particles are all reduced by the same amount c_γ, independently of m_ϕ. A combined ATLAS and CMS fit to Higgs coupling measurements from 8 TeV data yields the 2σ limit [537] $s_\gamma^2 \lesssim 0.12$, and the sensitivity reached with 36 fb^{-1} of data at 13 TeV is comparable [538, 539]. The HL- and HE-LHC are expected to probe values of s_γ^2 at, and possibly slightly below, the 5% level [32]. The current exclusion and future reach from Higgs coupling measurements is shown in Fig. 6.1.8. Constraints on the mixing angle from EW precision tests are subdominant with respect to those from Higgs coupling measurements, see *e.g.* Ref. [540].

Constraints from Trilinear Higgs coupling. The trilinear Higgs coupling g_{hhh} depends on γ, m_ϕ, and on the singlet VEV v_s, while its dependence on all other parameters is very mild [535] (we fix for definiteness $\lambda_S = \lambda_{HS} = 0.5$). We show its ratio with respect to its SM value in Fig. 6.1.8, for two representative values of v_s. The gray shaded region comes from a rough bound on g_{hhh} that we extract from Ref. [274], using the prediction of Ref. [541].[9] Deviations of order one and larger are allowed by all current and near-future constraints, motivating in particular the HE stage of the LHC, due to the increase of the sensitivity to g_{hhh} with energy [32].

[9] We assume that the only deviation in double Higgs production comes from deviations in g_{hhh}, the contribution from $pp\to\phi\to hh$ is negligibly small due to the large m_ϕ in the excluded region.

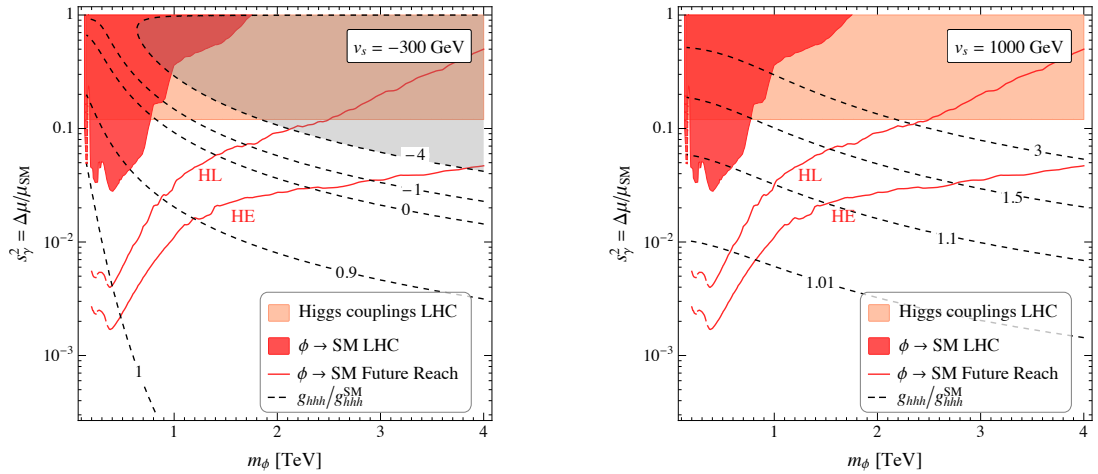

Fig. 6.1.8: Shaded: LHC exclusions from resonance searches (dark red), Higgs coupling measurements (light red) and double Higgs production (gray). Dashed black lines are contours of constant ratio between the trilinear Higgs coupling and its SM value, continuous red lines are expected sensitivities from resonance searches at the HL- and HE-LHC. The singlet VEV v_s is fixed to -300 GeV (left) and to 1000 GeV (right).

Constraints from direct searches of the extra singlet. The collider phenomenology of ϕ is fully controlled by only 3 parameters, m_ϕ, γ and $\mathcal{B}(\phi \to hh)$. Analogously to the case of the triple Higgs coupling g_{hhh}, $\mathcal{B}(\phi \to hh)$ depends dominantly on the model parameters v_s, γ, and m_ϕ [535]. Moreover, because of the Goldstone boson equivalence theorem, it reaches the asymptotic value $\mathcal{B}(\phi \to hh) = \mathcal{B}(\phi \to ZZ) = 25\%$ for $m_\phi \gg m_h$, further reducing the number of parameters relevant for the phenomenology of ϕ. Current resonance searches at the LHC exclude the red shaded area in Fig. 6.1.8, and are dominated by the CMS combined ZZ search in Ref. [542] at 13 TeV with 36 fb^{-1} of data. We rescale the expected sensitivity at 13 TeV [542] at higher energies and luminosities using quark parton luminosities, with a procedure analogous to the one presented in Ref. [535]. Our results for the expected sensitivities at the HL (14 TeV, 3 ab^{-1}) and HE (27 TeV, 15 ab^{-1}) stages of the LHC are also shown in Fig. 6.1.8. Direct searches for the new scalar constitute the strongest probe of the parameter space of these models for m_ϕ below about a TeV, while larger masses are (and will be) probed more efficiently by deviations in Higgs couplings, thus making these two strategies complementary in the exploration of these models.

Implications for the NMSSM. The NMSSM adds to the MSSM particle content a singlet S, so that the superpotential reads $W = W_{\rm MSSM} + \lambda\, S H_u H_d + f(S)$. The fine-tuning needed to reproduce the EW scale is parametrically alleviated, with respect to the MSSM, and for a given value of the stop and gluino masses, by a factor λ/g, see *e.g.* Ref.s [543–546]. Naturalness arguments thus favour a large λ, that is however bounded from above by perturbativity. Assuming the masses of the extra Higgs bosons in the TeV range, a model with $\lambda \simeq 2$ becomes strongly coupled at scales of order 10 TeV, and to have a perturbative coupling up to the GUT scale one needs $\lambda \lesssim 0.7$ [547].[10]

Here we employ the economical parametrisation of the NMSSM scalar sector put forward in Ref.s [548, 549]. We then assume the extra Higgs doublet to be (slightly) decoupled, and we study the phenomenology of the Higgs-singlet scalar sector, which can be described by 4 free parameters

$$m_\phi, \quad \lambda, \quad t_\beta, \quad \Delta_{hh}, \tag{6.1.18}$$

where t_β is the ratio of the up and down Higgs VEVS , and Δ_{hh} encodes the radiative contribution to the SM-like Higgs mass $m_h^2 \lesssim m_Z^2\, c_{2\beta}^2 + \lambda^2\, v^2\, s_{2\beta}^2/2 + \Delta_{hh}^2$. The phenomenology discussed in the previous

[10] It is conceivable that a strong sector exists at the scale where λ becomes non-perturbative, and without affecting the success of GUT in the NMSSM, see *e.g.* the model in Ref. [548] and references therein.

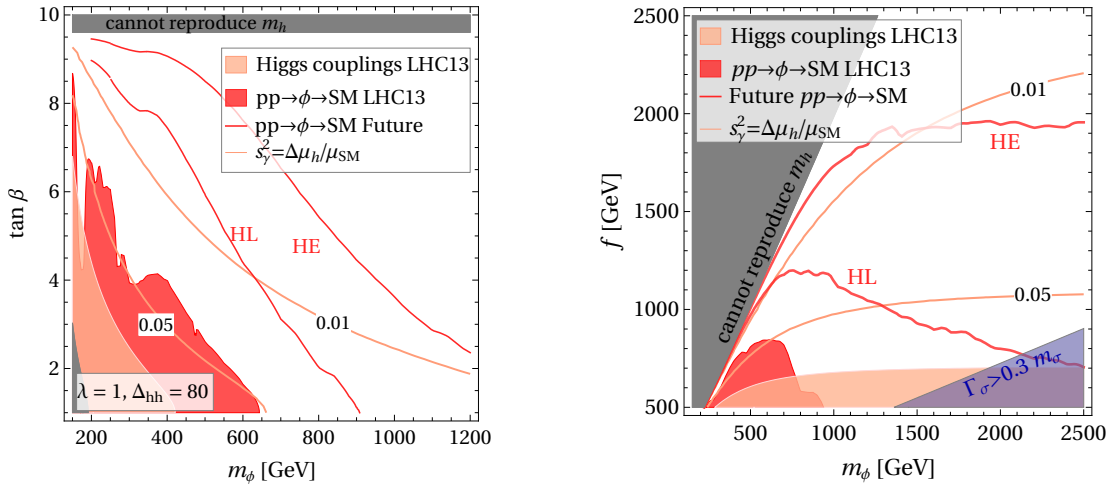

Fig. 6.1.9: Shaded: LHC exclusions from resonance searches (dark red) and Higgs coupling measurements (light red). Left: NMSSM with couplings $\lambda = 1$ and with $\Delta_{hh} = 80$ GeV. Right: Twin and Composite Higgs models. See text for more details.

section is displayed, for the NMSSM, in the left-hand panel of Fig. 6.1.9. We have fixed $\Delta_{hh} = 80$ GeV, a value obtainable for stop masses and mixing in the range of $1 - 2$ TeV. The precise value of Δ_{hh} does not affect the Higgs sector phenomenology as long as it is within order 10% of 80 GeV. We have also fixed $\lambda = 1$, smaller values would make all the exclusions and sensitivities weaker, while larger values would make them stronger.

As seen in Fig. 6.1.9 left, direct searches for the extra singlet are expected to constitute the most promising probe of the $\phi - h$ parameter space. Higgs coupling measurements will give a reach at most comparable to the one of resonance searches, and they will constitute a crucial complementary access to the parameter space of NMSSM scalars. Deviations in the trilinear Higgs coupling depend on more parameters than those in Eq. (6.1.18), and can reach around 50% or more if $\lambda \gtrsim 1$, see Ref. [550] for a precise quantification.

Twin and Composite Higgs. In both TH and CH models, the SM-like Higgs boson is the pseudo-Goldstone boson associated to the spontaneous breaking of a global symmetry at a scale f. The EW fine-tuning of CH models is comparable to the one of typical SUSY constructions, while TH models can achieve a tuning as good as the irreducible factor v^2/f^2 (mainly because the top partners are neutral under colour, and can thus be light). The radial scalar mode σ associated to the pseudo-Goldstone Higgs has a mass $m_\sigma \sim g_* f$, where the size of g_* corresponds to the typical one of the coupling of the UV completion. TH models with weakly coupled UV completions feature an extra scalar singlet that can be light, see *e.g.* Ref.s [551, 552]. The hunt for the extra scalar is a crucial test of TH models, because of the small couplings to the SM of the rest of the "Twin" states.

The scalar potential of TH and CH models has less free parameters, so that all the quantities relevant for the scalar phenomenology (including g_{hhh} and $\mathcal{B}(\phi \to hh)$) are a function of two free parameters only, that we choose to be f and m_σ. One for example obtains $s_\gamma \approx v/f$ and $g_{hhh} \approx 1$ up to terms suppressed by the small ratio v^2/f^2. In TH, an extra freedom is given by the decay channels of ϕ into the Twin sector, whose BR in the limit $m_\sigma \gg gf$ is fixed, through the Goldstone boson equivalence theorem, by the symmetries of the model (3/7 in the cases of $SO(8)/SO(7) \simeq SU(4)/SU(3)$). For simplicity, and because such decay is absent in CH models, we do not include it in our study.

The constraints and sensitivities discussed above are displayed in the right-hand panel of Fig. 6.1.9. Given our considerations above, in the case where these models are not too strongly coupled (we show in Fig. 6.1.9 the region where $\Gamma_\sigma > 0.3 m_\sigma$), they are expected to manifest themselves first via new diboson resonances. On the contrary, their strong-coupling regime is expected to show up first in deviations in

the Higgs couplings.

6.1.5 *Relaxion at the HL-LHC*

Contributors: E. Fuchs, M. Schlaffer

The relaxion mechanism [553] addresses the hierarchy problem differently than conventional symmetry-based solutions. In this framework, the Higgs mass is stabilised dynamically by the relaxion, a pseudo-Nambu-Goldstone boson. The Higgs mass is scanned by the evolution of the relaxion field. Eventually, the relaxion stops at the field value where the Higgs mass is much smaller than the theory's cutoff, hence addressing the fine tuning problem. Relaxion models do not require top, gauge or Higgs partners at the TeV scale. The possible mass range for the relaxion ranges from sub-eV to tens of GeV. Hence this framework can lead to signatures relevant for cosmology, for the low-energy precision frontier, for the intensity frontier, and for the high energy collider frontier. For detailed studies see Ref.s [554–556].

The aspects of the relaxion mechanism that are relevant for the phenomenology at colliders are summarised in the following. The effective scalar potential of the theory depends both on the Higgs doublet H and the relaxion ϕ,

$$V(H,\phi) = \mu^2(\phi) H^\dagger H + \lambda (H^\dagger H)^2 + V_{\rm sr}(\phi) + V_{\rm br}(h,\phi)\,, \tag{6.1.19}$$

$$\mu^2(\phi) = -\Lambda^2 + g\Lambda\phi + \dots\,, \tag{6.1.20}$$

where Λ is the cutoff scale of a Higgs loop. The relaxion scans μ^2 via the slow-roll potential

$$V_{\rm sr}(\phi) = rg\Lambda^3\phi\,, \tag{6.1.21}$$

where g is a small dimension-less coupling and $r > 1/(16\pi^2)$ due to naturalness requirements. Once $\mu^2(\phi)$ becomes negative, the Higgs gets a VEV $v^2(\phi) = -\frac{\mu^2(\phi)}{\lambda}$. The non-zero VEV activates a periodic (model-dependent) backreaction potential $V_{\rm br}$ associated with the backreaction scale $\Lambda_{\rm br}$ that eventually stops the rolling of the relaxion at a value ϕ_0, where $v(\phi_0) = 246$ GeV. Generically, the relaxion mechanism leads to CP violation and as a result, the relaxion ϕ mixes with the Higgs h and inherits its couplings to SM fields [554, 555]. The relaxion mass m_ϕ and the mixing angle $\sin\theta$ can be expressed as

$$m_\phi \simeq \frac{\Lambda_{\rm br}^2}{f}\sqrt{c_0}\,, \tag{6.1.22}$$

$$\sin\theta \simeq 8\frac{\Lambda_{\rm br}^4}{v^3 f} s_0\,, \tag{6.1.23}$$

where $s_0 \equiv \sin\phi_0$, $c_0 \equiv \cos\phi_0$, and f is the scale where the shift symmetry of the backreaction potential is broken. Combining Eq.s (6.1.22) and (6.1.23) with $4\Lambda_{\rm br}^2 s_0 < v^2\sqrt{c_0}$, which is fulfilled due to the suppressed value of s_0 at the endpoint of the rolling [555], the mixing angle as a function of the relaxion mass is approximately bounded by

$$\sin\theta \leq 2\frac{m_\phi}{v}\,. \tag{6.1.24}$$

This upper bound on the relaxion-Higgs mixing is indicated by the black line in Fig. 6.1.10.

Moreover, in the broken phase a trilinear relaxion-relaxion-Higgs coupling $c_{\phi\phi h}$ is generated [554, 556],

$$c_{\phi\phi h} = \frac{\Lambda_{\rm br}^4}{vf^2}c_0 c_\theta^3 - \frac{2\Lambda_{\rm br}^4}{v^2 f}s_0 c_\theta^2 s_\theta - \frac{\Lambda_{\rm br}^4}{2f^3}s_0 c_\theta^2 s_\theta - \frac{2\Lambda_{\rm br}^4}{vf^2}c_0 c_\theta s_\theta^2 + 3v\lambda c_\theta s_\theta^2 + \frac{\Lambda_{\rm br}^4}{v^2 f}s_0 s_\theta^3\,, \tag{6.1.25}$$

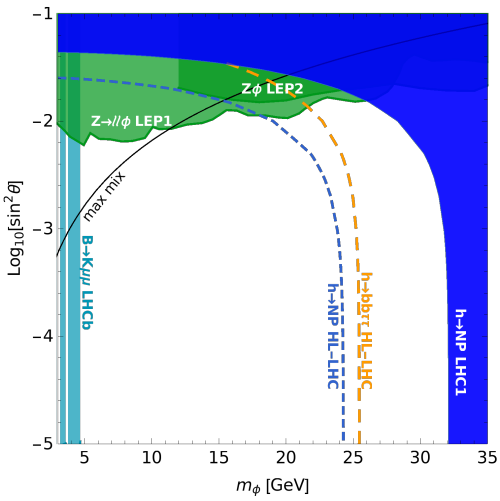

Fig. 6.1.10: Bounds and projections at the 95% C.L. for processes at hadron and lepton colliders. $Z \to Z^*\phi \to \ell\bar{\ell}\phi$ at LEP1 with $\sqrt{s} = M_Z$ [557] and $e^+e^- \to Z\phi$ at LEP2 with $\sqrt{s} = 192 - 202$ GeV [558]. Bound from $B^+ \to K^+\mu^+\mu^-$ at LHCb [559, 560]. Direct searches for exotic Higgs decays at the HL-LHC in the $bb\tau\tau$ channel inferred from Ref. [561] (orange, dashed). Upper bound on $\mathcal{B}(h \to \text{NP})$ from Higgs coupling fits at the LHC Run-1 (blue area) and projection for the HL-LHC with 3 ab^{-1} (blue, dashed). The maximal mixing according to Eq. (6.1.24) is indicated by the black line.

where $s_\theta \equiv \sin\theta$, $c_\theta \equiv \cos\theta$. Thus a bound on $c_{\phi\phi h}$ constrains the $(m_\phi, \sin\theta)$ parameter space. In the limit of small mixing, Eq. (6.1.25) reduces to $c_{\phi\phi h} \simeq m_\phi^2/v$, therefore directly constraining the mass.

There are two complementary ways to constrain $c_{\phi\phi h}$ via the exotic Higgs decay $h \to \phi\phi$: searching directly for the decay products of the ϕ pair, or bounding this BR by a global fit of Higgs couplings.

Concerning the Higgs phenomenology, the relaxion can be viewed as a singlet extension of the SM with a mixing of ϕ and h. The Higgs couplings to SM particles are reduced by the universal coupling modifier $\kappa \equiv \cos\theta$, and the total Higgs width $\Gamma_h^{\text{tot}} = \cos^2\theta\,\Gamma_h^{\text{tot,SM}} + \Gamma_h^{\text{NP}}$ contains the NP contribution $\Gamma_h^{\text{NP}} = \Gamma(h \to \phi\phi)$. For the LHC, $\mathcal{B}(h \to \text{NP})$ has been constrained via a Higgs coupling fit to Run-1 data to be at most 20% at the 95% C.L. while the HL-LHC has the potential to bound this BR to approximately 8.6% at the 95% C.L. Ref. [32, 562]. The resulting bounds in the $(m_\phi, \sin\theta)$ plane are shown in Fig. 6.1.10.

The parameter space probed by the HL-LHC enters the region below the upper bound of the mixing and is therefore relevant for the model. The HL-LHC may exclude a relaxion mass above 24 GeV for vanishing $\sin\theta$. In comparison, direct relaxion production via $B \to K\phi$, $\phi \to \mu\mu$ at LHCb excludes $2m_\mu \leq m_\phi \lesssim 5$ GeV also for $\sin\theta$ smaller than shown in Fig. 6.1.10. In contrast, the bounds set by LEP1 via the 3-body Z-decay into $f\bar{f}\phi$ and by LEP2 via relaxion strahlung in $Z\phi$ production are sensitive only to mixing angles of order $\sin^2\theta \gtrsim 10^{-2}$ and therefore constrain mostly parameter space above the theoretically motivated maximal mixing. Furthermore, the stronger bound reachable at the HL-LHC, compared to the Run-1 one, is highly beneficial for constraining the relaxion mass space down to small mixing angles.

Regarding direct searches for the relaxion decay products, each relaxion from the Higgs decay further decays into a pair of SM particles, resulting in a four-particle final state F. The ATLAS and CMS searches for such signatures yield m_ϕ-dependent bounds on $(\sigma_h/\sigma_h^{\text{SM}}) \times \text{BR}\,(h \to \phi\phi \to F)$. However, none of the current searches [275, 561, 567–572] is sensitive enough to probe parts of the relaxion parameter space displayed in Fig. 6.1.10, *i.e.* 5 GeV $\leq \text{m}_\phi \leq$ 35 GeV and $10^{-5} \leq \sin^2\theta \leq 10^{-1}$. In contrast, the HL-LHC can probe parts of the relevant parameter space via these channels. We estimate the potential reach of the HL-LHC with 3 ab^{-1} by rescaling the current limits by the ratio of luminosities and by the ratio of the Higgs production cross sections in the dominant channels at 8 or 13 TeV with respect to

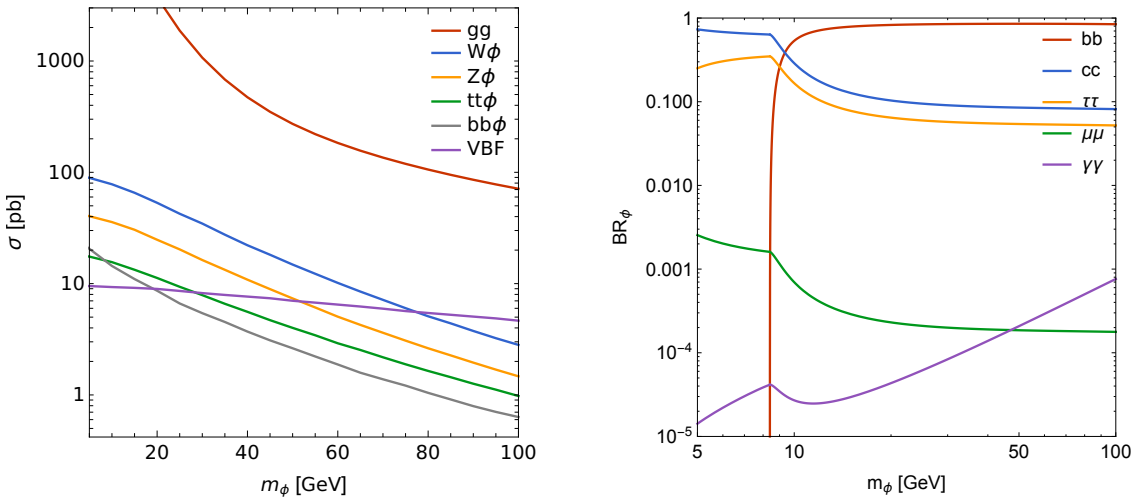

Fig. 6.1.11: Production and decay of ϕ for $\sin^2\theta = 1$. Left: hadronic cross sections, $\sigma(pp \to X)$ at $\sqrt{s} = 14$ TeV for $X = \phi$ (via gluon fusion), $W\phi$, $Z\phi$, $t\bar{t}\phi$, $b\bar{b}\phi$, and ϕjj (via VBF). The $\sigma(pp \to \phi)$ via gluon fusion is calculated using `ggHiggs v3.5` [563–566] at N^{3}LO including N^{3}LL resummation without a p_T-cut. The remaining hadronic cross sections are obtained from MADGRAPH5_aMC@NLO [67] at NLO with $p_T(\phi) > 20$ GeV. Right: BRs $\mathrm{BR}(\phi \to b\bar{b},\, c\bar{c},\, \tau^+\tau^-, \mu^+\mu^-, \gamma\gamma)$.

14 TeV for the search results from Run-1 or Run-2, respectively [573]. According to this scaling, we find that the strongest bound at the HL-LHC is expected in the $bb\tau\tau$ channel (inferred from the CMS search at Run-2 [561]), excluding $m_\phi > 26$ GeV at 95% C.L. as shown in Fig. 6.1.10.

Concerning the relaxion direct production at colliders, similarly to the Higgs, the dominant production modes for the relaxion are gluon fusion ($pp \to \phi$), relaxion strahlung ($pp \to Z\phi,\ W\phi$), $\{t\bar{t},\ b\bar{b}\}$-associated production, and vector boson fusion (VBF, $pp \to \phi jj$). The cross sections of these processes are shown for $\sin\theta = 1$ in the left panel of Fig. 6.1.11. For the HL-LHC, a promising channel is relaxion strahlung due to the relatively large cross sections in combination with the presence of a massive gauge boson that can be tagged. Various decay modes can be considered, see the right panel of Fig. 6.1.11. So far the $Z\phi$ and $W\phi$ searches do not cover the challenging low-mass range. With high luminosity, extending these searches to lower masses could yield complementary bounds.

6.1.6 The HL-LHC and HE-LHC scope for testing compositeness of 2HDMs

Contributors: S. De Curtis, L. Delle Rose, S. Moretti, A. Tesi, K. Yagyu

Much has been written about the ability of TeV scale compositeness to naturally remedy the hierarchy problem of the SM, in particular through the pseudo-Nambu Goldstone boson (pNGB) nature of the Higgs state. This idea is borrowed from QCD: the discovered Higgs boson is the analogue of the pion. Just like there are π, η, *etc.* mesons predicted by QCD, though, there could be several Higgs states predicted by compositeness beyond the one discovered. In this respect, a natural setting [574] is the Composite 2-Higgs Doublet Model (C2HDM) [575–577]. It is built upon the experimentally established existence of a doublet structure triggering Electro-Weak Symmetry Breaking (EWSB), generating the $W^\pm$, Z and SM-like Higgs state h, yet it surpasses it by providing one more composite doublet of Higgs states that can be searched for at the LHC, alongside additional composite gauge bosons (the equivalent of the ρ, ω, *etc.* of QCD) and composite fermions. We concentrate here on the Higgs sector of the C2HDM (see Ref. [578] for a comparative study between the 2HDM based composite solution to the hierarchy problem and the one driven instead by Supersymmetry) based on $SO(6) \to SO(4) \times SO(2)$, in presence of so-called *partial compositeness* [579] realised through the third generation of the SM fermions. The scalar potential and, thus, the masses of the Higgs bosons are generated at one-loop level by the linear mixing between the (elementary) SM and the (composite) strong sector fields. This implies

that masses and couplings are not free parameters, unlike in the elementary realisations, but they depend upon the strong sector dynamics and are strongly correlated. The compositeness scale f is within the energy domain of the LHC and the composite nature of the SM-like Higgs boson in the C2HDM can be revealed through corrections of $\mathcal{O}(\xi)$, where $\xi = v^2/f^2$, with v being the VEV of the SM Higgs field. As current lower limits on f are of order 750 GeV, this implies that such effects enter experimental observables at the $5-10\%$ level. In order to test these effects, the best strategy is to probe gauge interactions of the SM-like Higgs boson, universally affected by $\mathcal{O}(\xi)$ corrections. In particular, these effects are expected to be larger than the corresponding ones in Elementary realisations of a 2HDM (E2HDM) [479], and therefore accessible at the HL-LHC. However, if these were to be found consistent with those of the E2HDM, the last resort in the quest to disentangle the C2HDM from the E2HDM hypothesis would be to exploit the correlation among observable processes involving extra Higgs bosons. Hence, under the above circumstances, it becomes mandatory to assess the scope of the HL- and HE-LHC, the latter being necessary for processes involving Higgs boson self-interactions, which have rather small cross-sections at the current LHC, in exploring the structure of extended Higgs sectors. We shall do so by studying under which LHC machine conditions one could access the processes $gg \to H \to hh \to b\bar{b}\gamma\gamma$ and $gg \to H \to t\bar{t}$ (followed by semi-leptonic top decays), as these will enable one to extract crucial C2HDM parameters, wherein H is the heaviest of the two CP-even (neutral) Higgs states of the C2HDM, the lightest (h) being the SM-like one.

The construction of the model and the fundamental parameters of the C2HDM are described in Ref. [578, 580]. These correspond to the scale of compositeness f, the coupling of the spin-1 resonances, the masses of the heavy top partners, and the mixing between the latter and the elementary top quark (which represents the leading contribution to the effective scalar potential). In order to have phenomenologically acceptable configurations with EW parameters consistent with data, we require: (i) the vanishing of the two tadpoles of the CP-even Higgs bosons, (ii) the value of the top quark mass to match the measured one, and (iii) the value of the Higgs boson mass to match the measured one. Under these constraints, we explore the parameter space by scanning the scale of compositeness in the range $(750, 3000)$ GeV and all the other parameters in the range $(-10, 10)f$. As outputs, we obtain the masses of the charged Higgs boson ($m_{H^\pm}$), the CP-odd Higgs boson (m_A), and the heavier CP-even Higgs boson (m_H), the mixing angle θ between the two CP-even Higgs boson states (h, H), as well as their couplings to fermions and bosons. These quantities are then combined in physics observables and tested against experimental measurements through HiggsBounds [581] and HiggsSignals [582], which include current results from void Higgs boson searches and parameter determinations from the discovered Higgs state, respectively. Further, we extrapolated the latter (at present counting on about 30 fb^{-1} of accumulated luminosity after Run-1 and in Run-2) to $\sqrt{s} = 14$ TeV with 300 fb^{-1}(end of Run-3) and 3 ab^{-1}(HL-LHC), by adopting the expected experimental accuracies given in Ref. [583] (scenario 2 therein). These are listed against the so-called κ's (or 'coupling modifiers') of Ref. [584], among which those interesting us primarily are κ^h_{VV} ($V = W^\pm, Z$), $\kappa^h_{\gamma\gamma}$ and κ^h_{gg}, generally the most constraining ones.

Before proceeding with presenting our results, it is worth mentioning that a generic 2HDM Lagrangian introduces, in general, Flavour Changing Neutral Currents (FCNCs) at tree level via Higgs boson exchanges. To avoid them, we assume here an alignment (in flavour space) between the Yukawa matrices like in the elementary Aligned 2HDM (A2HDM) [585]. In this scenario, the coupling of the heavy Higgs H to the SM top quark is controlled (modulo small corrections induced by the mixing angle $\theta \sim \xi$) by

$$\zeta_t = \frac{\bar{\zeta}_t - \tan\beta}{1 + \bar{\zeta}_t \tan\beta}, \tag{6.1.26}$$

where $\bar{\zeta}_t$ and $\tan\beta$ are predicted, and correlated to each other, in terms of the aforementioned fundamental parameters of the C2HDM. Thus, being interested in the phenomenology of the H state, henceforth we will map the results of our scan in terms of m_H and ζ_t and restrict the parameter space to the region $m_{H,A,H^\pm} > 2m_h$. The ζ_t parameter and the Higgs trilinear coupling λ_{Hhh} set the hierarchy among the

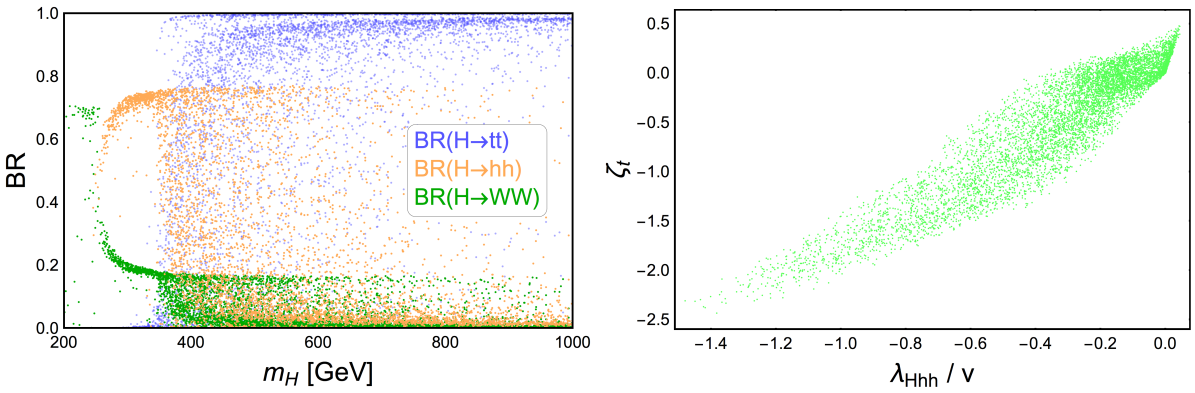

Fig. 6.1.12: Branching ratio of the H state of the C2HDM in the hh (orange) and $t\bar{t}$ (blue) channels (left) and correlation between the ζ_t and λ_{Hhh} couplings obtained upon imposing present HiggsBounds and HiggsSignals constraints at 13 TeV (right).

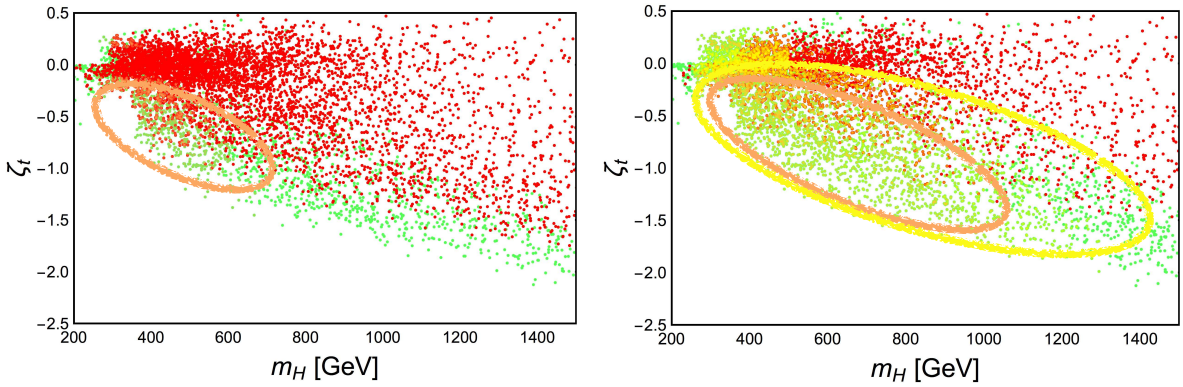

Fig. 6.1.13: Results of the C2HDM scan described in the text. Colour coding is as follows. Green: all points that pass present constraints at 13 TeV. Red: points that, in addition to the above, have κ^h_{VV}, $\kappa^h_{\gamma\gamma}$ and κ^h_{gg} within the 95% C.L. projected uncertainty at 14 TeV with $\mathcal{L} = 300$ fb^{-1} (left) and $\mathcal{L} = 3$ ab^{-1} (right). Orange: points that, in addition to the above, are 95% C.L. excluded by the direct search $gg \to H \to hh \to b\bar{b}\gamma\gamma$, at 14 TeV with $\mathcal{L} = 300$ fb^{-1} (left) and $\mathcal{L} = 3$ ab^{-1} (right). In the right plot the yellow points are 95% C.L. excluded by the same search at the HE-LHC with $\mathcal{L} = 15$ ab^{-1}. The orange and yellow elliptical shapes highlight the regions in which the points of the corresponding colour accumulate.

decay modes of the heavy state H. In particular, $H \to t\bar{t}$, when kinematically allowed, represents the main decay channel. Below the $t\bar{t}$ threshold, the diHiggs $H \to hh$ decay mode can reach, approximately, 80%, with the remaining decay space saturated by $H \to VV$. The corresponding BR observables are shown in Fig. 6.1.12 (left). Both of these can be notably different in the C2HDM with respect to the E2HDM, since the Hhh and $Ht\bar{t}$ couplings can carry the imprint of compositeness (see Fig. 6.1.12 (right) for their correlation). The hierarchy discussed above highlights the key role of the $H \to hh$ and $H \to t\bar{t}$ channels in the discovery and characterisation of the composite heavy Higgs boson.

Figures 6.1.13 and 6.1.14 illustrate the interplay between direct and indirect searches and the ability of the HL- and HE-LHC to discover both the $gg \to H \to hh \to b\bar{b}\gamma\gamma$ and the $gg \to H \to t\bar{t}$ (followed by semi-leptonic top decays) signals, respectively, over regions of the C2HDM parameter space mapped onto the (m_H, ζ_t) plane, even when no deviations are visible in the aforementioned κ's of the SM-like Higgs state h (red points) at the LHC at $\sqrt{s} = 14$ TeV with $\mathcal{L} = 300$ fb^{-1} and $\mathcal{L} = 3$ ab^{-1}. Notice that 95% C.L. exclusion limits are extracted by adopting the sensitivity projections of Ref.s [586, 587] while compliance with the coupling modifiers is here achieved by asking that $|1 - k^h_i|$

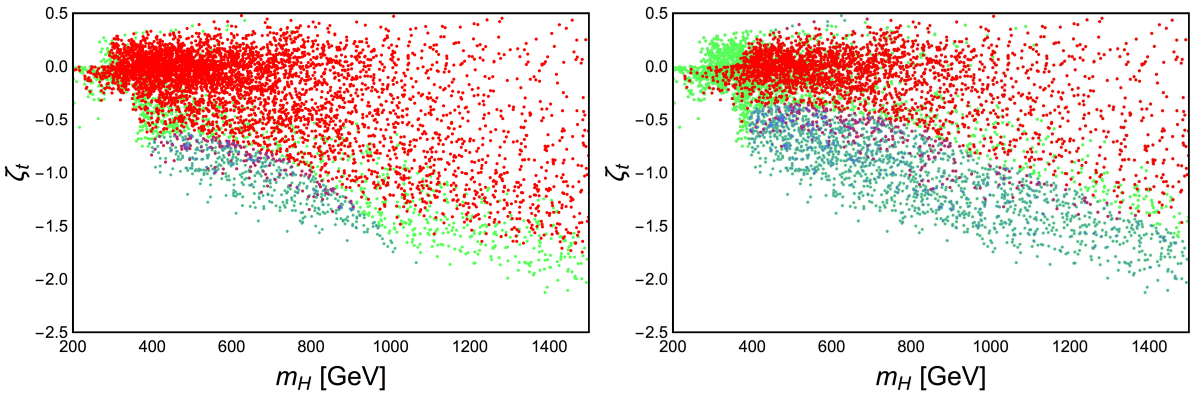

Fig. 6.1.14: Green an red points are as in the previous plot. Blue: points that, in addition to the above, are 95% C.L. excluded by the direct search $gg \to H \to t\bar{t}$, at 14 TeV with $\mathcal{L} = 300$ fb^{-1} (left) and $\mathcal{L} = 3$ ab^{-1} (right).

is less than the percentage uncertainty declared in Ref. [583], where $i = VV, \gamma\gamma$ and gg. Of some relevance, while tensioning the scope of the two search channels to one another, is to note that the orange points have a large overlap with the red ones for small $|\zeta_t|$ values while the corresponding overlap of the blue region is smaller but it reaches larger H masses. Hence, the first channel enables one to cover a larger C2HDM parameter space while the second one higher H masses. Clearly, the combination of the two allows one to combine the benefits of either. The HE-LHC, assuming $\sqrt{s} = 27$ TeV and $\mathcal{L} = 15$ ab^{-1}, will improve the reach in the H high mass region up to 1.2 TeV by studying the process $gg \to H \to hh \to b\bar{b}\gamma\gamma$. For the $gg \to H \to t\bar{t}$ channel, the naive extrapolation of the sensitivity with the parton luminosities is unreliable because it is affected by the SM $t\bar{t}$ threshold effects.

For a proper phenomenological analysis of the $t\bar{t}$ process, one should eventually account for interference effects with gg-induced (irreducible) background. For example, it is well-known that interference effects between the t, u-channel gg-induced Leading Order (LO) QCD diagrams and the one due to a Higgs boson in s-channel via gg-fusion generate a characteristic peak-dip structure of the $M_{t\bar{t}}$ spectrum. However, this contribution is only one of the many entering at the same order in perturbation theory. In fact, Ref. [588] investigated the effect of all one-loop corrections of $\mathcal{O}(\alpha_S^2\alpha_W)$ onto the $t\bar{t}$ invariant mass spectrum at the LHC in presence of both resonant and non-resonant Higgs boson effects. It was shown therein that corrections of $\mathcal{O}(\alpha_S^2\alpha_W)$ involving a non-resonant Higgs boson are comparable to or even larger than those involving interference with the s-channel resonant Higgs boson amplitude and that both of these are subleading with respect to all other (non-Higgs) diagrams through that order. Hence, a complete $\mathcal{O}(\alpha_S^2\alpha_W)$ calculation would be required to phenomenologically assess the relevance of such signal versus background effects in the C2HDM.

In summary, both the HL- and HE-LHC display clear potential in accessing production and decay channels of the heavy CP-even Higgs state of the C2HDM which can give direct access to key interactions that carry the hallmark of compositeness.

6.1.7 Axion-like particles at the HL- and HE-LHC

Contributors: M. Low, A. Mariotti, D. Redigolo, F. Sala, K. Tobioka

The main focus of this contribution is future search strategies for axion-like particles (ALPs) in the mass range between 1 and 90 GeV [589–591]. For simplicity we consider an ALP, a, that couples only to gauge bosons, including a non-zero coupling to gluons. We call this type of ALP a "KSVZ-ALP" because it is inspired by the simplest QCD axion model [592–594]. Such an ALP is perhaps the most theoretically compelling case and also the natural target for hadron colliders, such as the HL-LHC and

the HE-LHC. The effective Lagrangian for the KSVZ-ALP, below the Z mass, is

$$\mathcal{L}_{\rm int} = \frac{a}{4\pi f_a}\left[\alpha_s c_3 G^a\tilde{G}^a + \alpha_2 c_2 W^i\tilde{W}^i + \alpha_1 c_1 B\tilde{B}\right], \tag{6.1.27}$$

$$= \frac{a}{4\pi f_a}\left[\alpha_s c_3 G^a\tilde{G}^a + \alpha_{\rm em} c_\gamma F\tilde{F} + 2\alpha_2 c_W W^-\tilde{W}^+ + \frac{2\alpha_{\rm em}}{t_w} c_{Z\gamma} Z\tilde{F} + \alpha_2 c_w^2 c_Z Z\tilde{Z}\right], \tag{6.1.28}$$

where $\tilde{F}^{\mu\nu} = (1/2)\,\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}$ for any field strength, $\alpha_1 = \alpha'$ is the GUT-normalised $U(1)_Y$ coupling constant, and $t_w = s_w/c_w$ where $c_w^2 = 1 - s_w^2 = m_W^2/m_Z^2$. The coefficients c_i encode the Adler-Bell-Jackiw (ABJ) anomalies of the global $U(1)$ symmetry (of which the ALP is the pseudo-Goldstone boson) with $SU(3)$ and $SU(2)\times U(1)_Y$. After EWSB, one can write

$$c_\gamma = c_2 + \frac{5}{3}c_1, \quad c_W = c_2, \quad c_Z = c_2 + t_w^4\frac{5}{3}c_1, \quad c_{Z\gamma} = c_2 - t_w^2\frac{5}{3}c_1. \tag{6.1.29}$$

For $m_a \lesssim m_Z$, the relevant two-body decays of a are to two photons and to two jets, with widths

$$\Gamma_{gg} = \frac{K_g\alpha_s^2 c_3^2}{8\pi^3}\frac{m_a^3}{f_a^2}, \qquad \Gamma_{\gamma\gamma} = \frac{\alpha_{\rm em}^2 c_\gamma^2}{64\pi^3}\frac{m_a^3}{f_a^2}, \tag{6.1.30}$$

where K_g depends on the ALP mass and includes higher-order QCD corrections (see Appendix A in Ref. [590]). The couplings in Eq. (6.1.27) can be generated by heavy vector-like fermions with a mass at $g_* f_a$, where g_* can be as large as 4π. Explicit realisations include: i) KSVZ "heavy axion" models where the axion potential is UV-dominated, the axion mass is heavier than expected from QCD contributions alone, and the decay constant, f_a, can be as low as a TeV solving the axion quality problem (see Ref.s [595–599] for heavy axion models and Ref. [600] for a discussion of the axion quality problem); ii) ALPs arising in standard paradigms addressing the EW hierarchy problem, such as supersymmetry, where spontaneous SUSY-breaking below $M_{\rm Pl}$ predicts, on general grounds, the existence of an R-axion [601, 602]. iii) Axion portal Dark Matter scenarios where the DM is freezing out through its annihilation into gluons pairs [603, 604]. In Fig. 6.1.15 we show the expected decay constant for an accidental Peccei-Quinn symmetry broken by dimension 6 operators at $M_{\rm GUT} = 10^{15}$ GeV, and the one for an axion portal which account for all of the DM relic abundance, see Ref. [590] for more details.

Barring a huge hierarchy among the anomaly coefficients, $c_{1,2} \gtrsim 10^2 c_3$, the width into gluons dominates over the one into photons, $\Gamma_\gamma/\Gamma_{gg} = \alpha_{\rm em}^2/(8K_g\alpha_3^2) \sim 10^{-4}$. ALPs that couple to gluons decay promptly in any kinematical configuration and mass range of interest for the LHC. When accounting for the gluon coupling, searches based on rare decays of SM particles (Higgs, Z, Υ, and B-mesons) into ALPs have a weaker bound on f_a because the dominant BR of the ALP is now into hadronic final states, while the searches look for final states with muons or photons. The only two relevant decay processes for our parameter space are $Z \to \gamma a$ and $\Upsilon_X \to \gamma a$, and the corresponding decay widths are given by

$$\Gamma(Z\to\gamma a) = \frac{\alpha_{\rm em}^2 c_{Z\gamma}^2}{96\pi^2 t_w^2}\frac{m_Z^3}{f_a^2}\left(1 - \frac{m_a^2}{m_Z^2}\right)^3, \tag{6.1.31}$$

$$\Gamma(\Upsilon_X\to\gamma a) = \frac{\alpha_{\rm em} c_{\gamma\gamma}^2}{\pi}\left(\frac{m_{\Upsilon_X}}{4\pi f_a}\right)^2\left(1 - \frac{m_a^2}{m_{\Upsilon_X}^2}\right)^3\Gamma(\Upsilon_X\to ll), \tag{6.1.32}$$

where $\Gamma(\Upsilon_X\to ll) = \Gamma_{\Upsilon_X}\cdot\mathcal{B}(\Upsilon_X\to ll)$, $\mathcal{B}(\Upsilon_{2S,3S}\to ll) \simeq 3.84\,, 4.36\%$ and $\Gamma_{\Upsilon_{2S,3S}} \simeq 20, 32$ KeV. These constraints, together with those from the LHC, are shown in Fig. 6.1.15.

The bound from Z decays, in Eq. (6.1.31), is based on the LEP search in Ref. [608] which has sensitivity down to 12 GeV. In this range, this search is more powerful than the inclusive bound from the total Z-width [283]. The bound from Υ decays, in Eq. (6.1.32), is based on BABAR data [605]

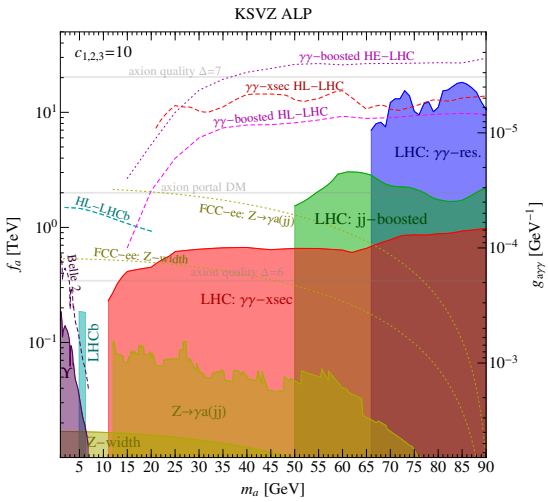

Fig. 6.1.15: Status of the current best experimental constraints on the KSVZ-ALP with ABJ anomalies $c_{1,2,3} = 10$. We include the BABAR bound on $\Upsilon \to \gamma a(jj)$ [605] **(purple)** and its rescaling at Belle II [606] **(purple dotted)**. LHCb bound derived in Ref. [590] from diphoton measurement around the B_s mass [607] **(cyan)**. The projection for HL is also shown **(dashed cyan)**. We also include LEP searches on $Z \to \gamma a(jj)$ [608] and constraints from the Z-width [283] **(yellow)** along with both of their rescalings at FCC-ee [609] **(yellow dotted)**. Constraints from inclusive cross section measurements at the Tevatron [610] and the LHC [611–613] derived in Ref. [589] **(red)** and the rescaled sensitivities of the 8 TeV cross section measurement [613] at the HL-LHC **(dashed red)** are shown. Finally, LHC bounds on boosted dijet resonances [614] reinterpreted for an ALP in Ref. [589] **(green)**, LHC searches for diphoton resonances [615–617] **(blue)**, and the sensitivity of the boosted diphoton resonance search based on the monojet trigger at the HL-LHC (3 ab^{-1}) and the HE-LHC (15 ab^{-1}) [591] **(dashed/dotted magenta)** are plotted. We also display **(gray)** two theory benchmarks motivated by freeze-out of ALP-mediated Dark Matter and by the QCD axion quality problem, see Ref. [590]. On the r.h.s. y-axis we show $g_{a\gamma\gamma} \equiv \frac{\alpha_{\rm em}}{\pi f_a} c_\gamma$ to make contact with the QCD axion notation.

corresponding to $1.21 \cdot 10^8$ Υ_{3S} and $0.98 \cdot 10^8$ Υ_{2S}. "Standard" inclusive diphoton resonance searches at the LHC do not probe masses below 65 GeV [615–617].

A first example of what can be done to improve the low mass reach is the CMS search for a dijet resonance recoiling against a hard jet [614] that we rescale here for an ALP produced in gluon fusion (see Ref. [589] for more details). As we see in Fig. 6.1.15, this probes ALPs down to 50 GeV. A second example is the bound from inclusive cross section measurements, derived in Ref. [589], that reach masses of 10 GeV. References [610–613] provide tables of the measured differential diphoton cross section per invariant mass bin, $\mathrm{d}\sigma_{\gamma\gamma}/\mathrm{d}m_{\gamma\gamma}$, with the relative statistical ($\Delta_{\rm stat}$) and systematical ($\Delta_{\rm sys}$) uncertainties. A conservative bound was derived in Ref. [589] assuming zero knowledge of the background and requiring

$$\sigma^{\rm th}_{\gamma\gamma}(m_a) < \left[m^{\rm Bin}_{\gamma\gamma} \cdot \frac{\mathrm{d}\sigma_{\gamma\gamma}}{\mathrm{d}m_{\gamma\gamma}} \cdot (1 + 2\Delta_{\rm tot}) \right] \cdot \frac{1}{\epsilon_S(m_a)}. \tag{6.1.33}$$

where $\Delta_{\rm tot} = \sqrt{\Delta^2_{\rm stat} + \Delta^2_{\rm sys}}$. The signal efficiency $\epsilon_S(m_a)$ (see Ref. [589] for its computation) does not go to zero below $p^{\rm min}_{T_{\gamma_1}} + p^{\rm min}_{T_{\gamma_2}}$ because the ALP can still pass the cuts recoiling against unvetoed jet activity in the diphoton cross section measurements. A lower limit on the invariant mass that can be measured, and thus on the testable m_a, is set by

$$m_{\gamma\gamma} > \Delta R^{\rm iso}_{\gamma\gamma} \sqrt{p^{\rm min}_{T_{\gamma_1}} p^{\rm min}_{T_{\gamma_2}}} \tag{6.1.34}$$

where $p^{\rm min}_{T_{\gamma_{1,2}}}$ are the minimal cuts on the photon transverse momenta, and $\Delta R^{\rm iso}_{\gamma\gamma} = 0.4$ is the standard

isolation requirement between the photons. A small mass range around the B_s mass is constrained by diphoton measurements at LHCb [607] as first derived in Ref. [590]. Projections for future stages of LHCb have also been derived in Ref. [590].

Here we discuss new LHC search strategies for the HL-LHC and the HE-LHC to improve the coverage in the f_a-m_a plane of KSVZ-like ALPs. The reaches of future experiments are summarised as dashed magenta lines named in Fig. 6.1.15, where we also display, for comparison, LHCb, the Belle II and FCC-ee projections.[11]

We show the reach of the HL-LHC from inclusive cross section measurements with the strategy outlined in the previous section, assuming the same diphoton trigger as in the 8 TeV run. Our signal cross section includes matching up to 2 jets and a K-factor accounting for NLO corrections computed with ggHiggs v3.5 [563–566] which includes full NNLO and approximate N^{3}LO corrections plus threshold resummation at N^{3}LL$'$. The error on the sensitivity is assumed to be dominated by the error on the measurements. In other words, we assume the MC uncertainties will be reduced below $\Delta_{\rm tot}$ (note that, at the present moment, MC uncertainties on the low-mass bins are at the level of 40% using SHERPA [195, 613, 618]). An unexplored direction in diphoton resonance searches is to reduce the photon isolation requirements and pass the trigger making the resonance recoiling against a hard jet. In Fig. 6.1.15 we show the sensitivity at the HL-LHC and the HE-LHC of a search based on this idea. The signal events are required to pass the existing monojet trigger (the leading jet with $p_{T_{j_1}} > 500$ GeV and $|\eta_{j_1}| < 2.5$). As a consequence the two photons produced from the boosted ALP are collimated: $\Delta R_{\gamma\gamma} \simeq 2m_a/p_{T_{j_1}} \lesssim 0.2\left(\frac{m_a}{50\ \text{GeV}}\right)$ where $p_{T_\gamma} \sim p_{T_{j_1}}/2$. To improve $S/\sqrt{B}$ we then require $p_{T_{\gamma_{1,2}}} > 120$ GeV and $\Delta R_{\gamma\gamma} < 0.8$ and bin the events in invariant mass bins with a constant width of 10 GeV. Since two photons fall into one isolation cone, $\Delta R^{\rm iso}_{\gamma\gamma} = 0.4$, standard photon isolation vetos the ALP signal. In order to access lower invariant masses, we modify the standard isolation requirement by simply subtracting the hardest photon (γ_1) in the isolation cone of every test photon, ($\gamma_{\rm test} \neq \gamma_1$). We require[12]

$$E_T^{\rm iso} - E_{T_{\gamma_1}} < 10\ \text{GeV} \quad \text{where} \quad E_T^{\rm iso} \equiv \sum_{i\neq\gamma_{\rm test}}^{\Delta R_{i,\gamma_{\rm test}}<0.4} E_{T_i}\,. \tag{6.1.35}$$

To validate our analysis we first checked that the standard isolation with $E_T^{\rm iso} < 10$ GeV in DELPHES can reproduce the photon fake rate from multijets and the real photon acceptance from the SM Higgs decay, given by Ref. [619]. We find that the isolation in Eq. (6.1.35) gives a similar fake rate and real photon acceptance to the standard ones while the photons from boosted ALP decay now pass the isolation. The modified isolation requirement allows us to go down to two-photon angular separation of $\Delta R \sim 0.1$.[13] Below this value the two photon showers will start to overlap and the photon identification will have to be modified [621, 622]. A similar strategy was employed by ATLAS in $Z \to \gamma a(\gamma\gamma)$ search (see Ref. [623]).

To estimate the sensitivities in Fig. 6.1.15 we simulated the SM background from $2\gamma+nj$, matched for $n = 1, 2$, and from $j\gamma+j$ with a jet faking a photon both at 14 and 27 TeV. We expect the background from $jj+j$ with two jets faking two photons to be subdominant. Finally, notice that the drop of sensitivity in the low mass range of our analysis is expected to ameliorate including the region of phase space with maximally asymmetric photon momenta $p_{T_{\gamma_2}} \ll p_{T_{\gamma_1}}$. Indeed $m^{\rm min}_{\gamma\gamma} = \sqrt{(p_{T_{j_1}} - p_{T_{\gamma_2}})p_{T_{\gamma_2}}}\,\Delta R^{\rm iso}$ after momentum conservation is imposed, so that minimising the momentum of the second photon becomes

[11] The Belle II and FCC-ee lines are obtained by rescaling of the present bounds from BABAR and LEP with the future luminosities of these experiments: 100 times more Υ_{2S}s and Υ_{3S}s are assumed for Belle II and 10^{12} Zs for FCC-ee.

[12] $E_T^{\rm iso}$ is usually calculated using calorimeter cells, while here we also include information of charged tracks. Objects with $E_{T_i} < 0.5$ GeVare not included in the sum [33].

[13] As minimal angular resolution we take for reference the square towers in the Layer 2 region of ATLAS ECAL [620].

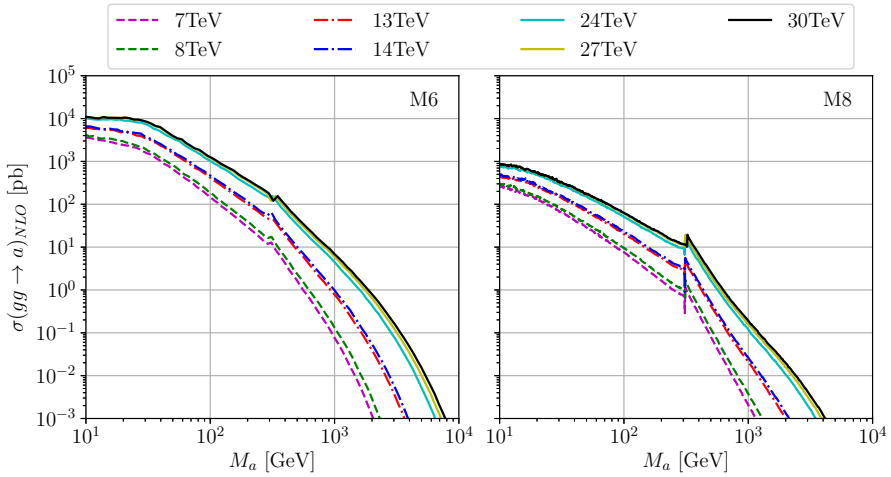

Fig. 6.1.16: Production cross section (dominated by gluon fusion) for the lightest pseudoscalar for the two benchmark models M6 (left) and M8 (right).

beneficial at low invariant masses (see Ref. [591]).

In conclusion, we showed how the sensitivity to KSVZ ALPs can be greatly improved at the HL-LHC and the HE-LHC. Both experiments have sensitivity that exceeds the one of FCC-ee. The type of searches discussed here will probe the parameter space of "heavy axion" models solving the strong CP-problem of the SM and probe SUSY scales, $g_* f_a$, as high as 100 TeV *independently* of any particular assumption on the structure of the SUSY spectrum, it will also probe well motivated scenarios of heavy Dark Matter freeze-in.

Our results have a broader application than the ones discussed here. For example, they can still be the strongest probe in ALP scenarios where the ALP also couples to fermions and the SM Higgs, such as in composite Higgs models [624, 625] where the couplings to photons and gluons are, in fact, generated by top loops. Last but not least, the invariant mass sensitivity can likely be further extended to lower masses by studying to what extent the two collimated photons themselves can trip the monophoton trigger [591], developing techniques to perform bump hunts with L1 triggers [626] and exploring the advantages of converted photons events in the inner tracker.

6.1.8 Search for light pseudoscalar with taus at HL-LHC

Contributors: G. Cacciapaglia, G. Ferretti, T. Flacke, H. Serodio

The discovered Higgs boson may be accompanied by additional light (pseudo-)scalars in models with an extended Higgs sector. We consider a pseudoscalar singlets ϕ, generically coupling as:

$$\mathcal{L} \supset -\sum_{\psi} \frac{iC_{\psi}^{\phi} m_{\psi} \phi}{f_{\phi}} \bar{\psi}\gamma^5\psi + \frac{\phi}{16\pi^2 f_{\phi}} \left(K_G^{\phi} G\tilde{G} + K_W^{\phi} W\tilde{W} + K_B^{\phi} B\tilde{B} \right), \tag{6.1.36}$$

where f_ϕ is a "decay constant" and ψ labels the SM fermions. We focus on models of composite Higgs with partial compositeness described in terms of confining hyper-quarks [624]. A universal feature of all these models is the presence of two such pseudoscalars ($\phi = a, \eta'$), whose couplings in Eq. (6.1.36) can be computed from the underlying model. Additional couplings, including the higher dimensional couplings to the Higgs boson, not included in Eq. (6.1.36), are also determined by the underlying theory (see Ref. [627] for details). In Ref. [627] we narrowed down this class of models to a total of twelve, providing possible benchmarks in the search of new physics.

We present results for two of the twelve models [628, 629], denoted respectively M6 and M8 in Ref. [627], which are those being studied on the lattice [630, 631]. The masses of the pseudoscalars can

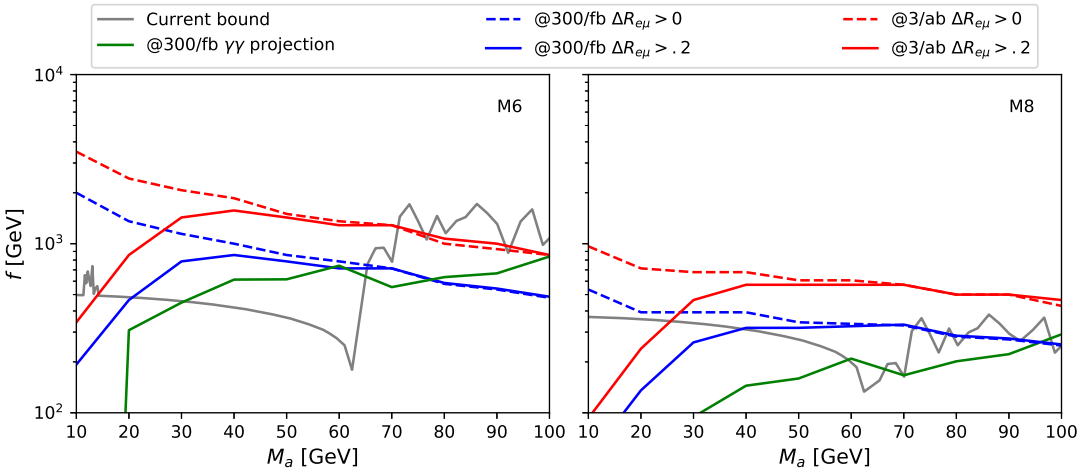

Fig. 6.1.17: Reach of the ditau search for the two models M6 (left) and M8 (right), compared to the existing bounds (gray lines). The existing bounds indicate the strongest exclusion amongst those arising from dimuon searches [632], diphoton searches [615, 617], and BSM decay width of the Higgs [537]. (The bounds from Ref. [300], that can be obtained adapting the analysis of Ref. [633] to these models, may also turn out to be competitive.) We have also indicated the current bounds obtained by adapting the results in Ref. [589] for diphotons (green). The projected reach is computed at 14 TeV using the HL-LHC detector simulation, for a luminosity of 300 fb^{-1}(blue) and 3 ab^{-1} (red), and two distinct cuts on $\Delta R_{\mu e}$.

be considered as free parameters, while their decay constants f_ϕ in Eq. (6.1.36) are related to the composite Higgs decay constant f, defined by $m_W = (g/2) f \sin\theta$, with $\theta \to \pi/2$ being the Technicolour limit [625, 627]. For small underlying hyper-quark masses, the lighter pseudoscalar a is nearly aligned with a spontaneously broken $U(1)$ symmetry and thus can be very light. Its total production cross-section is shown in Fig. 6.1.16 for fixed $f = 1$ TeV. The second pseudoscalar η' is related to an anomalous $U(1)$ (hence the name) and thus receives a larger mass from the strong dynamics.

We observe that the production cross-section of the pseudoscalars is rather large, in contrast to that of other light scalars arising in this class of models that only couple via EW interactions. Nevertheless, as their main decay channels suffer from large backgrounds, they are still fairly unconstrained in the low mass region, particularly between 14 and 65 GeV. In Ref. [625] we proposed a boosted search for the lighter pseudoscalar a in the (fully leptonic, opposite flavour) ditau channel between 10 and 100 GeV. Figure 6.1.17 shows the reach in the M_a/f plane for the two models above. A complementary proposed search in the diphoton channel has been discussed in the previous section, based on Ref. [589].

A crucial discriminating variable in such search, particularly for the low mass region, is the angular separation $\Delta R_{e\mu}$ between the electron and the muon. We present the reach estimated from a cut-and-count simulation with the conservative choice $\Delta R_{e\mu} > 0.2$ included or removed. In the plot we have not taken into account the systematic error in the background, but it is important to remark that, in order to take full advantage of the HL-LHC run, it should be kept below 2%. The additional cuts, discussed in Ref. [625], are: $p_{T\mu} > 50$ GeV, $p_{Te} > 10$ GeV, $\Delta R_{\mu j} > 0.5$, $\Delta R_{ej} > 0.5$, $p_{Tj} > 200$ GeV, $\Delta R_{\mu e} < 1$, $m_{\mu e} < 100$ GeV. Note that we also impose an upper bound on $\Delta R_{\mu e}$ to reduce the (mostly flat) $t\bar{t}$ background.

The heavier pseudoscalar η', not being a true Goldstone boson, could have a mass in the multi TeV range. Nevertheless, it may give observable signals at the LHC because it decays into final states such as $\gamma\gamma$, $Z\gamma$, ZZ, WW, $t\bar{t}$ and Zh (the last one via top loops). In Fig. 6.1.18 we present the lower bounds on f for the two models, in the $(M_a,\, M_{\eta'})$ mass plane. The white region corresponds to masses incompatible with the models [627]. The vertical band with a strong bound for $M_a \sim 215$ GeVcorresponds to Zh searches, which were not included in Ref. [627].

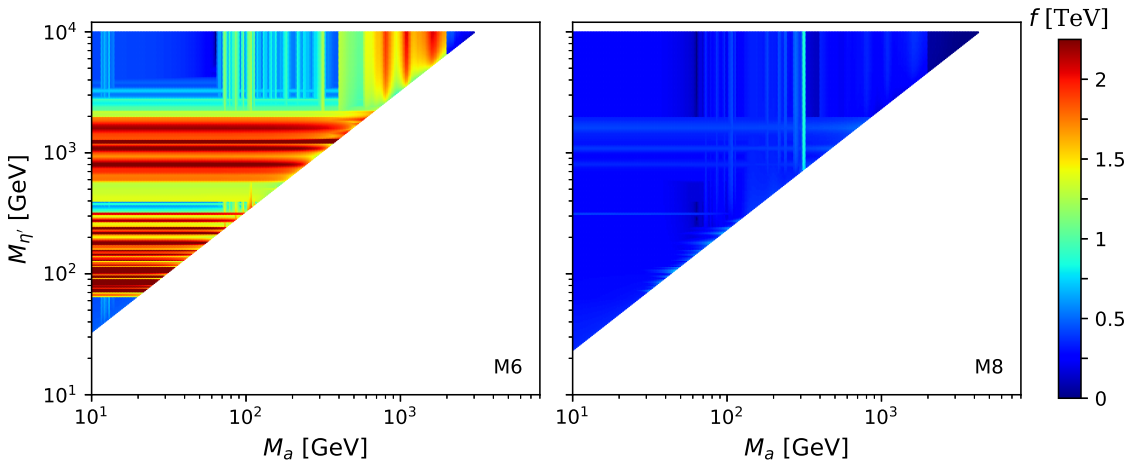

Fig. 6.1.18: Lower bound the Higgs decay constant f for the two benchmark models M6 (left) and M8 (right) in the presence of both pseudoscalars a and η'.

Figure 6.1.18 takes into account the relevant searches performed with the 2016 data of about 36 fb^{-1} of integrated luminosity at 13 TeV. Similar analyses can of course be performed for the remaining models, but the two presented in this work are amongst the least constrained by current data.

In conclusion, the HL and HE phases of the LHC present us with newer possibilities to search for BSM physics. The models discussed here provide concrete examples where new physics could arise both in the high and low mass regime, benefiting from both improvements.

6.1.9 Colour octet scalar into gluons and photons at HL-LHC

Contributors: G. Cacciapaglia, A. Deandrea, A.M. Iyer

We consider a colour octet scalar Φ which is present in various extensions of the SM, and in particular in composite models for the EW sector, where such a state can be a composite object made of fundamental fermions. The colour octet Φ can be produced by single and pair production at the LHC by QCD processes. Due to its nature and quantum numbers, in composite models, it can couple strongly to top quarks and give rise, at one loop in the fundamental theory, to a coupling to gluons and photons via a top loop and the topological anomaly. In particular it also gives rise to an effective vertex with a photon and a gluon which is highly suppressed in SM processes, giving rise to a distinctive mode for its search at the LHC. We therefore consider the decay mode $\Phi \to \gamma g$, thereby making it an exclusive signature for such a state. The effective Lagrangian for this interaction can be written as:

$$\mathcal{L} = a_1 \, f_{abc} G^a_{\mu\nu} G^{b\mu\nu} \Phi^c + a_2 \, f_{abc} f_{ade} \, \Phi^b \, \Phi^d \, G^c_{\mu\nu} \, G^e_{\mu\nu} + c \, G^a_{\mu\nu} \Phi^a B^{\mu\nu} \,, \tag{6.1.37}$$

where a_i are proportional to the strong coupling constant α_s while the ratio c/a depends on the model under consideration. The colour octet can decay into $t\bar{t}$, gg, $g\gamma$, or gZ. The gZ final state is subdominant in comparison to $g\gamma$ as it is suppressed by the Weinberg angle ($\Phi g\gamma$ vertex is derived from the $\Phi G^a_{\mu\nu} B^{\mu\nu}$ term in Lagrangian.). The corresponding comparison of rates of gg with respect to the $t\bar{t}$ final state is parameter dependent and is not considered here. It can however be taken into account by the corresponding reduction of the production rate $\sigma_{eff} = \sigma \times (1 - \mathcal{B}(t\bar{t}))^2$. In this note we are interested in exploring the possibility of the $g\gamma$ decay mode as a possible discovery prospect for the colour octet scalar. For scenarios considered in Ref. [627], where the colour octet arises as a bound state of colour-triplet fermions χ with hyper-charge $1/3$ or $2/3$, the branching fractions amongst the bosonic final states are fixed and given in Table 6.1.4.

We consider the following benchmarks for the mass of the coloured scalar Φ: $m_\Phi = 1, 1.5, 2, 2.5$ TeV. There are existing searches for the pair production of the scalar in the

	$Y_\chi = 1/3$	$Y_\chi = 2/3$
$\frac{\mathcal{B}(\Phi\to g\gamma)}{\mathcal{B}(\Phi\to gg)}$	0.048	0.19

Table 6.1.4: Values of ratios of BRs in di-bosons for the pseudoscalar octet for a mass of 1 TeV. The mass fixes the dependence due to the running of the strong gauge coupling, $\alpha_s(1\text{ TeV}) = 0.0881$ is used for this evaluation.

multi jet channel. For the branching fractions outlined in Table 6.1.4 we compare the efficiency for the multi jet final state corresponding to the existing searches with the following two final states corresponding to the signal: one single photon and three gluons; and two photons and two gluons. The parton level events are simulated at 14 TeV c.o.m. energy using MADGRAPH [67] and showering is done by PYTHIA 8 [50]. We use DELPHES 3 [33] for the detector simulation. The jets are reconstructed using FASTJET [67] with the standard AK4 jet reconstruction algorithm with $R = 0.4$ and $p_T = 60$ GeV. The strategy for the multi-jet final state in this contribution is similar to the analysis in CMS searching in the multi-jet channel for pair produced scalars [634]:

- The jets are reconstructed using the anti-kt algorithm with $R = 0.4$ and $p_T = 60$ GeV. Minimum of 4 jets are required for each event.
- Each jet is required to have a p_T of 80 GeV.
- In order to select the two best di-jet systems compatible with the signal, the four leading jets ordered in p_T are combined to create three unique combinations of di-jet pairs per event. Out of the three combinations, the di-jet configuration with the smallest $\Delta R_{dijet} = \sum_{i=1,2} |\Delta R_i - 0.8|$ is chosen where ΔR^i is the distance in the $\eta - \phi$ plane between the two jets in the i^{th} di-jet pair.
- Asymmetry parameter: Once a configurations is selected, two asymmetry parameters are constructed:

$$M_{asymm} = \frac{|m_{jj1} - m_{jj2}|}{m_{jj1} + m_{jj2}} \quad , \quad \Delta\eta_{asymm} = |\eta_{jj1} - \eta_{jj2}|. \tag{6.1.38}$$

  where m_{jjk} and η_{jjk} is the dijet mass and pseudorapidity combination of the k^{th} di-jet pair. Both these quantities are set < 0.1.

For the 3 jets and 1 photon final state there is no existing search undertaken thus far. Thus we adapt a similar criteria described above. Table 6.1.5 gives the signal and the corresponding background efficiencies (ϵ) for the two topologies and are simply $\epsilon = N_{cut}/N_{gen}$, where N_{cut} is the number of events which pass the cut and N_{gen} are the number of events generated. To facilitate the collider comparison between the gg and the $g\gamma$ decay for the colour octet scalar we define the following ratio:

$$\delta = \frac{S_{ggg\gamma}/\sqrt{B_{jjj\gamma}}}{S_{gggg}/\sqrt{B_{jjjj}}}, \tag{6.1.39}$$

which is computed for the two hypercharge assignments in Table 6.1.4. Here the number of signal or background events (S or B) at a given luminosity $\mathcal{L}$, is simply $\epsilon \times \sigma \times \mathcal{L}$. The ratio however, eliminates the dependence on the luminosity [14]. Using the numbers from Table 6.1.5, the results for the $jjj\gamma$ are given in the first two columns of Table 6.1.6.

The ratio in Eq. (6.1.39) eliminates the dependence on the production cross section and facilitates a transparent comparison of different decay modes. Given the large backgrounds in Table 6.1.5, the signal with the cuts used is not significant, thereby requiring a more detailed analysis. We now discuss the more optimistic 2 gluons and 2 photons final state.

[14] Note that for the $jjj\gamma$ signal $\sigma = \sigma_{prod} 2\,\mathcal{B}(\Phi \to g\gamma)$

	$4j$	$3j$+1γ	$2j$+ 2γ
Signal efficiency ϵ_S ($m_\Phi = 1$ TeV)	0.0067	0.0016	0.0593
Background Efficiency ϵ_B	0.00125	0.00035	0.000114
Background cross section (fb)	6800×10^3	18×10^3	18×10^3

Table 6.1.5: Pair production efficiencies for signal and background. The background cross-section is estimated by requiring the scalar sum of the parton $p_T > 1100$ GeV. The computed efficiencies are simply the ratio of events which pass the cuts to the total number of events generated. The background for $g\gamma g\gamma$ signal is still dominated by QCD $jjja$ background in comparison to the $\gamma\gamma$ + jets. The different efficiencies are a consequence of different selection criteria.

	$S_{ggg\gamma}$		$S_{gg\gamma\gamma}$	
	$Y_\chi = 1/3$	$Y_\chi = 2/3$	$Y_\chi = 1/3$	$Y_\chi = 2/3$
δ	0.84	3.33	1.36	20.56

Table 6.1.6: Comparison of the signal significances ratio δ (defined in Eq. (6.1.39)) between the $ggg\gamma$ and $gggg$ channels for $m_\Phi = 1$ TeV. Similar ratio is computed for the $gg\gamma\gamma$ final state.

In the case of 2 jets + 2 photons, there are only two combinatorial possibilities for the invariant mass reconstruction. Let the isolated photons be denoted as $\gamma_{1,2}$ and the jets as $j_{1,2}$. It is to be noted that the gluon jet and the photon from a given coloured scalar are fairly collimated. Thus in order to identify the correct pair of final states we take the hardest photon γ_1 and compute, $\Delta R_{\gamma_1 j_1}$ and $\Delta R_{\gamma_1 j_2}$ and extract the following:

$$\Delta R_{min} = min(\Delta R_{\gamma_1 j_1}, \Delta R_{\gamma_1 j_2}). \tag{6.1.40}$$

The presence of two photons greatly limits the QCD fake rate. We further impose a hard cut of 180 GeV on the transverse momentum of each photon. The large signal sensitivity in this case is an artefact that a simple p_T cut on the second photon reduces background drastically without affecting the signal significantly. The last two columns of Table 6.1.6 show the comparison of signal sensitivity between the $gg\gamma\gamma$ and $gggg$ channels, implying that they are both similar even for the pessimistic case of smaller branching fraction corresponding to $Y_\chi = 1/3$. The left plot of Fig. 6.1.19 shows the reconstructed invariant mass distribution and the right plot gives the signal significance as a function of luminosity for the optimistic case of $Y_\chi = 2/3$. Using the computation for production cross-sections for 14 TeV in [635], we estimate the sensitivity for different signal benchmarks from 0.3 to 3 ab^{-1}. With a high luminosity run one can reach a sensitivity close to $\sim 2.0\ \sigma$ for $m_\Phi = 1$ TeV. This, as well the sensitivity for the other benchmarks can be further improved by using information of signal kinematics and invariant mass cuts. We have performed a simplified preliminary study of the potential for the study of pair of a colour octet scalar decaying to gluon and photon at the LHC. This opens two additional possibilities for their searches corresponding to the $ggg\gamma$ and $gg\gamma\gamma$ final states. These final states not only serves as an unambiguous signature for colour octets but are also relatively cleaner than the conventional multi jet searches. We demonstrate that for the $gg\gamma\gamma$ channel, we can get a preliminary hint of the existence of the colour octet state at HL-LHC thereby strongly motivating the HE option of the LHC.

6.2 Spin 1 resonances

This section is devoted to the study of the prospects for vector resonances. These are neutral Z' and charged W', which are among the most standard benchmarks usually considered in studying the potential of future colliders, as well as RS gluons and other resonances arising from 2HDMs models.

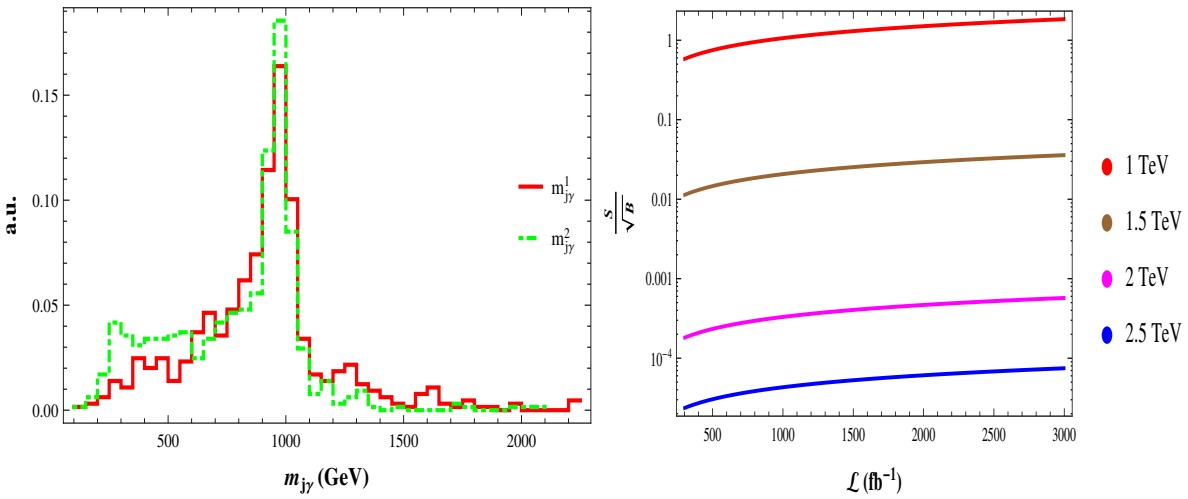

Fig. 6.1.19: Left: distribution of the two reconstructed invariant masses $m_{j\gamma}$ for the 1 TeV benchmark using the criterion in Eq. (6.1.40). $a.u.$ on the Y-axis denotes arbitrary units. Right: Sensitivity for the different signal benchmarks at 14 TeV COM energy for luminosities up to 3 ab^{-1}.

6.2.1 *Precision predictions for new dilepton and $t\bar{t}$ resonances at HL- and HE-LHC*

Contributors: M. Altakach, J. Fiaschi, T. Ježo, M. Klasen, I. Schienbein

We present higher order predictions for spin-1 resonance searches in two classes of observables, top-quark-pair production and dilepton production. In the former case, we use the PBZp code [636] which includes the NLO QCD corrections to the EW production of top-antitop pairs in the presence of a new neutral gauge boson implemented in the parton shower Monte Carlo program POWHEG [637–639]. The dilepton cross sections are calculated using the NLO+NLL code RESUMMINO [640] which matches a soft-gluon resummation at NLL accuracy to a fixed order NLO calculation.

We consider four models: the Un-Unified (UU) [641,642] and the Non-Universal (NU) [643,644] models, a leptophobic topcolour model (TC) (model IV in Ref. [645]), and the SSM [646]. The UU and NU models belong to the general class of G(221)= $SU(2)_1 \times SU(2)_2 \times U(1)_X$ gauge theories with an extra $SU(2)$ gauge symmetry. In the UU model the quarks and leptons belong to different representations of the two $SU(2)$ gauge factors whereas in the NU model the first two generations transform differently than the third generation. Both models take two input parameters, the mixing angle of the first stage symmetry breaking $t = \tan\phi = g_2/g_1$ and the mass of the heavy resonance $M_{Z'}$ (or $M_{W'}$). Exclusion limits on the parameters space for the G(221) models have been derived in Ref. [647] by performing a global analysis of low-energy precision data. Improved limits for the W' and Z' masses were found in Ref. [640] using LHC data at $\sqrt{s} = 7$ and 8 TeV. The TC model has three free parameters in addition to the resonance mass $M_{Z'}$: the width $\Gamma_{Z'}$, the relative strength (f_1) of the Z' coupling to right-handed up-type quarks w.r.t. left-hand up-type quarks, and similarly the relative strength (f_2) of the Z' coupling to right- and left-hand down-type quarks. Finally, in the SSM the only free parameters are the masses $M_{W'}$ and $M_{Z'}$.

We have chosen benchmark points such that the width $\Gamma_{Z'}$ in all models is the same as in the SSM. We have calculated the width in the SSM ($\Gamma^{\rm SSM}_{Z'}$) at leading order using PYTHIA 6 [68] with a running electro-magnetic coupling, $\alpha(M_{Z'})$, such that $\Gamma^{\rm SSM}_{Z'}/M_{Z'}$ slightly increases from 3.48% at $M_{Z'} = 1$ TeV to 3.61% at $M_{Z'} = 10$ TeV. This is achieved by setting the parameter $t = 1$ in the UU and NU models. As a consequence, the W' couplings to the SM fermions are the same in the SSM and NU cases, whereas the Z' couplings are different. For the TC model we set $f_1 = 1$ and $f_2 = 0$ which maximises the fraction of Z' bosons decaying into $t\bar{t}$ pairs. For the parton distribution functions (PDFs), in the $t\bar{t}$ case, we use a NLO PDF4LHC set for Monte Carlo studies (ISET = 90000 in LHAPDF6)

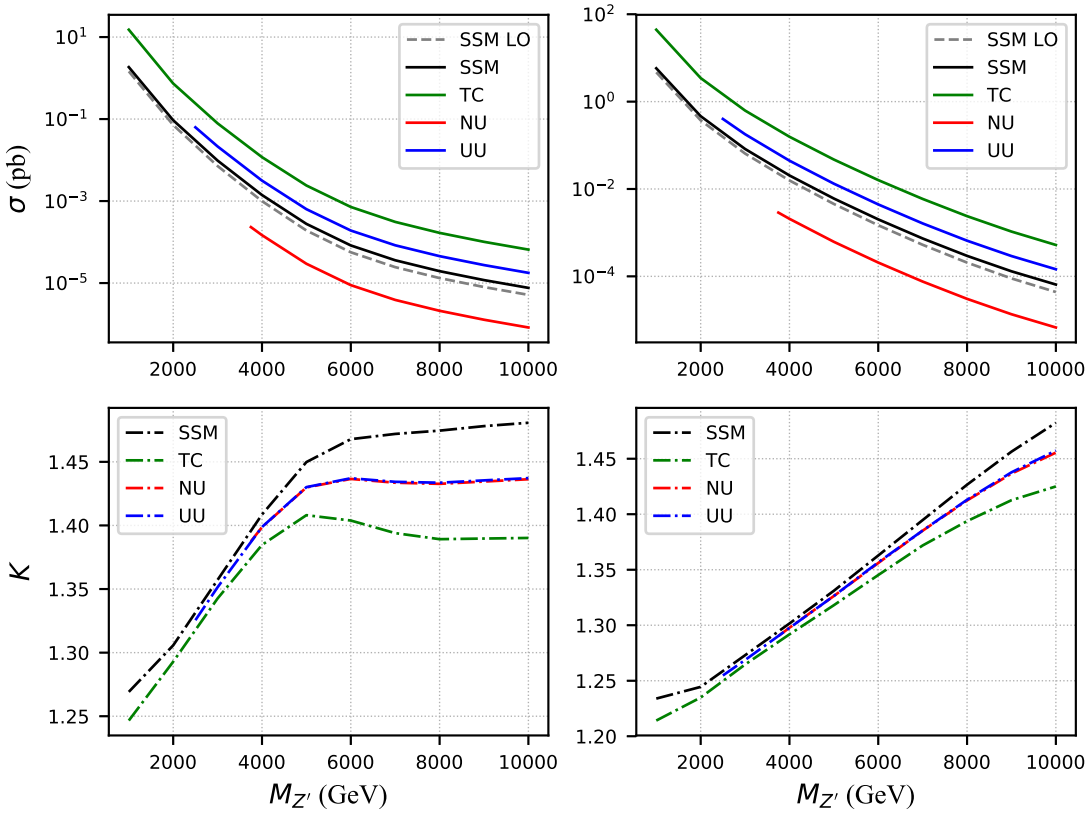

Fig. 6.2.1: Left: LO and NLO total cross section predictions in picobarns for $q\bar{q} \to Z' \to t\bar{t}[+g]$ (top) and the NLO/LO K-factors (bottom) at a c.o.m. energy $\sqrt{s} = 14$ TeV. Right: same as the left for a c.o.m. energy $\sqrt{s} = 27$ TeV.

and the renormalisation and factorisation scales μ_R and μ_F are identified with the invariant mass of the system. On the other hand, in the dilepton case, we use a NLO CT14 (ISET = 13100 in LHAPDF6) and the renormalisation and factorisation scales μ_R and μ_F are identified with the invariant mass of the system.

In Fig. 6.2.1, we show the total cross section for the EW production of $t\bar{t}$ pairs ($q\bar{q} \to Z' \to t\bar{t}[+g]$) in picobarn at a c.o.m. energy $\sqrt{s} = 14$ TeV (left) and 27 TeV (right). The results are given for LO (only for SSM) and NLO cross sections together with the NLO/LO K-factors (bottom) for the SSM, UU, NU, and TC in dependence of the Z' mass. No cut on the invariant mass of the $t\bar{t}$ pair has been applied.

In Fig. 6.2.2 we show the W' production cross sections at a c.o.m. energy $\sqrt{s} = 14$ TeV at NLO and NLO+NLL in the SSM as a function of the heavy gauge boson mass (top left). The ratios of the total cross sections at LHC14 at NLO and NLO+NLL over the LO cross section as a function of the W' mass is also presented (bottom left). Similarly, in the right side of Fig. 6.2.2 we show the same for a c.o.m. energy $\sqrt{s} = 27$ TeV. Interference terms between W and W' gauge bosons are included. The invariant mass of the lepton pair is restricted to $m_{ll} > 3M_{W'}/4$. Increasing the mass the threshold effects become more and more important leading to almost 16% (6%) increase of the cross section at $M_{W'} = 8$ TeV for $\sqrt{s} = 14$ (27) TeV.

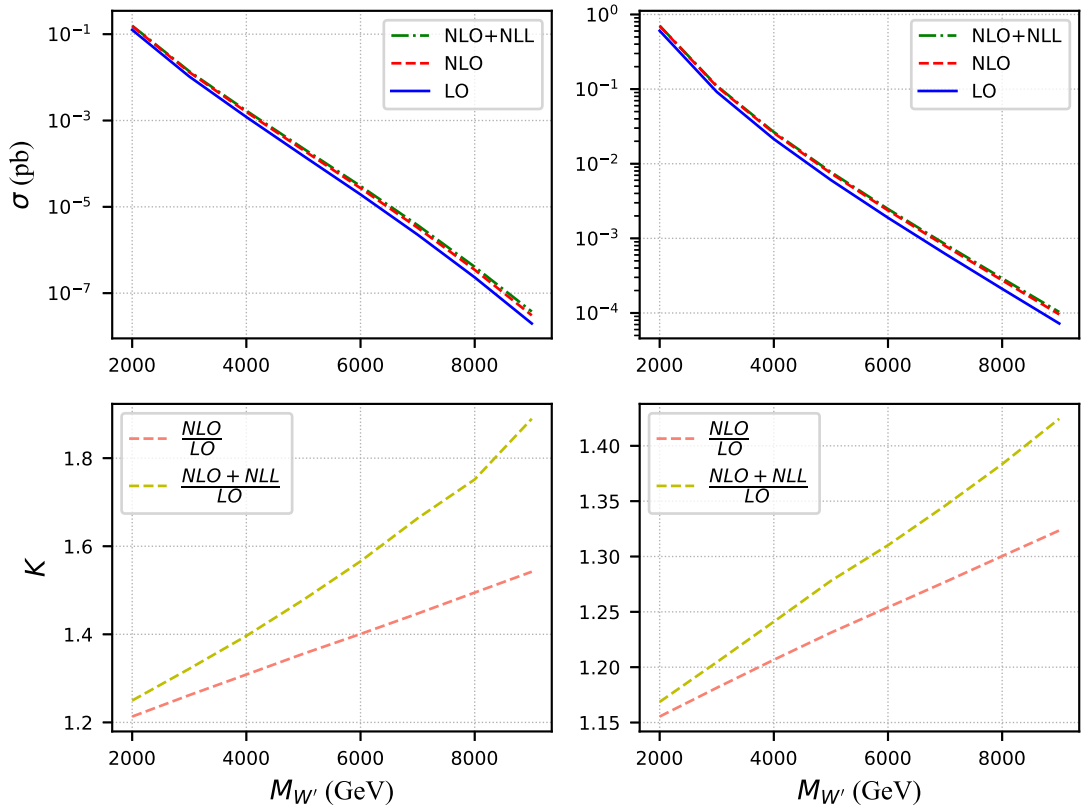

Fig. 6.2.2: Left: LO, NLO, and NLO+NLL total cross section predictions in picobarn for $q\bar{q} \to W|W' \to e\nu$ (top). The NLO/LO and the NLO+NLL/LO K-factors at a c.o.m. energy $\sqrt{s} = 14$ TeV (bottom). Right: same as the left for a c.o.m. energy $\sqrt{s} = 27$ TeV.

6.2.2 Searching for a RS gluon resonance in $t\bar{t}$ at the HL- and HE-LHC

Contributors: M. Narain, K. Pedro, S. Sagir, E. Usai, W. Zhang, CMS

Many models of new physics predict heavy resonances with enhanced couplings to the third generation of the SM [472, 648–654]. Thus, the study of the top quark can give important insight into the validity of such models. This analysis from CMS [655] presents projections for a heavy resonance, in particular a Randall–Sundrum Kaluza–Klein gluon (RSG) [472], decaying into a $t\bar{t}$ pair using the upgraded CMS Phase-2 detector design at HL-LHC, with a c.o.m. energy of 14 TeV. We also present projections for $t\bar{t}$ resonances at a c.o.m. energy of 27 TeV, accessible by the HE-LHC. Two distinct final states with either a single lepton or no leptons are considered. The topology where the hadronic decay products of the top quark are fully merged into a single jet is studied. For top quarks with a large boost (transverse momentum, p_T, greater than 400 GeV), an identification algorithm based on the soft-drop [504] jet grooming algorithm is used in combination with N-subjettiness [508] and subjet b-tagging algorithms to identify the decay of the top quark with no leptons. No lepton isolation is imposed because leptons are not expected to be well separated from other objects in final states.

The RSG signal processes are generated using PYTHIA 8.212 [68] at leading order (LO), assuming a decay width of 17%, and a RS parameter k value of $0.01 \times m_{\text{Planck}}$. The POWHEG 2.0 [638, 639, 656, 657] event generator is used to generate $t\bar{t}$ and single top quark events in the t-channel and tW channel to NLO accuracy. The single top quark events in the s-channel, Z+jets, and W+jets are simulated using MADGRAPH5_aMC@NLO 2.2.2 [67]. The PYTHIA event generator is

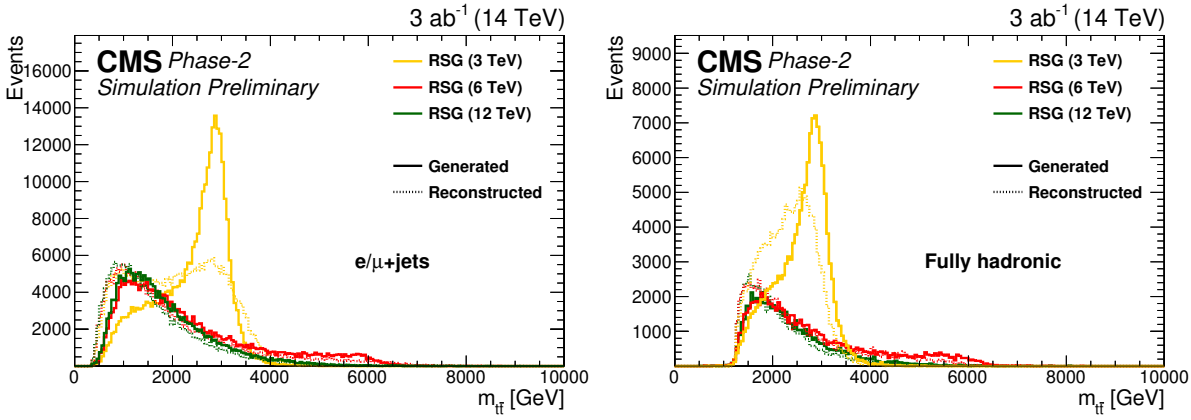

Fig. 6.2.3: Generated and reconstructed RSG mass distributions for the single-lepton (left) and fully hadronic (right) final states. The distributions are shown after full event selection in each final state. The signals are scaled to 1 pb.

used to simulate the QCD multijet and WW events at NLO. Parton showering, hadronisation, and the underlying event are simulated with PYTHIA, using the NNPDF 3.0 parton distribution functions (PDFs) and the CUETP8M1 [658, 659] tune for all Monte Carlo processes, except for the $t\bar{t}$ sample, which is produced with the CUETP8M2T4 [660] tune. The CMS Phase-2 detector simulation and the reconstruction of physics-level objects are simulated with the DELPHES software package [33]. The same signal and background processes are also considered for the HE-LHC projections in both final states at $\sqrt{s} = 27$ TeV, assuming the same number of pileup interactions as the HL-LHC. The reconstruction of physics-level objects for the HE-LHC is simulated with the DELPHES software package with the CMS Phase-2 detector design.

The particle flow (PF) algorithm [661] is used together with the pileup per particle identification (PUPPI) [410] method to reconstruct the final state objects such as electrons, muons, jets, and missing transverse momentum ($\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$). In both final states, large-radius anti-k_{T} jets with a distance parameter of 0.8 (AK8) are used. The AK8 jets are required to have $p_T > 400$ GeV, $|\eta| < 4$, soft-drop mass between 105 and 220 GeV, and N-subjettiness ratio $\tau_3/\tau_2 < 0.65$. AK8 jets passing these requirements are referred to as t-tagged jets. In the single-lepton final state, the AK8 jets are selected if they are isolated from lepton by ΔR(lepton, AK8 jet) > 0.8 and events with more than one such AK8 jets are vetoed to be orthogonal to the fully hadronic final state. In the fully hadronic final state, the sum of the p_T of the two AK8 jets, H_{T}, is additionally required to be > 1.2 TeV and the angle between the two AK8 jets, $\Delta\phi$, is required to be > 2.1. We require single-lepton events to have exactly one electron with $p_T > 80$ GeV and $|\eta| < 3$ or one muon with $p_T > 55$ GeV and $|\eta| < 3$. In order to limit the background contribution from QCD multijet events, we require $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}} > 120$ (50) GeV in the electron (muon) channel, where $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ is the magnitude of the missing transverse momentum defined as the the negative of the vector p_T sum of all reconstructed PF candidates.

Additionally, the single-muon events are required to have $H_T^{\mathrm{lep}} > 150$ GeV, where $H_T^{\mathrm{lep}} = \mathbf{p}_{\mathrm{T}}^{\mathrm{miss}} + p_T^{\mathrm{lep}}$. The single-lepton events are further required to have at least two AK4 jets with $p_T > 30$ GeV and $|\eta| < 4$. The leading and subleading jets are required to have a p_T greater than 185 (150) and 50 (50) GeV, respectively, in the electron (muon) channel. Because no isolation requirement is imposed on leptons, we require that the AK4 jet that is closest to the lepton is either separated by $\Delta R > 0.4$, or the magnitude of the lepton momentum that is transverse to the jet axis is greater than 25 GeV.

We use the Theta package [662] to derive the expected cross section limits at 95% C.L. on the production of a RSG decaying to $t\bar{t}$. The limits are computed using the asymptotic CLs approach. A binned likelihood fit on the distributions of reconstructed $t\bar{t}$ mass ($m_{t\bar{t}}$), shown in Fig. 6.2.3, is performed

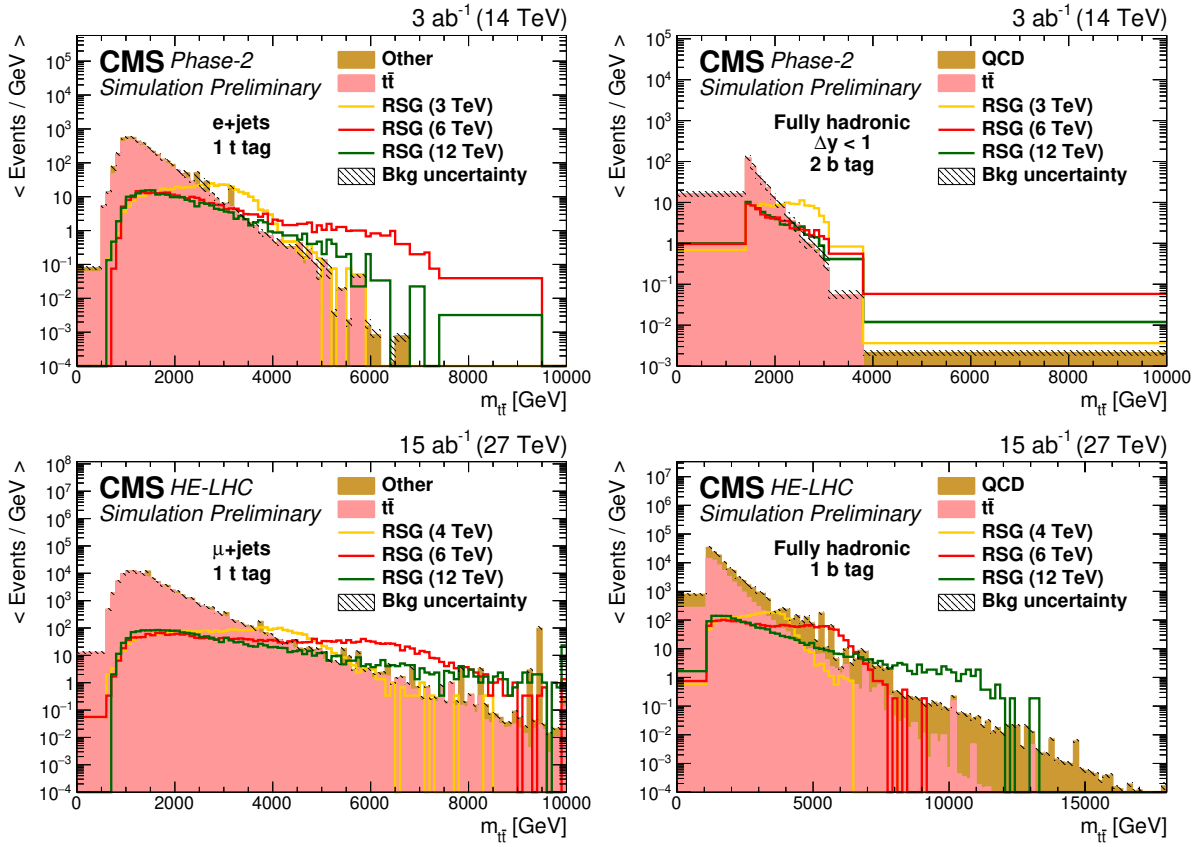

Fig. 6.2.4: Distributions of $m_{t\bar{t}}$ in events with single-electron and one t-tagged jet (top left) or zero lepton, $\Delta y < 1$ and two b tags (top right) for 3 ab^{-1} at 14 TeV. Distributions of $m_{t\bar{t}}$ in events with a single-muon and one t-tagged jet (bottom left) or zero lepton and one b-tag (bottom right) for 15 ab^{-1}at 27 TeV.

in both single-lepton and fully hadronic final states. To improve the sensitivity, the events are categorised based the number of subjet b tags (0, 1, or 2) and the rapidity difference ($|\Delta y(jet_1, jet_2)|$ <1 or >1) in the fully hadronic final state. Similarly, in the single-lepton final state, the categorisation is performed using the number of t-tagged jets (0 or 1) and the flavour of the lepton (e, μ). Example $m_{t\bar{t}}$ distributions of background and signal samples are shown in Fig. 6.2.4. Systematic uncertainties, following the recommendations in Ref. [411], are included in the fit as nuisance parameters with log-normal prior for both HL-LHC and HE-LHC. The results are limited by the statistical uncertainties in the background estimates. These uncertainties are scaled down by the projected integrated luminosity and are treated using the Barlow–Beeston light method [663, 664].

The expected limits at 95% C.L. and discovery reaches at 3 and 5σ for the combined single-lepton and fully hadronic final states are shown in Fig. 6.2.5. The RSG with masses up to 6.6 (10.7) TeV are excluded at 95% C.L. for a projected integrated luminosity of 3 (15) ab^{-1} at the HL-LHC (HE-LHC). This extends the current Run-2 limits of 4.5 TeV based on 36 fb^{-1} [665]. The discovery reach for an RSG is computed to be 5.7 (9.4) TeV at 5σ at the HL-LHC (HE-LHC).

6.2.3 $Z' \to t\bar{t}$ searches at HL-LHC

Contributors: A. Duncan, ATLAS

HL-LHC prospects at for Z' bosons in the $t\bar{t}$ final state were presented in Ref. [666] based on the event selection and systematic uncertainties from the Run-1 analysis with 20.3 fb^{-1} collected at $\sqrt{s} = 8$ TeV in Ref. [667]. These results have been updated [668] using a more recent parameterisation of the b-tagging efficiencies and misidentification rates as shown in Ref. [357] and are summarised below.

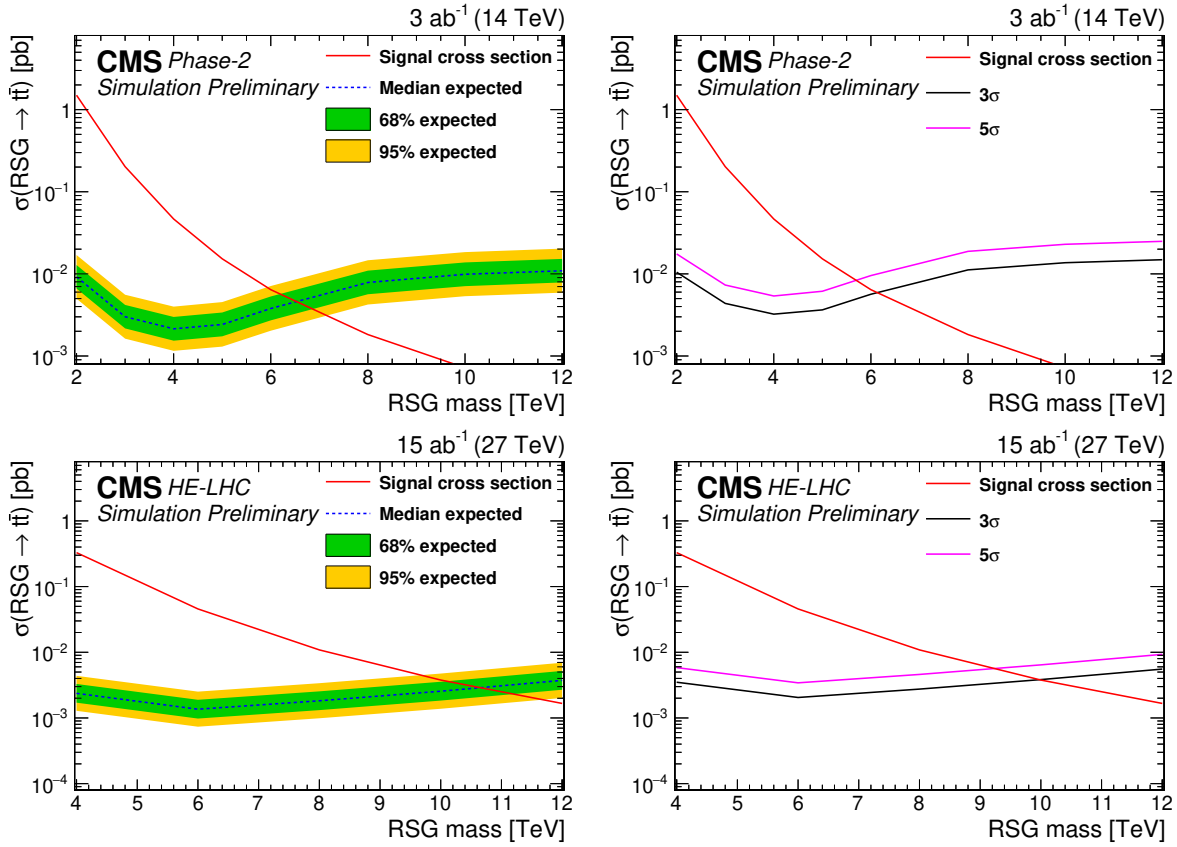

Fig. 6.2.5: 95% C.L. expected upper limits (left) and 3σ and 5σ discovery reaches (right) for a RSG decaying to $t\bar{t}$ at 3 ab^{-1} at 14 TeV (top) and 15 ab^{-1}at 27 TeV (bottom) for the combined single-lepton and fully hadronic final states.

The analysis looks for a narrow width Z' boson in a final state in which one of the W bosons from the top quark decays to two jets and the other decays to a lepton (electron or muon) and a neutrino ($t\bar{t} \to WbWb \to \ell\nu bqq'b$). Events are required to contain exactly one lepton, several jets and at least a moderate amount of missing transverse momentum must be present. Events are separated into boosted and resolved channels with most of the signal events falling in the former category. In the resolved channel the decay products of the hadronic top-quark decay are reconstructed as three separate jets and in total events must contain at least four jets. In the boosted channel, the hadronic top-quark decay products are highly boosted and end up in one broad large-radius jet. Events are selected if at least one large-radius jet and one jet (from the other top-quark decay) is present. Subsequently $m_{t\bar{t}}$ is reconstructed based on the reconstruction of the W bosons and b-jets in the event. Using $m_{t\bar{t}}$ as discriminant, upper limits are set on the signal cross section times BR as a function of the Z' boson mass. Using as benchmark a Topcolour-assisted Technicolour Z'_{TC2} boson with a narrow width of 1.2%, Z'_{TC2} bosons can be excluded up to masses of $\simeq 4$ TeV with 3 $\mathrm{ab}^{-1}$of pp collisions as shown in Fig. 6.2.6. This mass limit is conservative due to the use of systematic uncertainties from the Run-1 analysis [667]. These uncertainties are already smaller in the Run-2 analysis [669] and will be further reduced at the time of the HL-LHC. In particular the systematic uncertainty in the boosted channel is now reduced due to the significant improvements of the performance of boosted jets in Run-2 (in particular using more tracking information to look for sub-jets within the large-radius jets). This gain in performance also improves the signal over background ratio. In addition, the usage of the top-tagger algorithm will help to further reject background.

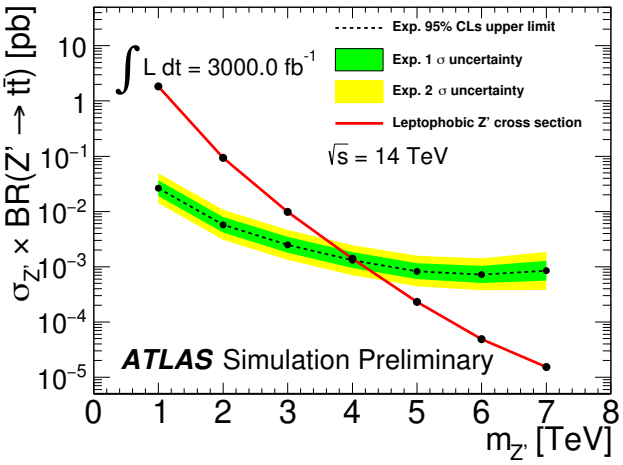

Fig. 6.2.6: Expected upper limits set on the cross section $\times$ BR of the Topcolour Z$'$ boson for masses $1-7$ TeV, with 3 ab^{-1} of simulated 14 TeV pp collisions compared to the theoretical signal cross section.

6.2.4 High mass dilepton (ee, $\mu\mu$, $\tau\tau$) searches at the HE-LHC

Contributors: C. Helsens, D. Jamin, M. Selvaggi

Models with extended gauge groups often feature additional $U(1)$ symmetries with corresponding heavy spin-1 bosons. These bosons, generally referred to as Z', would manifest themselves as a narrow resonance in the dilepton invariant mass spectrum. Among these models are those inspired by Grand Unified Theories, motivated by gauge unification, or a restoration of the left-right symmetry violated by the weak interaction. Examples include the Z' bosons of the E_6 motivated theories [670–672] and Minimal models [673]. The SSM [672] posits a $Z'_{\rm SSM}$ boson with couplings to fermions that are identical to those of the SM Z boson.

The decay products of heavy resonances are in the multi-TeV regime and the capability to reconstruct their momentum imposes stringent requirement on the detector design. In particular, reconstructing the track curvature of multi-TeV muons requires excellent position resolution and a large lever arm. In this section, the expected sensitivity is presented for a $Z' \to \ell\ell$ (where $\ell = {\rm e}, \mu$) and $Z' \to \tau\tau$ separately.

Monte Carlo simulated event samples were used to simulate the response of the future detector to signal and backgrounds. Signals are generated with PYTHIA 8.230 [68] using the leading order cross-section from the generator. All lepton flavour decays of the $Z'_{\rm SSM}$ are generated assuming universality of the couplings. The Drell-Yan background has been generated using MADGRAPH5_aMC@NLO 2.5.2 [67] at leading order only. A conservative overall k-factor of 2 has been applied to all the background processes to account for possibly large higher order QCD corrections.

For the $\ell\ell$ final-states events are required to contain two isolated leptons with $p_T > 500$ GeVand $|\eta| < 4$. For the $\tau\tau$ final state we focus solely on the fully hadronic decay mode which is expected to drive the sensitivity. The $\tau\tau$ event selection requires the presence of two reconstructed jets with $p_T > 500$ GeVand $|\eta| < 2.5$ identified as hadronic τ's. To ensure orthogonality between the ℓ and τ final states, jets overlapping with isolated leptons are vetoed. Additional mass dependent selection criteria on the azimuthal angle between the two reconstructed τ's are applied to further improve the QCD background rejection (see Table 6.2.1).

The left and central panels of Fig. 6.2.7 show the invariant mass distribution for a 6 TeV $Z'_{\rm SSM}$ in the ee and $\mu\mu$ channels. The mass resolution is better for the ee channel, as expected. The right panel of Fig. 6.2.7 shows the transverse mass [15] of a 6 TeV signal for the $\tau\tau$ channel. Because of the presence of neutrinos in τ decays, the true resonance mass cannot be reconstructed. Several arbitrary choices are

[15] The transverse mass is defined as $m_T = \sqrt{2p_{\rm T}^{Z'} * E_{\rm T}^{\rm miss} * (1 - \cos\Delta\phi(Z', E_{\rm T}^{\rm miss}))}$.

Z' mass [TeV]	$\Delta\phi(\tau_1,\tau_2)$	$\Delta R(\tau_1,\tau_2)$	$E_{\mathrm{T}}^{\mathrm{miss}}$
2	> 2.4	> 2.4 and < 3.9	> 80 GeV
4	> 2.4	> 2.7 and < 4.4	> 80 GeV
6	> 2.4	> 2.9 and < 4.4	> 80 GeV
8	> 2.6	> 2.9 and < 4.6	> 80 GeV
10	> 2.8	> 2.9 and < 4.1	> 60 GeV
12	> 2.8	> 3.0 and < 3.6	> 60 GeV
14	> 3.0	> 3.0 and < 3.3	> 60 GeV

Table 6.2.1: List of mass dependent cuts optimised to maximise the sensitivity for the $Z' \to \tau\tau$ search.

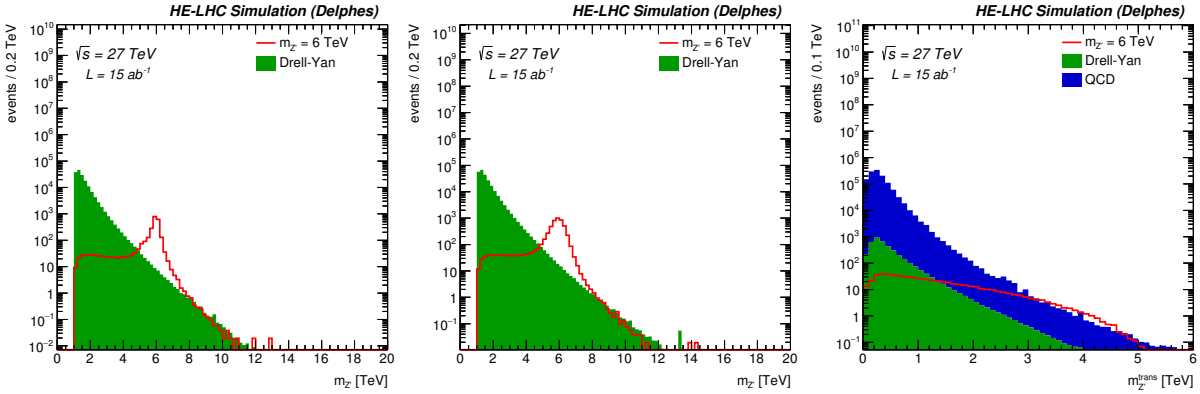

Fig. 6.2.7: Left, centre: Invariant mass for a 6 TeV signal after full event selection for ee channel (left) and $\mu\mu$ channel (centre). Right: Transverse mass for a 6 TeV signal after full event selection for the $\tau\tau$ channel.

possible to approximate the Z' mass. The transverse mass provided the best sensitivity and was therefore used to set limits and determine the discovery reach in $\tau\tau$ decay mode.

Hypothesis testing is performed using a modified frequentist method based on a profile likelihood that takes into account the systematic uncertainties as nuisance parameters that are fitted to the expected background predicted from Monte Carlo. For the ee and $\mu\mu$ analyses, the dilepton invariant mass is used as the discriminant, while for the $\tau\tau$ channel the transverse mass is used. A 50% uncertainty on the background normalisation is assumed.

The 95% C.L. exclusion limit obtained using 15 $\mathrm{ab}^{-1}$of data for the combination of the ee and $\mu\mu$ channels is shown in Fig. 6.2.8 (left) for a list of 6 different Z' models. A detailed discussion on model discrimination at HE-LHC following the observation of an excess at the HL-LHC can be found in Section 6.2.9. We simply note here that it is possible to exclude a Z' with $m_{Z'} \lesssim 10-13$ TeV (depending on the model) at $\sqrt{s} = 27$ TeV with 15 ab^{-1}. Figure 6.2.8 (right) shows the integrated luminosity required to reach a 5σ discovery for a Z'_{SSM} decaying leptonically as a function of the mass of the heavy resonance. Despite a worse di-lepton invariant mass resolution for the $\mu\mu$ final state, the $Z' \to ee$ and $Z' \to \mu\mu$ channel display very similar performances, due to the low background rates and a higher muon reconstruction efficiency. Acceptance for electron could have been recovered by optimising the isolation criteria, but was not done in this study. With the full dataset 15 ab^{-1}, a Z'_{SSM} up to $m_{Z'} \approx 13$ TeV can be discovered. Figure 6.2.9 shows the exclusion limits for 15 ab^{-1} of data (left) and the required integrated luminosity versus mass to reach a 5σ discovery (right) for the $\tau\tau$ resonances. We find that a Z'_{SSM} with $m_{Z'} \approx 6.5$ TeV can be discovered or excluded. As expected, the $Z' \to \tau\tau$ final-state yields to a worse discovery potential compared to the $\ell\ell$ final states because of the presence of a much larger background contribution as well as the absence of narrow mass peak.

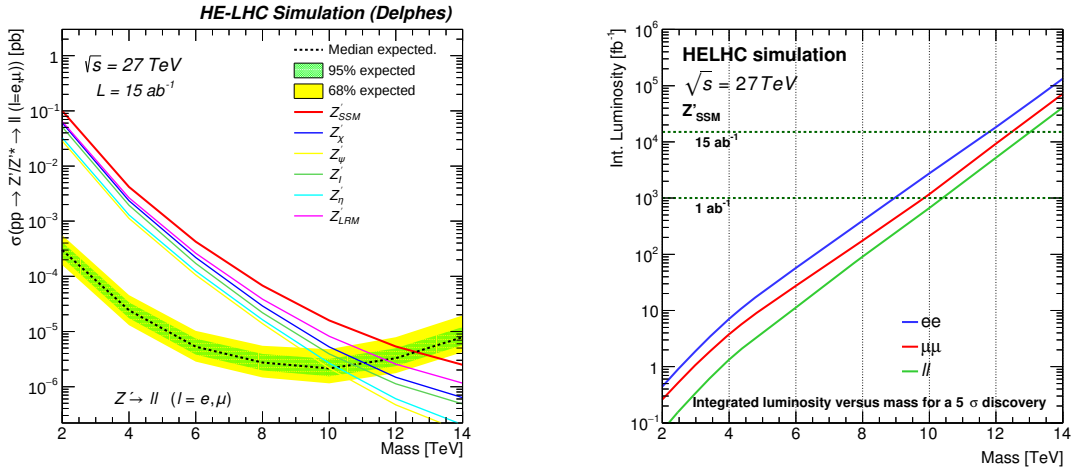

Fig. 6.2.8: Exclusion limit versus mass for the dilepton (ee,$\mu\mu$) channel (left) and luminosity for a 5σ discovery (right) comparing ee, $\mu\mu$ and combined channels.

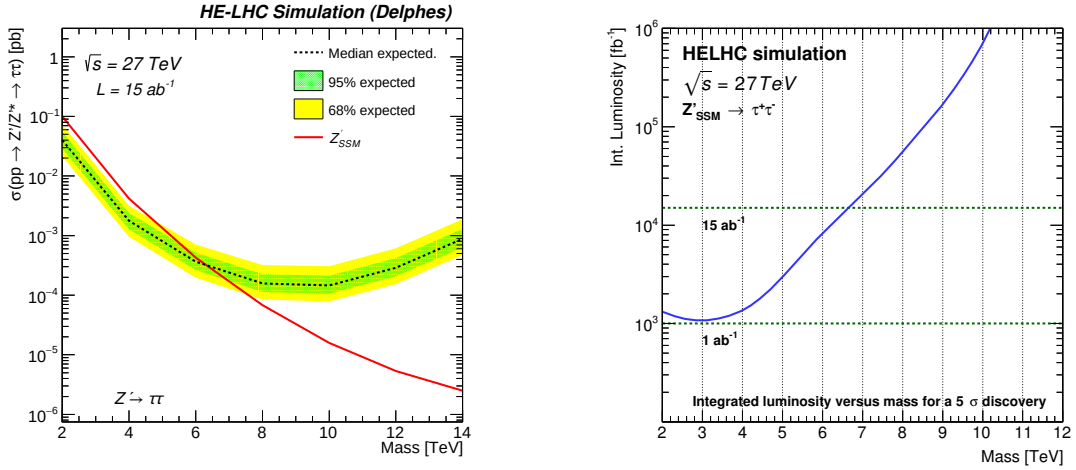

Fig. 6.2.9: Exclusion limit versus mass for the ditau channel (left) and luminosity for a 5σ discovery (right).

6.2.5 *Prospects for $Z' \to e^+e^-, \mu^+\mu^-$ searches at the HL- and HE-LHC*

Contributors: M. Bugge, D. Hayden, S. Kubota, G. Lee, J-P Ochoa, J-C Rivera Vergara, M. Wielers, ATLAS

The sensitivity to narrow Z' bosons decaying into the e^+e^- or $\mu^+\mu^-$ final state is studied for pp collisions at several c.o.m. energies: $\sqrt{s} = 13$, 14, and 15 TeV with 3 ab^{-1}, as well as $\sqrt{s} = 27$ TeV with 15 ab^{-1}. Results are based on studies documented in Ref. [668]. The latter is only studied in the e^+e^- channel since the work presented here is based on the latest layout of the upgraded ATLAS detector for the HL-LHC which is not optimised for extremely high muon momentum measurements. The study supersedes that from Ref. [674] since it uses the latest detector layout and higher pileup conditions. In addition, it was found that the signal cross-sections used in the previous analysis were too high.

The projection study relies on MC simulation for the signal based on PYTHIA 8 [50], the NNPDF23LO PDF set [675], and the A14 set of tuned parameters [676] for the parton shower, hadronisation, and the underlying event. The dominant Drell-Yan background source is generated with POWHEG-BOX [639, 657] and the CTEQ6L1 PDF set [52] interfaced with PYTHIA 8 for the parton shower, hadronisation and the underlying event using the AZNLO set of tuned parameters [677]. Generated samples also include off-shell production.

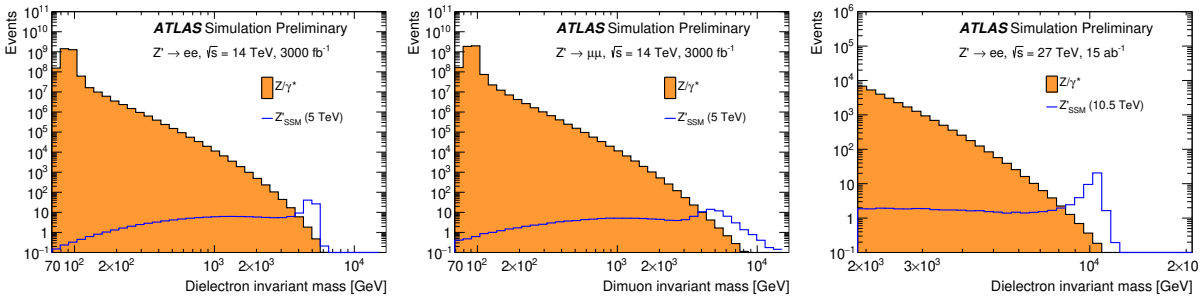

Fig. 6.2.10: Invariant mass distributions for events satisfying all selection criteria in the dielectron and dimuon channels at $\sqrt{s} = 14$ TeV and in the dielectron channel at $\sqrt{s} = 27$ TeV. Distributions of the Drell-Yan background and SSM Z' signal with a mass of 5.0 (10.5) TeV are shown for $\sqrt{s} = 14$ (27) TeV.

The event selection proceeds in a way similar to the analysis of the 13 TeV data with 36.1 fb^{-1} [442]. Events must pass either the single-electron trigger requirements with $p_{\mathrm{T}} > 22$ GeVand $|\eta| < 2.5$ or the single-muon trigger requirements with $p_{\mathrm{T}} > 20$ GeVand $|\eta| < 2.65$. Triggered events are further required to contain exactly two electrons with $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.47$ (excluding the barrel-endcap calorimeter transition region $1.37 < |\eta| < 1.52$) or two muons with $p_{\mathrm{T}} > 25$ GeVand $|\eta| < 2.65$. The electrons and muons have to satisfy the *tight* and *high-*p_{T} identification requirements, respectively. Invariant mass distributions of the reconstructed dielectron and dimuon candidates are shown in Fig. 6.2.10 for the Z'_{SSM} signal and the dominant Drell-Yan background. Background from diboson (WW, WZ, ZZ) and top-quark production is not considered as their contribution to the overall SM background is negligible for dilepton invariant masses ($m_{\ell\ell}$) exceeding 2 TeV. This background is more pronounced at lower masses and was found to amount to around 10% (20%) of the total background for an invariant mass of 1 TeV (300 GeV), see Ref. [442]. In the dielectron channel, additional background arises from W+jets and multijet events in which at most one real electron is produced and one or more jets satisfy the electron selection criteria. While this background is negligible in the dimuon channel, it amounts to approximately 15% of the total background for $m_{\ell\ell} > 1$ TeV [442] in the dielectron channel. This source of background is neglected in the analysis below but accounted for in the systematic uncertainties. The differences in the shape of the reconstructed Z' mass distributions in the dielectron and dimuon channels arise from differences in momentum resolution for electron and muon reconstruction. The differences in the shape of the dielectron mass distributions at $\sqrt{s} = 14$ TeV and 27 TeV arise from differences in the rapidity distributions.

The experimental and theoretical uncertainties assumed in this analysis are estimated from the Run-2 results [442] but scaled down to account for the increased statistical precision available at the HL-LHC following the recommendations in Ref. [7]. Only the largest sources of uncertainties are considered. As the uncertainties vary with $m_{\ell\ell}$, the uncertainties are expressed relative to the value of $m_{\ell\ell}$ given in TeV.

The experimental systematic uncertainties due to the reconstruction, identification, and isolation of electrons are negligible while those for muons add up to approximately $2.5\% \times m_{\ell\ell}$ [TeV]. Systematic uncertainties due to the energy resolution and scale are set to $1.5\% \times m_{\ell\ell}$ [TeV]. The uncertainties due to the resolution and reconstruction of the leptons are added in quadrature to the dominant sources of theoretical uncertainty due to the PDFs. The uncertainties due to the choice of PDF set are taken to be $2.5\% \times m_{\ell\ell}$ [TeV] and the uncertainties in the parameters of the nominal PDF set are assumed to be $5\% \times m_{\ell\ell}$ [TeV]. Overall these uncertainties add up to $6.5\% \times m_{\ell\ell}$ [TeV]. As the search looks for an excess in the high $m_{\ell\ell}$ tail, the sensitivity is primarily limited by the statistical uncertainties.

The statistical analysis relies on the Bayesian approach [678] used in Ref. [442]. The same statistical model implementation is used in the following for both the calculation of the exclusion limits and the discovery reach, the latter being based on a profile likelihood ratio test assuming an asymptotic

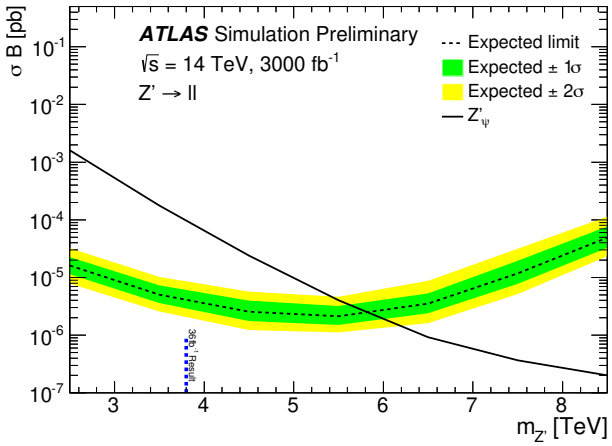

Fig. 6.2.11: Expected (dashed black line) upper limit on cross-section times branching fraction $\sigma \times \mathcal{B}$ as a function of the Z' boson mass in the combined dielectron and dimuon channels for $\sqrt{s} = 14$ TeV collisions and an integrated luminosity value of 3 ab^{-1}. The 1σ (green) and 2σ (yellow) expected limit bands are also shown. The predicted $\sigma \times \mathcal{B}$ for Z'_ψ production is shown as a black line. These limits are based on a NNLO cross-section calculation including off-shell production ($pp \to Z'/Z'^* \to \ell\ell$). The blue marker shows the current limit obtained with the Run-2 analysis based on 36 fb^{-1} of data.

test statistic distribution. In the absence of a signal, 95% C.L. upper limits are placed on the production cross section of a Z' boson times its branching fraction $\sigma \times \mathcal{B}$ to a single lepton generation, assuming lepton universality. These limits are extracted using Z' templates binned in $m_{\ell\ell}$ for a series of Z' masses in the range between 2.5 TeV and 11.5 TeV. The interpretation of results is performed in the context of the SSM and the E_6 ψ model. Exclusion limits are shown in Fig. 6.2.11 assuming the E_6 ψ model as a benchmark. These limits, as well as the ones presented below, are based on a NNLO cross-section calculation including off-shell production.

Lower mass limits and the discovery reach for the different models and $\sqrt{s}$ values at the HL-LHC are summarised in Table 6.2.2. The projected exclusion limits extend the current Z'_{SSM} (Z'_ψ) lower mass limit of 4.5 (3.8) TeV obtained using 36.1 fb^{-1} of data taken at $\sqrt{s} = 13$ TeV to 6.5 (5.8) TeV for $\sqrt{s} = 14$ TeV. Higher limits are obtained in the dielectron channel due to the superior energy resolution of the calorimeter as compared with the momentum resolution for muons in the muon spectrometer. Assuming similar detector performance at the LHC and HL-LHC, a corresponding lower mass limit of 5.4 (4.8) TeV are expected with 300 fb^{-1}at the end of Run-3. The 95% C.L. limits and discovery reach are close due to the absence of background at very high $m_{\ell\ell}$. Compared to the results presented in Ref. [357] the discovery reach reported here is higher due to a change in how the reach is calculated. The analysis described here is based on the shape of the signal and background $m_{\ell\ell}$ distributions while the 5σ significance was calculated in a mass range between $m(Z')/2$ to infinity in Ref. [357].

The discovery reach and lower exclusion limits at 95% C.L. in mass are also calculated for a detector at the HE-LHC in the dielectron channel. This is done assuming the same physics performance as for the ATLAS detector at the HL-LHC. The exclusion limits and the discovery reach are summarised in Table 6.2.3.

At the HE-LHC, Z'_{SSM} and Z'_ψ bosons can be discovered up to 12.8 TeV and 11.2 TeV, respectively, thus increasing their discovery reach by 6.5 TeV compared to the HL-LHC, *i.e.* an increase in the discovery potential by a factor of two. In case Z' bosons are not discovered yet, the HE-LHC will be able to further rule out Z'_{SSM} and Z'_ψ bosons up to 12.8 TeV and 11.4 TeV, respectively.

Decay	$\sqrt{s} = 13$ TeV		$\sqrt{s} = 14$ TeV		$\sqrt{s} = 15$ TeV	
	Exclusion	Discovery	Exclusion	Discovery	Exclusion	Discovery
$Z'_{\mathrm{SSM}} \to ee$	6.0 TeV	5.9 TeV	6.4 TeV	6.3 TeV	6.7 TeV	6.6 TeV
$Z'_{\mathrm{SSM}} \to \mu\mu$	5.5 TeV	5.4 TeV	5.8 TeV	5.7 TeV	6.0 TeV	5.9 TeV
$Z'_{\mathrm{SSM}} \to \ell\ell$	6.1 TeV	6.1 TeV	6.5 TeV	6.4 TeV	6.7 TeV	6.7 TeV
$Z'_{\psi} \to ee$	5.3 TeV	5.3 TeV	5.7 TeV	5.6 TeV	6.1 TeV	6.0 TeV
$Z'_{\psi} \to \mu\mu$	4.9 TeV	4.6 TeV	5.2 TeV	5.0 TeV	5.5 TeV	5.2 TeV
$Z'_{\psi} \to \ell\ell$	5.4 TeV	5.4 TeV	5.8 TeV	5.7 TeV	6.1 TeV	6.1 TeV

Table 6.2.2: Expected 95% C.L. lower limit on the Z' mass in TeV in the dielectron and dimuon channels and their combination for two benchmark Z' models for different centre of mass energies assuming 3 $\mathrm{ab}^{-1}$of data to be taken at the HL-LHC. In addition, the discovery reach for finding such new heavy particles is shown.

Decay	Exclusion [TeV]	Discovery [TeV]
$Z'_{\mathrm{SSM}} \to ee$	12.8	12.8
$Z'_{\psi} \to ee$	11.4	11.2

Table 6.2.3: Lower limits at 95% C.L. and discovery reach on the Z'_{SSM} and Z'_{ψ} boson mass in the dielectron channel assuming 15 $\mathrm{ab}^{-1}$of pp data to be taken at the HE-LHC with $\sqrt{s} = 27$ TeV.

6.2.6 $W' \to e\nu, \mu\nu$ or $tb, t \to b\ell\nu$ searches at HL-LHC

Resonances decaying into a lepton and missing transverse momentum

The sensitivity to W' resonances decaying into an electron or a muon and a neutrino is studied for $\sqrt{s} = 14$ TeV pp collisions at the HL-LHC [668]. Such resonances would manifest themselves as an excess of events above the SM background at high transverse mass m_{T}. The SM background mainly arises from processes with at least one prompt final-state electron or muon, with the largest source being off-shell charged-current Drell-Yan (DY), leading to a final state with an electron or a muon and a neutrino. Other non-negligible contributions are from top-quark pair and single-top-quark production, neutral-current DY process, diboson production, and from events in which one final-state jet or photon satisfies the lepton selection criteria. This last component of the background, referred to in the following as the multijet background, receives contributions from multijet, heavy-flavour quarks and γ + jet production; it is one of the smallest backgrounds in this analysis. It is evaluated in a data-driven way in the Run-2 analysis and cannot be yet reliably estimated from MC samples and is therefore not considered here. It was found to be negligible in the muon channel at $m_{\mathrm{T}} > 3$ TeV in the Run-2 analysis based on 79.8 fb^{-1} of pp collisions [679]. In the electron channel, the contribution constitutes around 10% of the total background at $m_{\mathrm{T}} \approx 3$ TeV and mainly arises from jets misidentified as electrons.

The projection study relies on MC simulation with the SSM W' signal generated using PYTHIA 8 in the same setup as for the SSM Z' signal described in Section 6.2.5. This also includes off-shell production. The charged and neutral Drell-Yan background is also generated in the same way. Background from $t\bar{t}$ events is produced with POWHEG-BOX and the NNPDFL30NNLO PDF set interfaced with PYTHIA 6 using the A14 tune. Diboson events are generated with SHERPA [195] and the CT10 PDF set [680].

The event selection proceeds similarly to the Run-2 analysis described in Ref. [679]. Events are required to satisfy the single-election or single-muon triggers. The single electron trigger selects events containing at least one electron with $p_{\mathrm{T}} > 22$ GeV and $|\eta| < 2.5$, while the single muon trigger requires a muon with $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.65$. Events are required to contain exactly one lepton which can be either an electron or a muon. Muons must have $p_{\mathrm{T}} > 55$ GeV and $|\eta| < 2.65$ as well as satisfy the *high-*p_{T} identification criteria [7]. Electrons must have $p_{\mathrm{T}} > 55$ GeV and $|\eta| < 1.37$ or

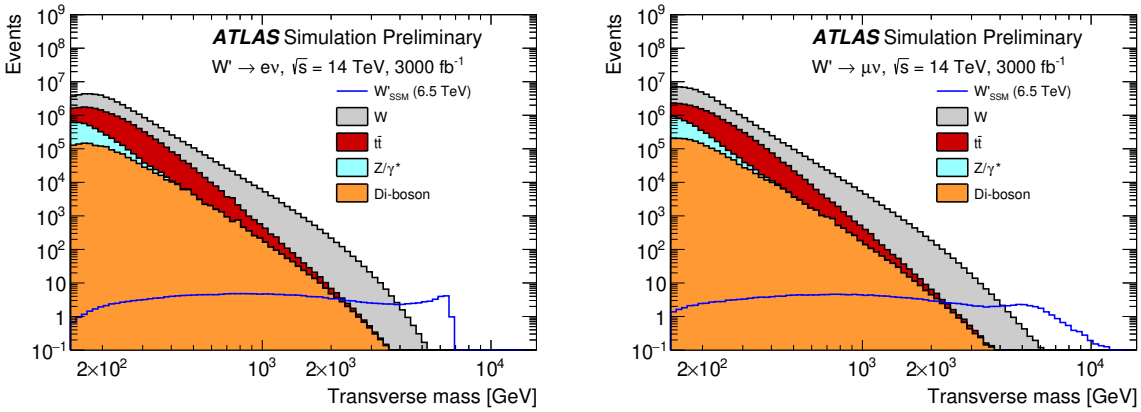

Fig. 6.2.12: Transverse mass distributions for events satisfying all selection criteria in the electron and muon channels of the $W' \to \ell\nu$ search. The different background contributions are shown as a stacked sum and the expected signal distributions for a W' boson with a mass of 6.5 TeV is shown. The bin width is constant in $\log m_{\mathrm{T}}$.

$1.52 < |\eta| < 2.47$, as well as satisfy the *tight* identification criteria. These p_{T} thresholds are the same as in the Run-2 analysis and are motivated by the triggers which select events containing leptons with loose identification criteria and without isolation requirements. Though not applied in this analysis, such events will be needed for the data-driven background subtraction methods, as employed in Run-2, to work. The p_{T} thresholds for these "looser" triggers are not yet available and therefore in the following it is assumed that the thresholds will be similar to those used in Run-2. The magnitude of the missing transverse momentum ($E_{\mathrm{T}}^{\mathrm{miss}}$) must exceed 55 GeV (65 GeV) in the electron (muon) channel. Events in both channels are vetoed if they contain additional leptons satisfying loosened selection criteria, namely electrons with $p_{\mathrm{T}} > 20$ GeVsatisfying the *medium* identification criteria or muons with $p_{\mathrm{T}} > 20$ GeV passing the *loose* muon selection.

The total acceptance times efficiency in the electron (muon) channel decreases from a value of $\sim 85\%$ (70%) at a W' mass of 1 TeV to $\sim 65\%$ (60%) for masses between 5 and 9 TeV. The resulting m_{T} distributions are shown in Fig. 6.2.12 for both the expected background and the W' signal with a mass of 6.5 TeV.

Systematic uncertainties arise from both experimental and theoretical sources. Since the uncertainties from the Run-2 analysis are found to increase as a function of m_{T} these are parametrised as a percentage of the m_{T} value expressed in units of TeV. The uncertainties are then scaled down to account for the increased statistical power at the HL-LHC according to recommendations in Ref. [7]. The experimental systematic uncertainties due to the reconstruction, identification, and isolation of muons result in a value of $2.5\% \times m_{\mathrm{T}}$ [TeV], while these uncertainties are negligible for electrons. Systematic uncertainties due to the energy resolution and scale are set to $2.5\% \times m_{\mathrm{T}}$ [TeV]. The main systematic uncertainties in the $E_{\mathrm{T}}^{\mathrm{miss}}$ calculation and on the jet energy scale are found to be negligible in Run-2 and are therefore not considered in this analysis. Theoretical uncertainties are related to the production cross sections estimated from MC simulation. The effects when propagated to the total background estimate are significant for charged and neutral current DY, and to some extent for top-quark production, but are negligible for diboson production. No theoretical uncertainties are considered for the W' boson signal in the statistical analysis. The largest uncertainties arise from the PDF uncertainty in the DY background. The uncertainties due to the choice of PDF set are taken to be $5\% \times m_{\ell\ell}$ [TeV] and the uncertainties in the parameters of the nominal PDF set are assumed to be $2.5\% \times m_{\ell\ell}$ [TeV]. The uncertainty in the multijet background in the electron channel is assumed to be $2.5\% \times m_{\mathrm{T}}$ [TeV]. Overall these uncertainties in the background event yield add up to $\sim 7\% \times m_{\mathrm{T}}$ [TeV]. As the search looks for an excess in the high m_{T} tail, the sensitivity is primarily limited by the statistical uncertainties.

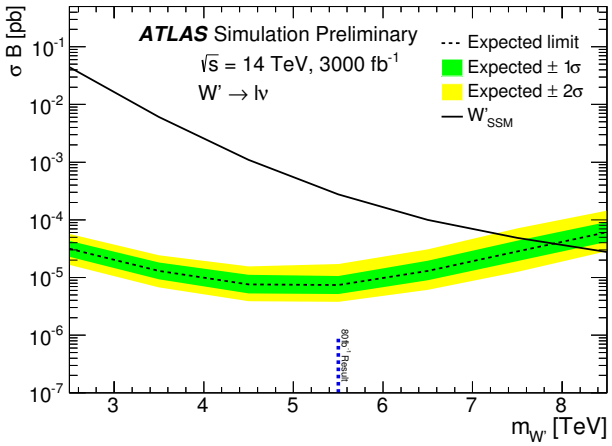

Fig. 6.2.13: Expected (dashed black line) upper limit on cross section times branching fraction ($\sigma \times \mathcal{B}$) as a function of the W' boson mass in the electron, muon, and combined electron and muon channels of the $W' \to \ell\nu$ search assuming $3\,\mathrm{ab}^{-1}$of data. The 1σ (green) and 2σ (yellow) expected limit bands are also shown. The predicted $\sigma \times \mathcal{B}$ for W' production in the SSM is shown as a black line. These limits are based on a NNLO cross-section calculation including off-shell production ($pp \to W^{'}/W^{'*} \to \ell\nu$). The blue marker shows the current limits obtained with the latest Run-2 analysis based on $79.8\,\mathrm{fb}^{-1}$ of data.

The statistical analysis relies on a Bayesian approach to set cross section times branching fraction upper limits and a profile likelihood approach to derive the discovery reach as for the $Z' \to \ell\ell$ search described above. The branching fraction corresponds to that for decays into a single lepton generation, assumed to be universal in the combination of the two channels. The 95% C.L. upper limit on $\sigma \times \mathcal{B}$ as a function of W' mass is shown in Fig. 6.2.13 for an integrated luminosity of $3\,\mathrm{ab}^{-1}$after combination of the electron and muon channels. The upper limits on $\sigma \times \mathcal{B}$ for W' bosons start to weaken above a pole mass of $\sim$ 5 TeV, which is mainly caused by the combined effect of a rapidly falling signal cross section towards the kinematic limit and the increasing proportion of the signal being produced off-shell in the low-m_{T} tail of the signal distribution. The W' bosons in the SSM can be excluded up to masses of 7.6 (7.3) TeV in the electron (muon) channel. These limits are based on a NNLO cross-section calculation including off-shell production for the signal. The limits in the electron channel are stronger due to the superior energy resolution of the calorimeter for high-momentum electrons as compared to that of the muon spectrometer for high-momentum muons. The combination of the two channels increases the limits to just over 7.9 TeV. This is an improvement of more than 2 TeV with respect to the current exclusion limits using $79.8\,\mathrm{fb}^{-1}$ of $\sqrt{s} = 13$ TeV data. For comparison, assuming the performance of the upgraded ATLAS detector and a luminosity of $300\,\mathrm{fb}^{-1}$, W' masses up to 6.7 TeV can be excluded for the combined electron and muon channels. Though the detector resolutions for the upgraded detector at the HL-LHC are applied, this is a good approximation of the reach with the current detector at the end of LHC Run-3.

The discovery reach is based on a 5σ significance. In the context of the SSM, W' bosons can be discovered up to masses of 7.7 TeV. The discovery reach is shown in Table 6.2.4 together with the exclusion limits discussed above. As can be seen, the discovery reach typically is only few hundred GeV lower than the mass limits obtained with a background-only hypothesis. The similarity of the values for the discovery reach and the exclusion limit is expected, as in the high-m_{T} tail the background contribution approaches zero, while the number of signal events is about three. The expected reach with $300\,\mathrm{fb}^{-1}$of data will be 1.2 TeV lower assuming the same detector performance.

Decay	Exclusion [TeV]	Discovery [TeV]
$W'_{\mathrm{SSM}} \to e\nu$	7.6	7.5
$W'_{\mathrm{SSM}} \to \mu\nu$	7.3	7.1
$W'_{\mathrm{SSM}} \to \ell\nu$	7.9	7.7

Table 6.2.4: Expected 95% C.L. lower limit on the W' mass in the electron and muon channels as well as their combination in the context of the SSM assuming 3 $\mathrm{ab}^{-1}$of data. In addition, the discovery reach for finding such new heavy particles is shown. These limits are based on a NNLO cross-section calculation including off-shell production ($pp \to W^{'}/W^{'*} \to \ell\nu$).

Resonances decaying into a top quark and a bottom quark

The search for W' bosons in the lepton plus neutrino channel is sensitive to large mass scales but it is not sensitive to right-handed W' bosons. This can be alleviated by searching for $W'_{\mathrm{R}} \to t\bar{b}$ decays with subsequent decays $t \to Wb$ and $W \to \ell\nu$. The final-state signature consists of two b-quarks, one charged lepton (electron or muon) and $E_{\mathrm{T}}^{\mathrm{miss}}$ from the escaping neutrino.

Events are required to pass one of the single-lepton triggers: at least one electron with $p_{\mathrm{T}} > 22$ GeV and $|\eta| < 2.5$ or at least one muon with $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.65$. Electrons must satisfy the *tight* identification requirements [681] requirements and have $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.47$ but outside the barrel–endcap transition region, $1.37 < |\eta| < 1.52$. Similarly, muon candidates must meet the *tight* identification criteria [682] and have $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.65$.

The projection study relies on MC simulation for the W' signal based on MADGRAPH5_aMC@NLO with the NNPDF23LO PDF set interfaced to PYTHIA 8 and the A14 tune for the parton shower, hadronisation, and the underlying event. Background for the various top-quark production mechanisms is generated by POWHEG-BOX. In the case of the dominant $t\bar{t}$ background, events are produced with the CTEQ6L1 PDF set and interfaced to PYTHIA 6 using the PERUGIA2012 tune [683]. W+jets events are produced with MADGRAPH5_aMC@NLO with the NNPDF23NLO PDF set interfaced to PYTHIA 8 and the A14 tune, whereas Z+jets events are produced with POWHEG-BOXand the CT10 PDF set interfaced to PYTHIA8 and the AU2 tune [684]. Diboson events are generated as for the $W' \to \ell\nu$ search above.

The dominant background processes are the production of $t\bar{t}$ pairs and W+jets. Smaller contributions are also expected from single top quarks (t-channel, Wt and s-channel), Z+jets and diboson (WW, WZ, and ZZ) production. All background processes are modelled with MC simulation. Instrumental background coming from misidentified electrons, referred to as the multijet background, is also present but it is very small and further suppressed by applying dedicated selection criteria, and it is neglected in the following. Events are required to satisfy $E_{\mathrm{T}}^{\mathrm{miss}} > 80$ (30) GeV in the electron (muon) channel as well as $m_{\mathrm{T}}^{W} + E_{\mathrm{T}}^{\mathrm{miss}} > 100$ GeV.

The W' candidates are built from W boson and top-quark candidates. The W bosons are reconstructed from the lepton–$E_{\mathrm{T}}^{\mathrm{miss}}$ system with the longitudinal momentum component of the neutrino from the W decay extracted by imposing a W-boson mass constraint. This W boson candidate is then combined with all selected jets in the event to reconstruct a top-quark candidate as the W+jet combination that has a mass closest to the top-quark mass. The jet used to form the top-quark candidate is referred to as "b_{top}". Finally, the candidate W' boson is reconstructed by combining the top-quark candidate with the highest-p_{T} remaining jet (referred to as "b_1"). The invariant mass of the reconstructed $W' \to t\bar{b}$ system ($m_{t\bar{b}}$) is the discriminating variable of this search. An event selection common to all signal regions is defined as: lepton $p_{\mathrm{T}} > 50$ GeV, $p_{\mathrm{T}}(b_1) > 200$ GeV, and $p_{\mathrm{T}}(\mathrm{top}) > 200$ GeV. As the signal events are expected to be boosted, the angular separation between the lepton and b_{top} is required to satisfy $\Delta R(\ell, b_{\mathrm{top}}) < 1.0$.

The phase space is divided into eight signal regions (SR) defined by the number of jets and b-tagged jets, and are labelled as "X-jet Y-tag" where $X = 2, 3$ and $Y = 1, 2$, that are further sep-

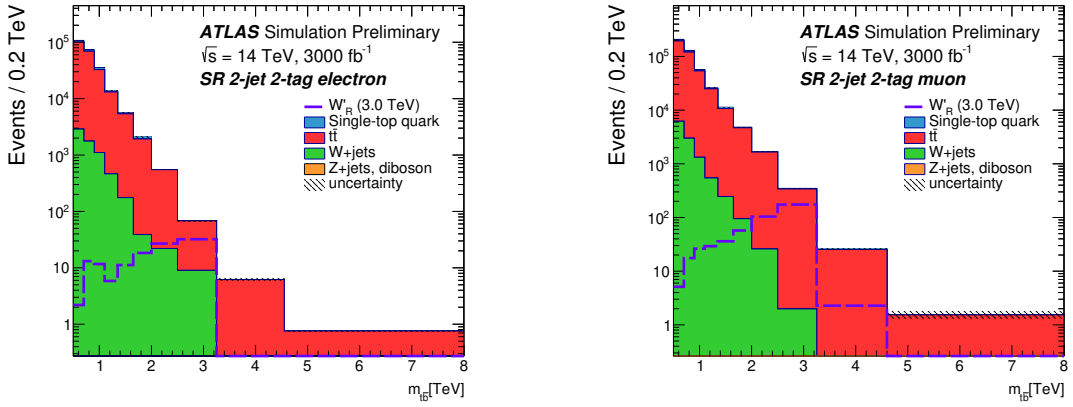

Fig. 6.2.14: Post-fit distributions of the reconstructed mass of the W'_{R} boson candidate in the 2-jet 2-tag signal region for the electron (left) and muon (right) channels. An expected signal contribution corresponding to a W'_{R} boson mass of 3 TeV is shown. Uncertainty bands include all systematic uncertainties.

arated into electron and muon channels. The signal selection acceptance times efficiency rises from $\sim$ 4.4% (7.7%) at a W'_{R} mass of 1 TeV to 4.6% (11.0%) at 2 TeV, then decreasing to 2.6% (8.2%) at 5 TeV in the electron (muon) channel. This decrease is due to the b-tagging performance and the higher boost at higher mass. The muon channel outperforms the electron channel due to overlap removal requirements, as they are relaxed by using a variable ΔR cone size. The variable ΔR cone size is not used for electrons because of the possible double counting of the energies of electron and jet.

Systematic uncertainties are evaluated following the analysis of 36.1 fb^{-1} of $\sqrt{s} = 13$ TeV pp data in Ref. [685] and then scaled according to the recommendations in Ref. [7]. The uncertainty in the luminosity (1%) and in the theory cross sections (5% for diboson, 10% for Z+jets, and 3% for single top) are included in the expected limits and significance calculation. The b-tagging and the modelling uncertainties (which are the dominant uncertainties in the shape of the discriminating variable from the previous analysis) are also included.

The presence of a massive resonance is tested by simultaneously fitting the m_{tb} templates of the signal and background simulated event samples using a binned maximum–likelihood approach (ML). Each signal region is treated as an independent search channel with correlated systematic uncertainties.

The normalisations of the $t\bar{t}$ and W+jets backgrounds were found to be different than those in the analysis of 36.1 fb^{-1}, therefore they are free parameters in the fit. They are constrained by Asimov dataset to one by construction. The other background normalisations are assigned Gaussian priors based on their respective normalisation uncertainties. The signal normalisation is a free parameter in the fit.

As an example, the m_{tb} distributions for two of the eight signal regions after the ML fit are shown in Fig. 6.2.14 for the expected background and signal contribution corresponding to a W'_{R} boson with a mass of 3 TeV. The binning of the m_{tb} distribution is chosen to optimise the search sensitivity while minimising statistical fluctuations.

The limits are evaluated assuming the modified frequentist $\mathrm{CL_s}$ method [95] with a profile-likelihood-ratio test statistic [257] and using the asymptotic approximation. The 95% C.L. upper limits on the production cross section multiplied by the branching fraction for $W'_{\mathrm{R}} \to t\bar{b}$ are shown in Fig. 6.2.15 as a function of the resonance mass for 3 ab^{-1}. The expected exclusion limits range between 0.02 pb and 6×10^{-3} pb for W'_{R} boson masses from 1 TeV to 7 TeV. The existence of W'_{R} bosons with masses below 4.9 TeV is expected to be excluded, assuming that the W'_{R} coupling g' is equal to the SM weak coupling constant g. This would increase the limit obtained with 36.1 fb^{-1} [685] by 1.8 TeV.

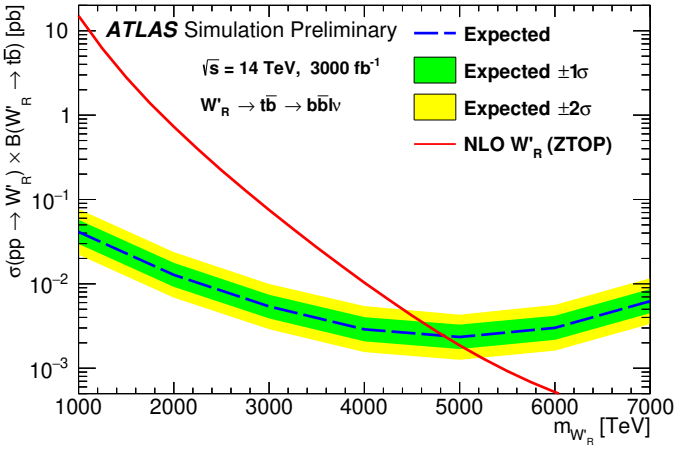

Fig. 6.2.15: Upper limits at the 95% C.L. on the W'_{R} production cross section times branching fraction as a function of resonance mass. The dashed curve and shaded bands correspond to the limit expected in the absence of signal and the regions enclosing one/two standard deviation (s.d.) fluctuations of the expected limit. The theory prediction is also shown.

The expected discovery significance is calculated using the profile likelihood test statistic for different mass hypotheses for a luminosity of $3\ \mathrm{ab}^{-1}$with the asymptotic approximation. Based on 5σ significance, it is found that W'_{R} with masses up to 4.3 TeV can be discovered at the HL-LHC.

6.2.7 Searches for $W' \to \tau + E_{\mathrm{T}}^{\mathrm{miss}}$

Contributors: K. Hoepfner, C. Schuler, CMS

New W′ heavy gauge bosons might decay as $\mathrm{W}' \to \tau\nu$. This yields to final states characterised by a single hadronically decaying tau (τ_h) as the only detectable object, and missing energy due to the neutrinos. Hadronically decaying tau leptons are selected since the corresponding branching fraction, about 60%, is the largest among all τ decays. Tau-jets are experimentally distinctive because of their low charged hadron multiplicity, unlike QCD multi-jets, which have high charged hadron multiplicity, or other leptonic W′ boson decays, which yield no jet. This Phase-2 study [686] follows closely the recently published Run-2 result [687], using hadronically decaying tau leptons.

The signature of a W′ boson (see Fig. 6.2.16), is considered similar to a high-mass W boson. It could be observed in the distribution of the transverse mass (M_T) of the transverse momentum of the τ (p_T^{τ}) and the missing transverse momentum: $M_T = \sqrt{2p_T^{\tau}E_{\mathrm{T}}^{\mathrm{miss}}(1 - cos\Delta\phi(\tau, E_{\mathrm{T}}^{\mathrm{miss}}))}$. Unlike the leptonic search channels, the signal shape of W' bosons with hadronically decaying tau leptons does not show a Jacobian peak structure because of the presence of two neutrinos in the final state. Despite the multi-particle final state, the decay appears as a typical two-body decay; the axis of the hadronic tau jet is back to back with $E_{\mathrm{T}}^{\mathrm{miss}}$ and the magnitude of both is comparable such that their ratio is about unity.

The results are interpreted in the context of the sequential standard model in terms of W′ mass and coupling strength. A model-independent cross section limit allows interpretations in other models. The signal is simulated at LO and the detector performance simulated with DELPHES. The W′ boson coupling strength, $g_{\mathrm{W}'}$, is given in terms of the SM weak coupling strength $g_{\mathrm{W}} = e/\sin^2\theta_W \approx 0.65$. Here, θ_{W} is the weak mixing angle. If the W′ boson is a heavier copy of the SM W boson, their coupling ratio is $g_{\mathrm{W}'}/g_{\mathrm{W}} = 1$ and the SSM W′ boson theoretical cross sections, signal shapes, and widths apply. However, different couplings are possible. Because of the dependence of the width of a particle on its couplings the consequent effect on the transverse mass distribution, a limit can also be set on the coupling strength.

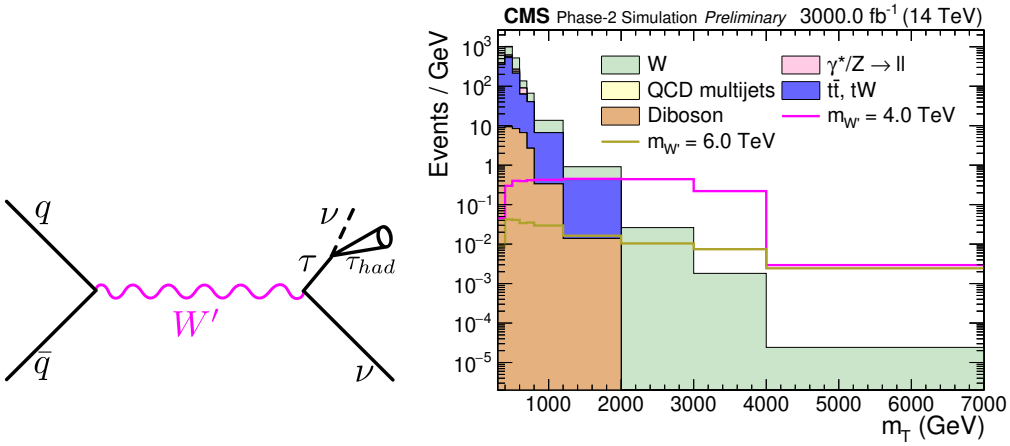

Fig. 6.2.16: Left: Illustration of the studied channel $W' \to \tau\nu$ with the subsequent hadronic decay of the tau (τ_h). Right: The discriminating variable, M_T, after all selection criteria for the HL-LHC conditions of 3 $\mathrm{ab}^{-1}$and 200 PU. The relevant SM backgrounds are shown according to the labels in the legend. Signal examples for W′ boson masses of 4 TeV and 6 TeV are scaled to their SSM LO cross section and 3 ab^{-1}.

The dominant background appears in the high mass tail of the M_T distribution of SM W boson events. Subleading background contributions arise from $t\bar{t}$ and QCD multijet events. These backgrounds primarily arise as a consequence of jets misidentified as τ_h candidates and populate the lower transverse masses while the signal exhibits an excess of events at high M_T. Events with one hadronically decaying τ and $E_{\mathrm{T}}^{\mathrm{miss}}$ are selected if the ratio of p_T^{τ} to $E_{\mathrm{T}}^{\mathrm{miss}}$ satisfies $0.7 < p_T^{\tau}/E_{\mathrm{T}}^{\mathrm{miss}} < 1.3$ and the angle $\Delta\phi(\vec{p_T}^{\,\tau}, E_{\mathrm{T}}^{\mathrm{miss}})$ is greater than 2.4 radians.

The physics sensitivity is studied based on the M_T distribution in Fig. 6.2.16 (right). Signal events are expected to be particularly prominent at the upper end of the M_T distribution, where the expected SM background is low. So far, there are no indications for the existence of a SSM W′ boson [687]. With the high luminosity during Phase-2, the W′ mass reach for potential observation increases to 6.9 TeV and 6.4 TeV for 3σ evidence and 5σ discovery, respectively, as shown in Fig. 6.2.17 (left). Alternatively, in case of no observation, one can exclude SSM W′ boson masses up to 7.0 TeV with 3 ab^{-1}. These are multi-bin limits taking into account the full M_T shape.

While the SSM model assumes SM-like couplings of the fermions, the couplings could well be weaker if further decays occur. The HL-LHC has good sensitivity to study these couplings. The sensitivity to weaker couplings extends significantly. A model-independent cross section limit for new physics with τ+$E_{\mathrm{T}}^{\mathrm{miss}}$ in the final state is depicted in Fig. 6.2.17 (right), calculated as a single-bin limit by counting the number of events above a sliding threshold M_T^{min}.

6.2.8 HL- and HE-LHC sensitivity to 2HDMs with $U(1)_X$ Gauge Symmetries

Contributors: D. A. Camargo, L. Delle Rose, S. Moretti, F. S. Queiroz

Extended Higgs sectors belonging to various BSM scenarios offer the possibility to solve some of the open problems of the SM. Such frameworks with extended Higgs sectors have recently come together with new $U(1)_X$ gauge symmetries, offering a natural solutions to the DM and the neutrino mass problems. These scenarios [688–693] predict a rich new phenomenology due to the presence of a massive Z' gauge boson arising after the $U(1)_X$ spontaneous symmetry breaking.

Our goal is to explore the potential of the HL- and HE-LHC to study such a scenario. To do so, we fist use the latest available dilepton data from the LHC [442,694] to constrain the mass and couplings of such Z' gauge bosons and, consequently, the viable parameter space of the underlying model. Then we use this result to asses the capabilities of the HL- and HE-LHC to test the existence of such heavy

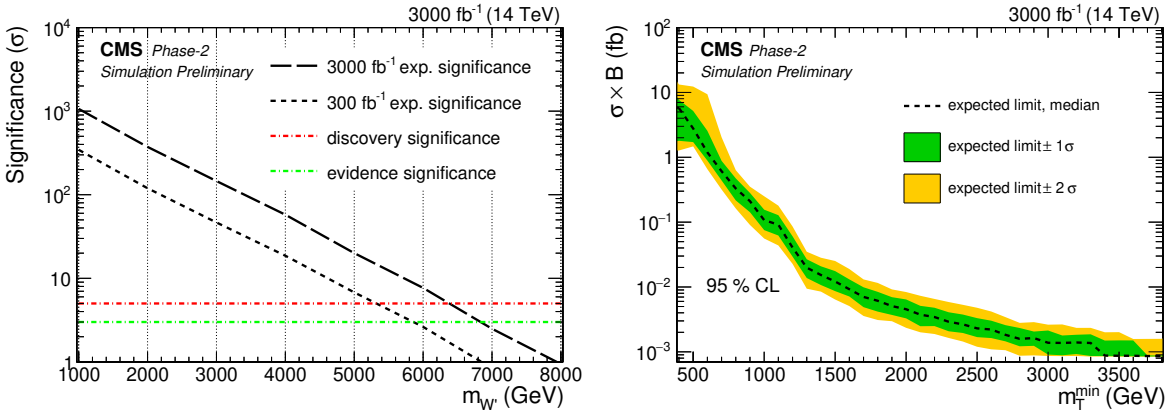

Fig. 6.2.17: Left: Discovery significance for SSM W′ to tau leptons. Right: Model-independent cross section limit. For this, a single-bin limit is calculated for increasing $M_T^{\min}$ while keeping the signal yield constant in order to avoid including any signal shape information on this limit calculation.

neutral vector bosons. An extended version of this contribution can be found in Ref. [695].

The relevant part of the Lagrangian of the model we consider is

$$\mathcal{L}_{\rm NC} \supset -\left(\tfrac{g_Z}{2} J^\mu_{NC} \cos\xi\right) Z_\mu - \left(\tfrac{g_Z}{2} J^\mu_{NC} \sin\xi\right) Z'_\mu \tag{6.2.1}$$

$$+\tfrac{1}{4} g_X \sin\xi \left[\left(Q^R_{Xf} + Q^L_{Xf}\right) \bar\psi_f \gamma^\mu \psi_f + \left(Q^R_{Xf} - Q^L_{Xf}\right) \bar\psi_f \gamma^\mu \gamma_5 \psi_f\right] Z_\mu \tag{6.2.2}$$

$$-\tfrac{1}{4} g_X \cos\xi \left[\left(Q^R_{Xf} + Q^L_{Xf}\right) \bar\psi_f \gamma^\mu \psi_f - \left(Q^L_{Xf} - Q^R_{Xf}\right) \bar\psi_f \gamma^\mu \gamma_5 \psi_f\right] Z'_\mu, \tag{6.2.3}$$

where ξ represents the $Z - Z'$ mixing parameter, g_X the gauge coupling of the new abelian symmetry while $Q^L_X(Q^R_X)$ are the left(right)-handed fermion charges under $U(1)_X$ defined according to Ref. [695]. This interaction Lagrangian represents the key information for the collider phenomenology we are going to tackle, because it dictates Z' production rates at the LHC as well as its most prominent decays to be searched for.

Present LHC bounds are obtained here by simulating at 13 TeV of c.o.m. energy the process

$$pp \to l^+ l^- + X, \tag{6.2.4}$$

where $l = e, \mu$, leading to dilepton signals, and X represents the surrounding hadronic activity. (The dijet signal case was studied in Ref. [695] and found to be less sensitive.) Since this channel is mediated by a heavy Z', alongside γ and Z, a peak around the Z' mass would appear at large values of the invariant mass of the dilepton final state. We describe our results adopting both the Narrow Width Approximation (NWA) and also introducing Finite Width (FW) effects. In this respect, we have implemented in FEYNRULES [696] the models shown in Ref. [695], where the corresponding $U(1)_X$ charge assignment is explicitly shown, and we have simulated the partonic events with MADGRAPH5_aMC@NLO [697]. For hadronisation and detector effects we used PYTHIA 8 [50] and DELPHES [33], respectively.

Assuming, for the sake of definiteness, the NWA with $g_X = 0.1, 0.2$ and 0.3, we project the current experimental limits to the HL- and HE-LHC. In order to extrapolate the current bound to a new collider configuration, one would need to scale the relevant backgrounds and find the new point giving the same number of background events, which, assuming same efficiencies and acceptances, would lead to the same excluded signal cross section, as outlined in Ref. [698]. However, in the case of the dilepton final state, the signal and the background scale equally with energy/luminosity, so that one can employ a simpler strategy, based on a direct rescaling of the bound on the number of signal events. Therefore, in order to find the future sensitivities we just solve an equation for $M_{\rm new}$ (*i.e.*, the new limit on $m_{Z'}$),

Table 6.2.7: HL-LHC and HE-LHC projected sensitivities for all $U(1)_X$ models studied in this work using dilepton data at 13 TeV, 14 TeV and 27 TeV of CM energy and for $\mathcal{L} = 300$ fb^{-1} and $\mathcal{L} = 3$ and 15 ab^{-1}. Here, $g_X = 0.3$.

knowing the current bound M, as follows:

$$\frac{N_{\text{signal events}}(M^2_{\text{new}}, E_{\text{new}}, \mathcal{L}_{\text{new}})}{N_{\text{signal events}}(M^2, 13\,\text{TeV}, 36\,\text{fb}^{-1})} = 1, \tag{6.2.5}$$

with obvious meaning of the subscripts.

The results from this iteration are summarised in Tables 6.2.5, 6.2.6 and 6.2.7. The lower mass bounds found presently compared to the expected ones at the HL-LHC and/or HE-LHC clearly show how important is any LHC upgrade to test new physics models including a Z'. For some models and benchmark points, such as, *e.g.*, $U(1)_A$ with $g_X = 0.1$, the HE-LHC will potentially probe Z' masses up to 7 TeV, while for others, such as, *e.g.*, $U(1)_F$ with $g_X = 0.3$, it will potentially exclude masses up to 12 TeV. In short, both LHC upgrades can generally extend the current reach in $m_{Z'}$ by a factor 2 to 3. The results are summarised in the tables.

6.2.9 *Z' discrimination at HE-LHC in case of an evidence/discovery after the HL-LHC*

Contributors: C. Helsens, D. Jamin, M. L. Mangano, T. Rizzo, M. Selvaggi

Context of the study and HL-LHC bounds

It is still legitimate to assume that a heavy resonance could be seen at the end of HL-LHC. If that is the case a new collider with higher energy in the c.o.m. is needed to study its properties as too few events will be available at $\sqrt{s} = 14$ TeV. In this section we present the discrimination potential between six Z' models of a HE-LHC with an assumed c.o.m. energy of 27 TeV and an integrated luminosity of $\mathcal{L} = 15\ \text{ab}^{-1}$. Under the assumption that these Z''s decay only to SM particles, we show that there are sufficient observables to perform this model differentiation in most cases.

As a starting point it is needed to estimate what are, for $\sqrt{s} = 14$ TeV, the typical exclusion/discovery reaches for standard reference Z' models assuming $\mathcal{L} = 3\ \text{ab}^{-1}$ employing only the e^+e^- and $\mu^+\mu^-$ channels. The production cross section times leptonic branching fraction is shown in Fig. 6.2.18 (left) for these models at $\sqrt{s} = 14$ TeV in the narrow width approximation (NWA). It has been and will be assumed here that these Z' states only decay to SM particles.

Studies presented in this report on prospects for searches of Z' by ATLAS (see Section 6.2.5) shows that discovery and exclusion reaches are between 5 and 6.5 TeV in $M_{Z'}$ depending on the model assumption. Based on these results, we will assume in our study below that we are dealing with a Z' of mass 6 TeV. Figure 6.2.18 (right) shows the NWA cross sections for the same set of models but now at $\sqrt{s} = 27$ TeV with $\mathcal{L} = 15\ \text{ab}^{-1}$. We note that very large statistical samples will be available for the case of $M_{Z'} = 6$ TeV for each dilepton channel.

Definition of the discriminating variables

The various Z' models can be disentangled with the help of 3 inclusive observables: the production cross section times leptonic branching fraction σB_l, the forward-backward asymmetry A_{FB} and the rapidity ratio r_y. The variable A_{FB} can be seen as an estimate of the charge asymmetry

$$A_{FB} = A_C = \frac{\sigma(\Delta|y| > 0) - \sigma(\Delta|y| < 0)}{\sigma(\Delta|y| > 0) + \sigma(\Delta|y| < 0)}, \tag{6.2.6}$$

where $\Delta|y| = |y_l| - |y_{\bar{l}}|$. It has been checked that this definition is equivalent to defining

$$A_{FB} = \frac{\sigma_F - \sigma_B}{\sigma_F + \sigma_B}, \tag{6.2.7}$$

with $\sigma_F = \sigma(cos\theta^*_{cs}) > 0$ and $\sigma_B = \sigma(cos\theta^*_{cs}) < 0$ where θ^*_{cs} is the Collins-Soper frame angle. The variable r_y is defined as the ratio of central over forward events:

$$r_y = \frac{\sigma(|y_{Z'}| < y_1)}{\sigma(y_1 < |y_{Z'}| < y_2)}, \tag{6.2.8}$$

where $y_1 = 0.5$ and $y_2 = 2.5$.

Model discrimination

The model discrimination presented in this section has been performed assuming the HE-LHC detector parametrisation [699] in DELPHES [33]. In such a detector, muons at $\eta \approx 0$ are assumed to be reconstructed with a resolution $\sigma(p)/p \approx 7\%$ for $p_T = 3$ TeV.

Leptonic final states The potential for discriminating various Z' models is first investigated using the leptonic ee and $\mu\mu$ final states only. The signal samples for the 6 models and the Drell-Yan backgrounds have been generated with PYTHIA 8.230 [68] including the interference between the signal and background. The Z' decays assume lepton flavour universality. For a description of the event selection and a discussion of the discovery potential in leptonic final states for the list of Z' models being discussed here, the reader should refer to Section 6.2.4. We simply point out here that with $\mathcal{L} = 15$ ab^{-1}, all Z' models with $m_{Z'} \lesssim 10$ TeV can be excluded at $\sqrt{s} = 27$ TeV.

Figure 6.2.19 (left) shows the correlated predictions for the A_{FB} and the rapidity ratio r_y observables defined previously for these six models given the above assumptions. Although the interference with the SM background was included in the simulation, its effect is unimportant due to the narrowness of the mass window around the resonance that was employed. Furthermore, the influence of the background uncertainty on the results has been found to have little to no impact on the model discrimination potential. Therefore the displayed errors on A_{FB} and r_y are of statistical origin only. The results show that apart from a possible near degeneracy in models ψ and η, a reasonable Z' model separation can indeed be achieved.

Using a profile likelihood technique, the signal strength μ, or equivalently, σB_l, can be fitted together with its corresponding error using the the di-lepton invariant mass shape. The quantity σB_l and its total estimated uncertainty is shown in Fig. 6.2.19 (centre) as a function of the integrated luminosity. The σB_l measurement seems to be able to resolve the degeneracy between the ψ and η models with $\mathcal{L} = 15$ ab^{-1}. It should be noted however that since the cross-section can easily be modified by an overall rescaling of the couplings, further handles will be needed for a convincing discrimination.

Hadronic final states Model discrimination can be improved by including an analysis involving three Z' addition hadronic final states: $t\bar{t}$, $b\bar{b}$ and $q\bar{q}$, where $q = u, d, c, s$. The sample production and event selection for the $t\bar{t}$, $q\bar{q}$ final states will be described to some extent in Section 6.4.6. We simply remind the reader that the analysis involves requiring the presence of two central high p_T jets. In order to ensure complete orthogonality between the various final states, jets are required to be tagged as follows. In the $Z' \to t\bar{t}$ analysis both jets should be *top-tagged*. For the $Z' \to b\bar{b}$ final state both jets are required to be *b-tagged* and we veto events containing at least one top-tagged jet. Finally, in the $Z' \to q\bar{q}$ analysis, we veto events that contain at least one b-tagged or top-tagged jet.

Figure 6.2.19 (right) summarises the discrimination potential in terms of fitted cross-section of the different models considering the three aforementioned hadronic decays, $t\bar{t}$, $b\bar{b}$ and $q\bar{q}$. An good overall discrimination among the various models can be achieved using all possible final states. For example, the SSM and ψ models, which have very close predictions for r_y and A_{FB}, have measurably different fractions of $t\bar{t}$ or $b\bar{b}$ final states. We note however that the degeneracy between η and ψ can only be partially resolved resolved at $\approx 1\sigma$ by exploiting the difference in $t\bar{t}$ yield.

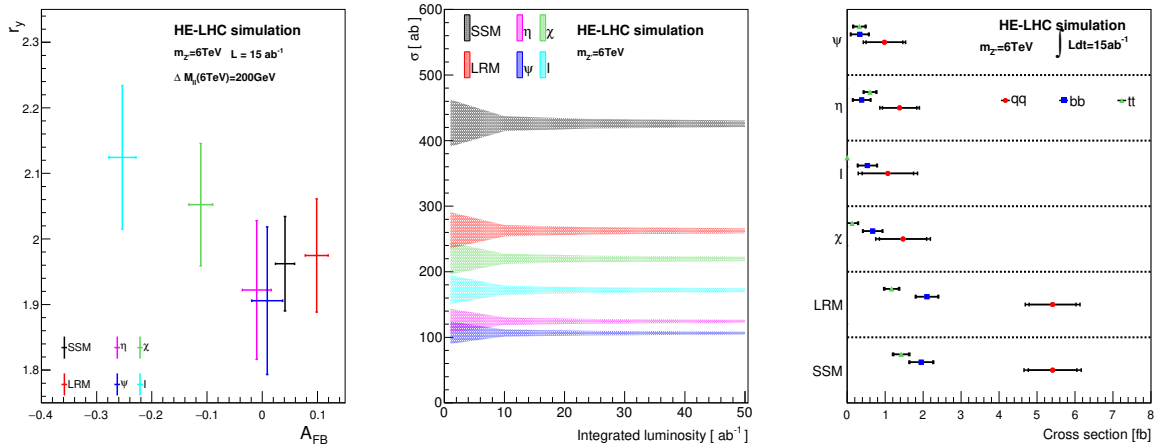

Fig. 6.2.19: Left: scatter plot of r_y versus A_{FB} with 200 GeV and mass window. The full interference is included. Centre: Fitted signal cross-section together with its corresponding error versus integrated luminosity. Right: fitted cross-section of the three hadronic analyses. Statistical and full uncertainties are shown on each point.

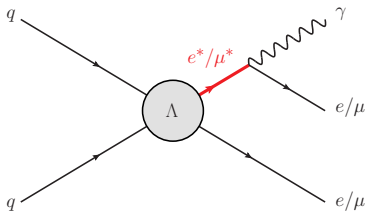

Fig. 6.3.1: Feynman diagram of the production of excited leptons in $\ell\ell\gamma$ final states.

In summary, in this section we studied the discrimination potential of six Z' models at HE-LHC with an assumed c.o.m. energy of 27 TeV and an integrated luminosity of $\mathcal{L} = 15$ ab^{-1}. The exercise has been performed assuming the evidence of an excess observed at $\sqrt{s} = 14$ TeV at a mass $m_{Z'} \approx 6$ TeV. Overall it was found that it is possible to distinguish among most models. Finally, it should be noted that further studies, perhaps employing 3-body decay modes or associated Z' production will be clearly needed to be pursued in case of discovery to further characterise the resonance properties.

6.3 Spin 1/2 resonances

In this section, prospect studies for spin-1/2 resonances are presented, targeting excited leptons and heavy vector-like quarks. Resonances coupled to leptons and quarks or gauge bosons and quarks are considered.

6.3.1 Search for excited leptons at HL-LHC

Contributors: S. Ha, B. Kim, M. S. Kim, K. Nam, S. W. Lee, H. D. Yoo, CMS

A search for excited leptons (electrons and muons) is studied at the HL-LHC with the upgraded CMS detector using simulation [700]. Excited leptons are predicted by many BSM theories where quarks and leptons are not elementary but instead are themselves composite objects. The HL-LHC environment (a c.o.m.energy of 14 TeV and an integrated luminosity of 3 ab^{-1}) allows to extend the discovery potential of excited leptons. This analysis presents a search for excited leptons ($\ell^* = \mathrm{e}^*, \mu^*$) in $\ell\ell\gamma$ ($\ell = \mathrm{e}, \mu$) final states where the excited lepton decays to a SM lepton and a photon ($\ell^* \to \ell\gamma$). An illustration of the production decay mode is shown in Fig. 6.3.1.

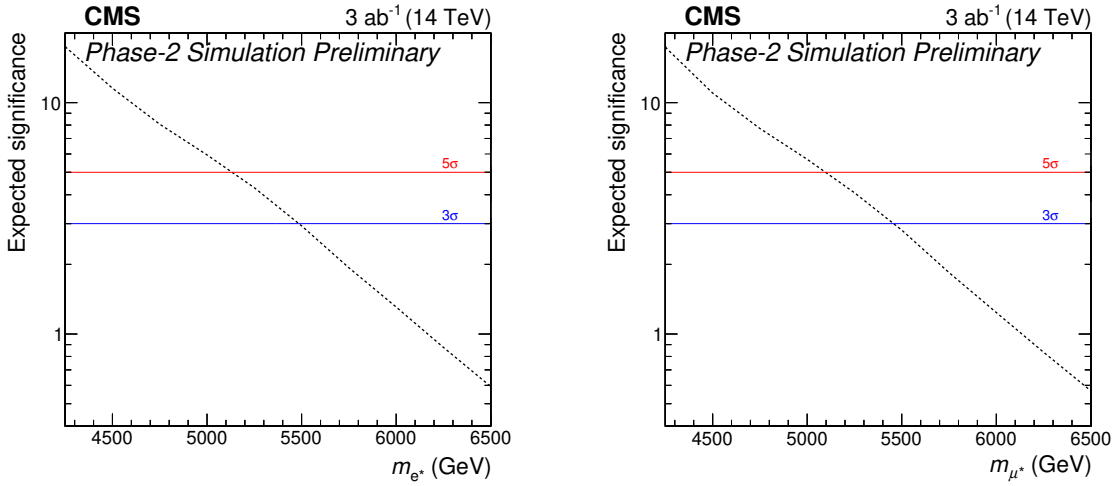

Fig. 6.3.2: Discovery significance for excited electrons (left) and muons (right) with 3 ab^{-1} at the HL-LHC.

In this search, a clear signature of an opposite-sign same-flavour lepton pair and a photon allows highly efficient signal selection to assess the CMS upgrade physics reach. However, an ambiguity between the lepton from the excited lepton decay and the lepton from the contact interaction makes it challenging to identify the reconstructed mass of the excited lepton due to two possible pairings of a lepton and the photon. For this search, information from both invariant mass combinations is used to discriminate the excited lepton signal from SM background processes. We consider a benchmark model based on the formalism described in Ref. [394].

The signal samples are generated with PYTHIA 8.205 [92] at $\Lambda = 10$ TeV for ℓ^* masses ranging from 3.5 TeV to 6.5 TeV in steps of 250 GeV, where Λ is the compositeness scale. The simulated signal samples are generated at leading order (LO) in perturbative quantum chromodynamics. The main background is the SM $\mathrm{Z}\gamma$ process, which is generated at NLO using MADGRAPH5_aMC@NLO 2.3.3 [67, 697]. The generated signal and background samples are interfaced to delphes [33], which features a parametric simulation of the CMS Phase 2 detector at the particle level.

We select events having two isolated electrons or muons and a photon with requirements as follows. Electron and photon candidates are required to have pseudorapidity $|\eta| < 2.5$ and transverse momentum $p_T > 35$ GeV, and they are excluded in the electromagnetic calorimeter barrel-endcap transition region ($1.44 < |\eta| < 1.57$). Muon candidates should be isolated with $|\eta| < 2.4$ and $p_T > 35$ GeV. The leptons are required to have opposite charge and the selected electrons and muons must be separated from the photon by $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} > 0.7$. In addition, the invariant mass of the two same flavour leptons $m_{\ell\ell}$ is required to be larger than 116 GeV in order to suppress the dominant background contribution from real Z boson production (Z resonance veto criteria).

The main SM background after the event selection is Drell-Yan production associated with a photon ($\mathrm{Z}\gamma$), which has the same signature as the final state of the signal, when the Z boson decays into two leptons. This background is significantly suppressed by the Z boson veto requirement. Contributions of other SM processes like diboson and top quark pair production in association with a photon ($t\bar{t} + \gamma$) are relatively small, in particular in the signal search region of excited lepton masses above 2 TeV. Simulated $t\bar{t} + \gamma$ events are studied in this analysis, however the background events are imperfectly estimated due to the insufficient sample size. Hence, we only consider the dominant $\mathrm{Z}\gamma$ background in this search, and additional background contributions are considered as systematic uncertainties on the total background estimate. The photon misidentification rate under the HL-LHC conditions is studied in Ref. [701] using PHASE-2 DELPHES samples. The photon misidentification rate is expected to be about 1% when the photon p_T is on the order of 100 GeV, which is compatible with the 2016 result. In the previous CMS Run-2 ℓ^* search [702], we observed 20% and 5% contribution from $t\bar{t} + \gamma$ and misidentified photon

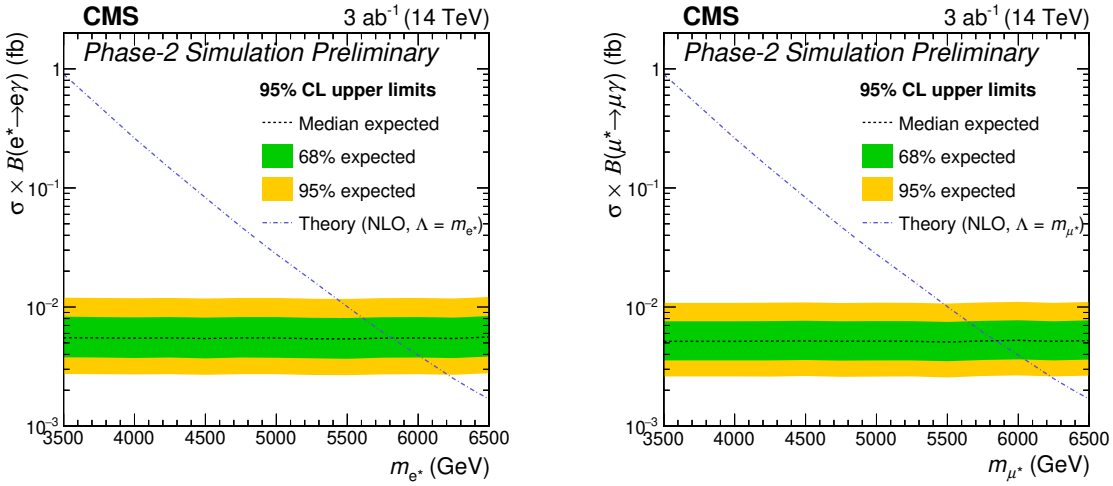

Fig. 6.3.3: Exclusion limits for excited electrons (left) and muons (right) on the product of cross section and branching fraction.

backgrounds, respectively, at $M_{\ell^*} > 1$ TeV; therefore a 25% systematic uncertainty is assigned for the missing background contributions.

To distinguish between signal and background events, a two-dimensional distribution of the two invariant masses $M_{\ell\gamma}^{\text{min}}$ and $M_{\ell\gamma}^{\text{max}}$ is used. A search window is set in the two-dimensional distribution of $M_{\ell\gamma}^{\text{max}}$ versus $M_{\ell\gamma}^{\text{min}}$. For ℓ^* events, either $M_{\ell\gamma}^{\text{min}}$ or $M_{\ell\gamma}^{\text{max}}$ corresponds to the reconstructed invariant mass of ℓ^*. Therefore, the mass resonance of the signal is concentrated in an "L" shape [703,704]. On the other hand, background events have no such correlation in $M_{\ell\gamma}^{\text{min}}$ and $M_{\ell\gamma}^{\text{max}}$ and are scattered around at low masses below about 2 TeV. This distinction between signal and background events in the distribution of $M_{\ell\gamma}^{\text{max}}$ versus $M_{\ell\gamma}^{\text{min}}$ is used to set the search window. We set the lower $M_{\ell\gamma}^{\text{max}}$ bound at 2 TeV in the two-dimensional distribution as the search window in order to maximise the signal yields. The reason why the L-shaped search window is not applied in this analysis is due to the insufficient MC statistics. Therefore the results of the limits presented here are likely to be improved upon with an actual search. The product of signal acceptance and efficiency ($A \times \varepsilon_{\text{sig}}$) is obtained using the simulated DELPHES signal samples and the results are 58% (μ^*) and 45% (e^*) with negligible M_{ℓ^*} dependence.

Systematic uncertainties for the performance of the lepton (0.5%) and photon (2.0%) reconstruction and identification, and the integrated luminosity (1.0%) follow the recommendation for upgrade analyses [705]. The theoretical systematic uncertainty is reduced by a factor of 1/2 with respect to the 2016 result. The statistical uncertainty in the entire signal region is dominant in this analysis. The missing background contribution is considered to be the main systematic uncertainty in the background estimation.

The upper limit of the excited electrons and muons is determined under the the HL-LHC scenario, based on an integrated luminosity of 3 ab^{-1}. We set 95% C.L. upper limits on the production cross sections, which are computed with the modified frequentist CL_s method [94, 95], with a likelihood ratio used as a test statistic. The systematic uncertainties are treated as nuisance parameters with log-normal priors.

The discovery potential as a function of excited lepton mass shown in Fig. 6.3.2 indicates that 3σ evidence (5σ discovery) is possible for both excited electrons and excited muons with masses up to 5.5 (5.1) TeV. Figure 6.3.3 shows the expected upper limits for e^* (left) and μ^* (right). The expected exclusion of the excited leptons is $M_{\ell^*} < 5.8$ TeV for both e^* and μ^* in the case where $M_{\ell^*} = \Lambda$. While the electron channel has a lower signal yield than the muon channel, it also has lower background, and the net result is that the excluded cross sections differ only by about 10%, producing a similar exclusion limit on the excited lepton mass.

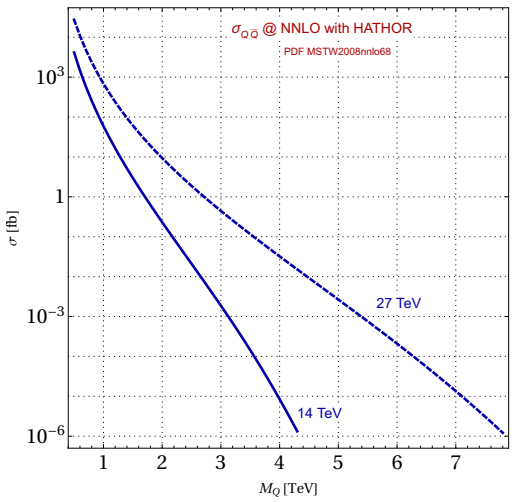

Fig. 6.3.4: VLQ pair production cross section for the 14 and 27 TeV LHC.

6.3.2 VLQs at HL- and HE-LHC: discovery and characterisation

Contributors: D. Barducci, L. Panizzi

Vector Like Quarks (VLQs) are hypothetical heavy quarks whose left- and right-handed chiral components transform under the same representation of the SM gauge group. In minimal extensions of the SM, VLQs couple to SM quarks via Yukawa-type interactions and gauge invariant renormalisable operators can be written only for the singlet, doublet and triplet representations of $SU(2)$ [706]. It can be shown that the couplings of the VLQs with the SM bosons and quarks always have a dominant chiral component [706, 707] and this depends only on whether their weak isospin is integer or half-integer, the other component being suppressed by a factor proportional to $m_q^{\rm SM}/m_{\rm VLQ}$, with $m_q^{\rm SM}$ the mass of the SM quark with which the VLQ mixes.

This property affects the polarisation of the gauge bosons and quarks arising from the VLQs decay. While the gauge bosons tend to have a dominant longitudinal polarisation, the polarisation of the final state quarks allows one to extract useful information. In particular if the VLQ decays into a top quark, its polarisation properties will affect the kinematic distributions of the final decay products. This can slightly affect the reach of new physics searches but, more importantly, in the fortunate event of a signal excess being observed, this difference can be used to probe the structure of the interactions between the VLQs and the SM sector.

In this contribution, based on the results of Ref. [708], we analyse the possibility of discriminating the chiral structure of VLQ couplings at the HL- and HE-LHC, under the hypothesis that the VLQ decays to the SM top quark. This eventually allows one to discriminate its representations under the SM $SU(2)$ gauge group.

The polar angle distribution of the top quark decay product f in the top rest frame is described by

$$\frac{1}{\Gamma_l}\frac{{\rm d}\Gamma_l}{{\rm d}\cos\theta_{f,\rm rest}} = \frac{1}{2}(1 + P_t\cos\theta_{f,\rm rest}) \tag{6.3.1}$$

where Γ_l is the partial width, $\theta_{f,\rm rest}$ is the angle between the momentum of the decay product f and the top spin vector and P_t is the polarisation of the top. From Eq. (6.3.1) one sees that for positive (negative) polarised top quarks most of the decay products come in the forward direction, that is the directions of the would-be momentum of the top quark in the laboratory frame. In the same frame the θ_f distribution is now described by Eq. (6.3.1) combined with a boost from the top rest frame to the laboratory frame. This implies that positive polarised top quarks will produce harder decay products.

To show how the polarisation information can be used to disentangle a VLQ chiral structure we focus on a VLQ with charge $2/3$ interacting exclusively with the top quark and the Z boson. We recast

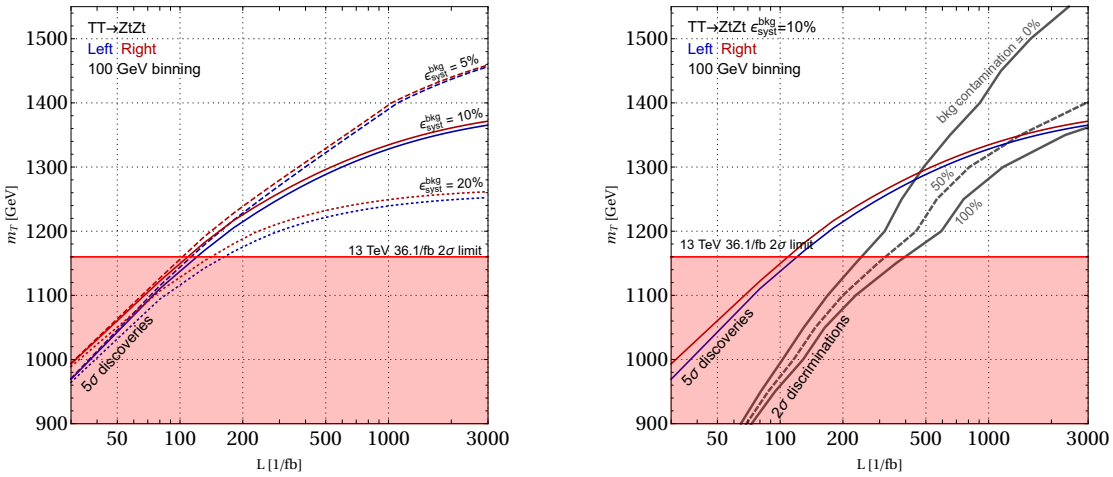

Fig. 6.3.5: Left: projected 5σ discovery (blue and red) for different assumptions for the systematic uncertainties on the background determination of the ATLAS single lepton search [709] for a T VLQ decaying with 100% BR into the Zt final state extrapolated for the 14 TeV LHC (see main text for details). The blue and red lines correspond to the discovery reach for the left-handed and right-handed coupling structure. The red shaded area correspond to the experimental limit from [709] for the 13 TeV LHC from for a VLQ decaying with 100% BR into the Zt final state, namely 1160 GeV. Right: projected 2σ discrimination (gray) reaches assuming $\epsilon^{\rm bkg}_{\rm syst} = 10$ %.

a search for pair produced VLQs performed by the ATLAS collaborations in the single lepton channel with an integrated luminosity of 36.1 fb^{-1} at $\sqrt{s} = 13$ TeV [709]. Throughout this work the VLQ pair production cross sections have been computed with HATHOR [204] and are reported in Fig. 6.3.4.

We then project the discovery and exclusion reach of the ATLAS search for the case of the 14 TeV LHC assuming the same signal acceptances than for the 13 TeV case and rescaling the backgrounds by the relevant parton luminosities ratios. We do these projections for higher values of integrated luminosities and different values of the systematic uncertainties on the background determination, $\epsilon^{\rm bkg}_{\rm syst}$, and then perform a χ^2 fit on the leading lepton p_T between the left- and right-handed coupling scenario considering the number of bins of the distribution as degrees of freedom, and under the simplifying assumption that the background (conservatively assumed to be distributed as the signal) can be subtracted with a certain efficiency, ranging from the extreme scenarios of 0% and 100%: the relation we use is therefore $\chi^2 = \sum_{i=1}^{\rm bins}(L_i - R_i)^2 / \max[\{L_i, R_i\} + \epsilon^{\rm bkg}_{\rm cont}(B + (\epsilon_{\rm syst}B)^2)]$, where L_i and R_i are the number of events in the left- and right-handed coupling scenario, $\epsilon^{\rm bkg}_{\rm cont}$ represents the contamination percentage of background events considered for the discrimination, and we consider Poissonian uncertainties for the signal.

The results are shown in Fig. 6.3.5, where we illustrate the 5σ discovery reaches for different $\epsilon^{\rm bkg}_{\rm syst}$ values (left panel) and the 2σ discrimination contours from the χ^2 fit assuming $\epsilon^{\rm bkg}_{\rm syst} = 10\%$ (right panel). We see that, if it is possible to perform a discrimination χ^2 test after removing all background events, should a VLQ with a mass lighter than around 1300 GeV be discovered, a mild increase in integrated luminosity will be needed to disentangle the two hypotheses, while the collected dataset will already be enough for the discrimination if a VLQ heavier than 1300 GeV is found with a 5σ significance. If background events cannot be removed the discrimination becomes more difficult, as the differences in the shapes become less relevant. The intersection between the discovery reach and the discrimination reach moves therefore towards higher luminosities, and in the limit of 100% background contamination we find that the discovery reach corresponds to the discrimination power at the nominal luminosity of 3 ab^{-1}.

The results obtained for the 14 TeV LHC show that with the signal region currently used in the

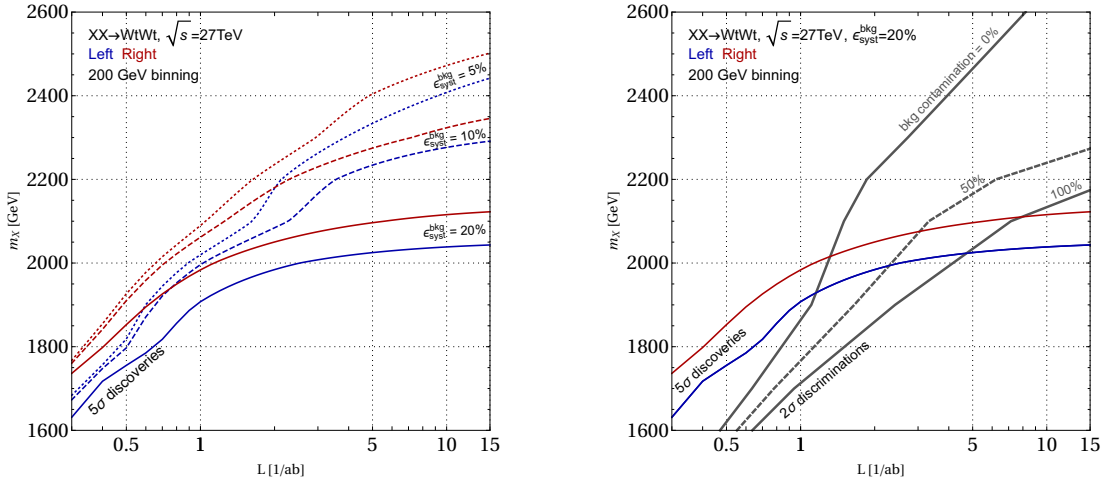

Fig. 6.3.6: Same as Fig. 6.3.5 for the 2SSL search for a X VLQ decaying with 100% BR into the Wt final state at $\sqrt{s} = 27$ TeV. We use the p_T distribution of the sub-leading lepton with a binning of 200 GeV and assume an uncertainty on the background determination of 20% (right).

ATLAS search we have considered, the LHC discovery reach will mildly increase when further data will be collected (unless one assumes a strong reduction of the current systematic uncertainties on the background determination), due to the fact that at hadron colliders the contribution of the PDFs drops when the transferred momentum of the process approaches the kinematic limit $\sqrt{s}/2$.[16] We then estimate here what is the mass reach of the high energy upgrade of the LHC for discovering pair-produced VLQs and discriminate their coupling structure.

We focus on the case of a VLQ with charge $5/3$ decaying into a W boson and a top quark and closely follow the search strategy defined in Ref. [710]. In this case we consider for discrimination the p_T distribution of the sub-leading lepton, which is almost always coming from the SM top decay. With the same statistical procedure adopted above, and rescaling the backgrounds yields given in Ref. [710] for $\sqrt{s} = 27$ TeV we show the results in Fig. 6.3.6. Our results show that a discrimination among the left- and right-handed coupling hypotheses is possible in all the discovery range accessible at the HE-LHC for $\epsilon_{\rm syst}^{\rm bkg} = 20\%$, regardless of the background contamination. In particular, if the background can be entirely subtracted, should a VLQ with mass greater than ~ 2 TeV be discovered, the collected data set will already be sufficient to exclude one of the two coupling structure, while if the background is entirely considered, discrimination is possible at the same time as discovery for a VLQ with mass greater then ~ 2100 GeV.

6.4 Signature based analyses

Several contributions that are constructed around experimental signatures rather than specific theoretical models are presented in this section. This includes analyses of dijets, diphotons, dibosons and ditops final state events at HL- and HE-LHC.

6.4.1 Coloured Resonance Signals at the HL- and HE-LHC

Contributors: T. Han, I. Lewis, Z. Liu

While much of the attention for new physics discovery has centred on precision measurements of the Higgs and EW sectors, the LHC is a QCD machine and most initial states are composed of coloured particles. Hence, new coloured dijet resonances that couple to partons will be produced with favourable rates at the HL-LHC and HE-LHC.

[16] Clearly an optimisation of the signal regions can be performed to increase the sensitivity already at the current LHC energy.

In Ref. [711] we classified the possible coloured resonances at the LHC according to their spin, electric charge, and colour representation. We now update those results for the HE-LHC. This involves comparing the cross sections of the various resonances at the LHC and HE-LHC.

Most initial states at the LHC are composed of coloured particles, *i.e.* quarks and gluons. We now review the possible interactions of coloured resonances with SM partons. A more detailed discussion, including examples of specific realisations of the various resonances in the existing literature, is given in Ref. [711]. All interactions are after EWSB.

Quark-quark annihilation can produce colour antitriplet or sextet scalars and vectors, so-called "diquarks". Please note that the diquarks under discussion here are fundamental particles and not composite. The possible scalar diquark are denoted as E_{N_D}, U_{N_D}, and D_{N_D} with electric charges $4/3, 2/3, -1/3$ respectively. The subscript $N_D = 3,\ 6$ for the $\mathbf{\bar{3}}$ and $\mathbf{6}$ colour representations, respectively. Vector diquarks are represented with an additional Lorentz index μ. The interaction Lagrangian between quarks and diquarks is then

$$\begin{aligned}\mathcal{L}_{qqD} &= K^j_{ab}\Big[\lambda^E_{\alpha\beta}E^j_{N_D}\,\overline{u^C_{\alpha a}}P_\tau u_{\beta b}+\lambda^U_{\alpha\beta}U^j_{N_D}\,\overline{d^C_{\alpha a}}P_\tau d_{\beta b}+\lambda^D_{\alpha\beta}D^j_{N_D}\,\overline{d^C_{\alpha b}}P_\tau u_{\alpha a}\\ &+ \lambda^{E'}_{\alpha\beta}E^{j\mu}_{N_D}\,\overline{u^C_{\alpha a}}\gamma_\mu P_R u_{\beta b}+\lambda^{U'}_{\alpha\beta}U^{j\mu}_{N_D}\,\overline{d^C_{\alpha a}}\gamma_\mu P_R d_{\beta b}+\lambda^{D'}_{\alpha\beta}\,D^{j\mu}_{N_D}\overline{u^C_{\alpha a}}\gamma_\mu P_\tau d_{\beta b}\Big]+\text{h.c.},\end{aligned} \tag{6.4.1}$$

where $P_\tau = \frac{1}{2}(1\pm\gamma_5)$ with $\tau = R, L$ for the right- and left-chirality projection operators, a, b are colour indices for the $SU(3)_C$ fundamental representation, j are colour indices of the N_D representation of $SU(3)_C$, α, β are flavour indices, and K^j_{ab} are $SU(3)_C$ Clebsch-Gordan (CG) coefficients.

Quarks and gluons annihilate into colour triplet or antisextet fermions with $1/2$ or $3/2$ spin. It is possible to produce a $\mathbf{15}$ colour representation, but the existence of such a fermion would spoil asymptotic freedom [712]. The spin $1/2$ $(3/2)$ fermion states are denoted by $d^*_{N_D}, u^*_{N_D}$ $(d^{*\mu}_{N_D}, u^{*\mu}_{N_D})$ with electric charged $-1/3$ and $2/3$, respectively. The lowest order gauge invariant interactions between a gluon, quark, and heavy fermion is dimension five:

$$\begin{aligned}\mathcal{L}_{qgF} &= \frac{g_s}{\Lambda}F^{A,\rho\sigma}\Big[\bar{u}\bar{K}_{N_D,A}(\lambda^U_L P_L+\lambda^U_R P_R)\sigma_{\rho\sigma}u^*_{N_D}+\bar{d}\bar{K}_{N_D,A}(\lambda^D_L P_L+\lambda^D_R P_R)\sigma_{\rho\sigma}d^*_{N_D}\\ &+\bar{u}\bar{K}_{N_D,A}(\lambda^U_L P_L+\lambda^U_R P_R)\sigma_{\rho\sigma}\gamma_\mu u^{*\mu}_{N_D}+\bar{d}\bar{K}_{N_D,A}(\lambda^D_L P_L+\lambda^D_R P_R)\sigma_{\rho\sigma}\gamma_\mu d^{*\mu}_{N_D}\Big]+\text{h.c.}\,,\end{aligned} \tag{6.4.2}$$

where A is the adjoint colour index, $F^{A,\rho\sigma}$ is the gluon field strength tensor, $\sigma_{\rho\sigma} = \frac{i}{2}[\gamma_\rho, \gamma_\sigma]$, Λ is the scale of new physics, and $K_{N_D,A}$ are $3\times N_D$ CG coefficient matrices.

Gluon-gluon annihilation can result in many different representations, that unlike the $\mathbf{15}$ fermion do not spoil asymptotic freedom. A complete list of the possible resonances from gluon-gluon annihilation can be found in Table 1 of Ref. [711]. We will focus on the theoretically motivated colour octet resonances. Two possible resonances that can result from gluon-gluon annihilation are colour octet scalars, S_8, and tensors, $T_8^{\mu\nu}$. These interactions can be described in a gauge invariant way by dimension five operators:

$$\mathcal{L}_{gg8} = g_s d^{ABC}\left(\frac{\kappa_S}{\Lambda_S}S_8^A F^B_{\mu\nu}F^{C,\mu\nu}+\frac{\kappa_T}{\Lambda_T}(T_8^{A,\mu\sigma}F^B_{\mu\nu}F_\sigma^{C\ \nu}+fT_{8\ \rho}^{A,\rho}\,F^{B,\mu\nu}F^C_{\mu\nu})\right), \tag{6.4.3}$$

where $\Lambda_{S,T}$ are the new physics scales, and the relative coupling factor f is expected to be order one.

Finally, quark-antiquark annihilation can produce colour octet or singlet scalars and vectors with zero or unit charge. The neutral vector-octet is denoted by V_8^0 and the charged vector octet states $V_8^\pm$.

Particle Names (leading coupling)	J	$SU(3)_C$	$\lvert Q_e\rvert$	B	Related models

Table 6.4.1: Summary for resonant particle names, their quantum numbers, and possible underlying models.

The interaction Lagrangian is then

$$\begin{aligned}\mathcal{L}_{q\bar{q}V} \;=\; & g_s\Big[V_8{}^{0,A,\mu}\;\bar{u}T^A\gamma_\mu(g^U_L P_L + g^U_R P_R)u + V_8{}^{0,A,\mu}\;\bar{d}T^A\gamma_\mu(g^D_L P_L + g^D_R P_R)d \\ & + \Big(V_8{}^{+,A,\mu}\;\bar{u}T^A\gamma_\mu(C_L V_L^{\text{CKM}} P_L + C_R V_R^{\text{CKM}} P_R)d + \text{h.c.}\Big)\Big]\,,\end{aligned} \tag{6.4.4}$$

where $V^{\text{CKM}}_{L,R}$ are the left- and right-handed Cabibbo-Kobayashi-Maskawa matrices, respectively. To avoid constraints from flavour physics it is assumed that the CKM matrices align with the SM CKM matrices and that there are no tree level flavour changing neutral currents, *i.e.*, $g^{U,D}_{L,R}$ and $C_{L,R}$ are flavour-diagonal. To obtain the interactions with the colour singlet bosons it is sufficient to replace the representation matrices $T^{A,a}{}_b$ with the Kronecker delta $\delta^a{}_b$. The couplings between octet and singlet scalar and light quarks is constrained to be small by minimal flavour violation [713]. It is possible for a new scalar to have substantial couplings to the third generation quarks consistent with minimal flavour violation if it has a non-trivial representation under the SM flavour groups [714]. We will only consider particles that couple to the light quarks and can be resonantly produced at the LHC. Hence, we ignore scalar singlet and octet contributions to s-channel resonances with quark/anti-quark initial states.

In Table 6.4.1 we summarise the different coloured resonances discussed in this section. We list our notation for the different states along with the leading couplings to SM partons and spin, colour representation, and electric charge of each state. The subscript S on $\mathbf{8}_S$ indicates that this colour octet representation is the symmetric combination of two other octets, as shown in Eq. (6.4.3).

Since all of the resonances listed in Table 6.4.1 couple to SM partons, they can decay back into SM partons. Hence, they can be observed as dijet resonances. We assume that the resonances decay exclusively back into (slim) dijets, *i.e.* not new particles or fat jets from top quarks. If there are additional decay channels, our results can be simply rescaled by a BR.

The cross section for resonance R production via quark and/or gluon initial states at the LHC is

$$\sigma = \mathcal{L}_{12}(\tau_0)\frac{4\pi^2}{S_H}\frac{N_D(2J_R+1)}{N_1\,N_2}\frac{\Gamma(R\to X_1X_2)}{M_R}(1+\delta_{X_1X_2}), \tag{6.4.5}$$

where X_1, X_2 are the initial state particles, M_R is the resonance mass, $S_H = 14, 27$ TeV is the c.o.m. energy, and J_R is the spin of the resonance. The dimension of the colour representation of the resonance and initial state particles are denoted by N_D and N_1, N_2, respectively. The parton luminosity is

$$\mathcal{L}_{12}(\tau_0) = \frac{1}{1+\delta_{X_1X_2}}\int_{\tau_0}^1\frac{dx}{x}\left(f_1(x)f_2(\tau_0/x) + f_2(x)f_1(\tau_0/x)\right), \tag{6.4.6}$$

where $\tau_0 = M_R^2/S_H$, f_1 is the PDF of X_1, and f_2 is the PDF of X_2.

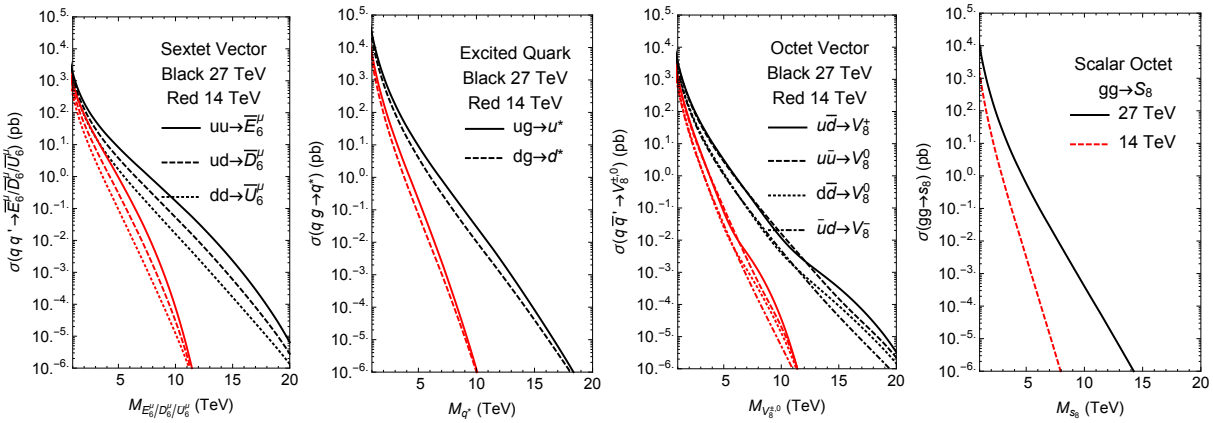

Fig. 6.4.1: Cross sections at HL- and HE-LHC shown in red and black curves, respectively, for (a) sextet diquarks, (b) excited quark, (c) octet vectors, and (d) S_8.

In Fig. 6.4.1 we show the cross sections of (a) sextet diquarks, (b) excited quarks, (c) octet vectors, and (d) S_8 for both the (red) HL- and (black) HE-LHC. These cross sections are calculated using the NNPDF [121] PDF set, the coupling constants $\lambda^{E,U,D}$ and κ_S are set to one, and the new physics scales $\Lambda = \Lambda_S = M_R$. The sextet scalar cross sections are the largest for large resonance mass due to an enhancement from having two valence quarks in the initial state. Somewhat surprisingly, despite the LHC having a reputation as having a large gluon pdf, at very high masses the vector octets produced from quark/anti-quark initial states have larger cross sections than resonances from gluon initial states. This is because the gluon PDF drops precipitously at high momentum fraction. In fact, at the highest resonance masses, S_8 produced from gluon fusion has the lowest cross sections. Although the precise value of these rates depends on the choices of couplings and new physics scale, the gluon pdf suppression is clearly seen by how quickly the excited quark and S_8 cross sections decrease at high resonance masses as compared to the vector octets.

As can be clearly seen, the cross sections greatly increase at the HE-LHC. For a resonance mass around $10 - 11$ TeV, we might expect $\mathcal{O}(1)$ events at the HL-LHC with $3\ \mathrm{ab}^{-1}$ of data for diquarks, excited quarks, and vector octets. For these resonances and resonance mass, at the HE-LHC with $3\ \mathrm{ab}^{-1}$ of data we may expect $\mathcal{O}(10^3 - 10^5)$ events. For S_8, for a resonance mass of 8 TeV for $3\ \mathrm{ab}^{-1}$ we expect $\mathcal{O}(1)$ events at the HL-LHC and $\mathcal{O}(10^4)$ events at the HE-LHC. This is a factor of $\mathcal{O}(10^3 - 10^5)$ increase in the cross sections at the HE-LHC.

Additionally, at the HE-LHC, the mass reach is considerably extended. The baseline for the HE-LHC is $15\ \mathrm{ab}^{-1}$by its end run. For $15\ \mathrm{ab}^{-1}$we expect $\mathcal{O}(10)$ events for 21 TeV diquarks (E_6^u), 19 TeV excited quark (u^*), 21 TeV octet vectors (V_8^+), and 15 TeV octet scalar S_8. Comparing this to the masses for which we expect $\mathcal{O}(10)$ events by the end of the HL-LHC, we see that we may expect the mass reach of the HE-LHC to be twice that of the HL-LHC.

6.4.2 Precision searches in dijets at the HL- and HE-LHC

Contributors: S. V. Chekanov, J. T. Childers, J. Proudfoot, R.Wang, D. Frizzell

Model-independent searches for deviations in dijet invariant mass distributions (M_{jj}) predicted by the SM is one of the central studies at the LHC. The main goal of such searches is to find small deviations from background distributions, under the assumption that a new resonant state decaying to partons that form two jets may introduce an excess in dijet masses localised around the resonance mass. In recent years, such searches for new physics at the LHC have been performed by both ATLAS and CMS collaborations (see the recent studies in Ref. [114, 114, 715–720]), but no statistically significant deviations from background expectations were found. Such searches are usually performed for resonances with a

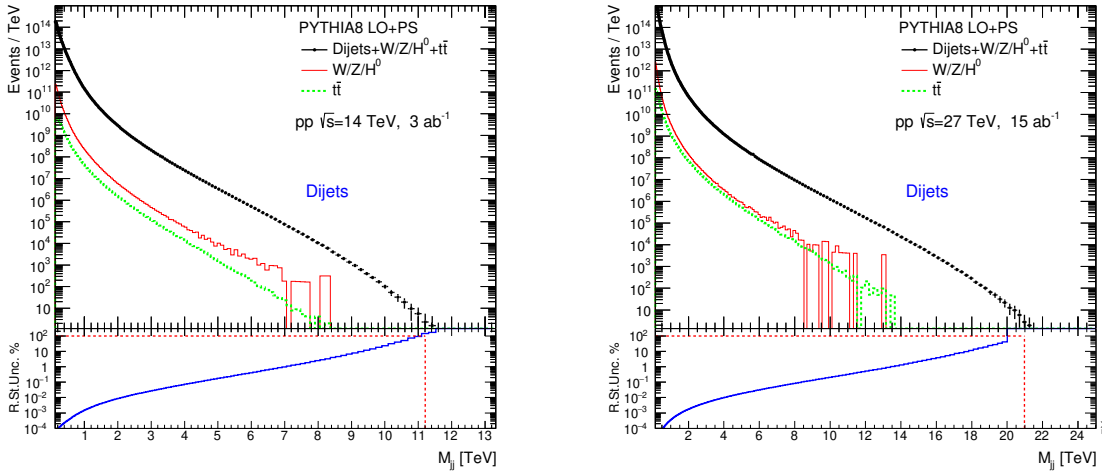

Fig. 6.4.2: Expectations for the dijet invariant mass distribution for 3 ab^{-1}at HL-LHC and 15 ab^{-1} at the HE-LHC using the Pythia generator. Contributions from $W/Z/H^0$ -boson processes and top-quark processes are shown separately (without stacking the histograms). The bottom plots show the relative statistical uncertainties in each bin, together with the line indicating the mass point at which the uncertainty is 100%. The figures are taken from [721].

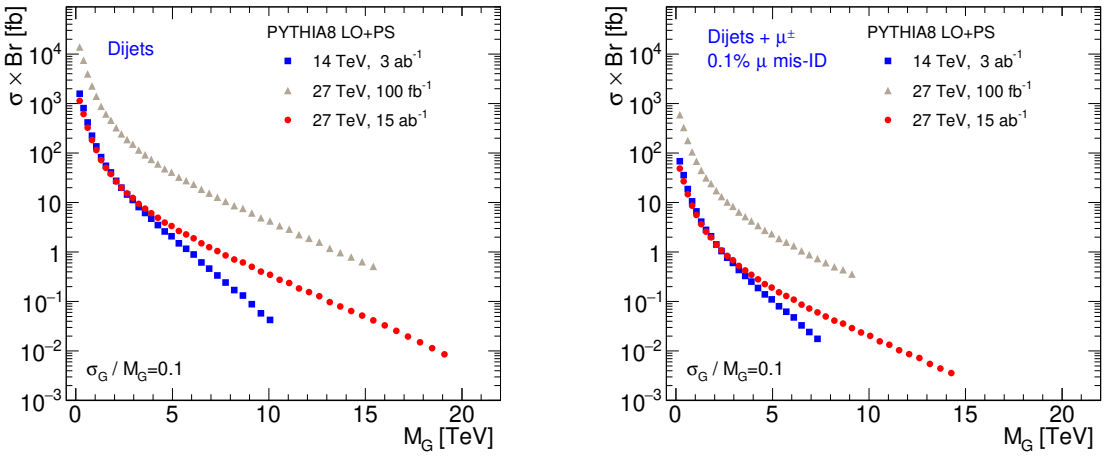

Fig. 6.4.3: Expected 95% C.L. upper limits obtained from the M_{jj} distribution on fiducial cross-section times the BR to two jets for a hypothetical BSM signal approximated by a Gaussian contribution to the dijet mass spectrum. The limits are obtained for the HL-LHC and HE-LHC energies. The figure shows the limits for inclusive dijet production (left) and for events with at least one isolated muon with $p_T > 60$ GeV.

width of up to 15% of the resonance mass. Searches for broader resonances are usually more difficult since the available tools to determine the background hypothesis have a number of limitations that do not allow for reliable estimates of background shapes in the presence of broad resonances. Despite the generality of dijet searches, such studies can exclude a number of BSM models, such as models with quantum black holes, excited quarks, and Z' bosons and so on. Currently, the LHC run II data provide the 95% C.L. exclusion limits on BSM resonances up to 6.5 TeV in masses.

Shapes of the background M_{jj} distributions can be affected by several instrumental factors, making such studies difficult for low-mass regions where statistics are large. In the case of inclusive jet production, the rate of dijets is reduced due to triggers with low acceptance rate, which leads to complicated shapes of in the region of M_{jj} below 1 TeV. This leads to difficulties in interpretation of the shapes

of the M_{jj} distributions using QCD-motivated fit functions. Recently, such searches have been extended to less inclusive events, such as events with $b-$jets and associated leptons [722, 723]. These studies rely on less inclusive triggers with low thresholds, thus accessing regions with small dijet masses.

With the increase of the LHC luminosity, searches for new physics beyond the SM in the invariant mass of two jets become increasingly important since the large event rate allows one to explore a large M_{jj} phase space with improved statistics. The proposed HL-LHC and HE-LHC experiments will open a new chapter in model independent searches, both in terms of the physics reach and the complexity of derivations of data-driven backgrounds. Here we will give an overview of the physics potential for model-independent searches [721] in dijets for the HE-LHC and HL-LHC experiments, as well as describe some technical problems in understanding of "signal-like" feature on a smoothly falling dijet mass distributions. We will cover searches in inclusive jets, as well as more exclusive searches in events with $b-$jets and leptons.

The presented studies use MC event generation with representative for the HL-LHC experiment event statistics. This was achieved using high-performance computers at NERSC. The PYTHIA 8 [50] generator with the default parameter settings and the ATLAS A14 tune [676] was used. The c.o.m. collision energy of pp collisions was set to 14 TeV and 27 TeV for the HL-LHC and HE-LHC respectively. About 100 billion MC events with the multi-jet QCD, $t\bar{t}$ and $W + jet$ categories of processes were simulated using the HepSim software [724] deployed on supercomputers at NERSC. Such a large number of events is required in order to obtain M_{jj} distributions which are sufficiently smooth for calculations of limits. In addition, a phase-space re-weighting was used for $2 \to 2$ processes to increase the statistics in the tail of the M_{jj} distribution as discussed in Ref. [50]. The jets were reconstructed with the anti-k_T algorithm [34], as implemented in the FastJet package [35], using a distance parameter of $R = 0.4$. The minimum transverse momenta of jets was 40 GeV, and the pseudorapidity range was $|\eta| < 2.4$. Dijet invariant masses were reconstructed by combining the two leading jets having the highest transverse momentum. The b-jets are selected by requiring a distance, defined in pseudorapidity and azimuthal angle, between the b-quark and jet to be less than 0.4 and the b-quark p_T to be at least 50% of the jet p_T. A constant 10% mis-tag rate was assumed, which is sufficiently realistic [725] for large $p_T(jet)$.

In addition to jets, muons were also used for such studies. They are required to be isolated using a cone of the size 0.2 in the azimuthal angle and pseudorapidity is defined around the true direction of the lepton. A lepton is considered to be isolated of it carries more than 90% of the cone energy. We also simulated a misidentification rate of muons (or “fake” rate) assuming that a muon can be mis-identified with a rate of 0.1% [726].

Figure 6.4.2 shows two representative M_{jj} distributions using the simulations discussed above. The results are shown for the HL-LHC and HE-LHC colliders using different integrated luminosities, $3\ \mathrm{ab}^{-1}$(for HL-LHC) and $15\ \mathrm{ab}^{-1}$ (for HE-LHC). The figure also shows contributions to the total event rate from $W/Z/H^0$-boson processes combined and top-quark processes from the hard interactions (shown separately). The lower panel shows the relative statistical uncertainty on the data points, *i.e.* $\Delta d_i/d_i$, where d_i is the number of the events in the bins, and Δd_i its statistical uncertainty (which is $\sqrt{d_i}$ in the case of counting statistics). For a quantitative characterisation of the dijet mass reach, the dash lines on the lower panel show the M_{jj} point at which statistical uncertainty in a bin is 100% (or $\Delta d_i/d_i = 1$). We have chosen this point to define the statistical reach for the measurements using the M_{jj} distributions. The M_{jj} mass reach at the HL-LHC is 11.2 TeV, while the mass reach at the c.o.m. of 27 TeV is close to 21 TeV for the the nominal luminosity of $15\ \mathrm{ab}^{-1}$.

The dijet distributions discussed above were used to set the 95% C.L. upper limit on fiducial cross-section times the BR for a generic Gaussian signal with the width (σ_G) being 10% of the Gaussian peak position. Figure 6.4.3 shows the obtained limits. In addition to inclusive dijet events, this figure shows the upper limits for events with at least one isolated muon with transverse momentum above 60 GeV. The results show that even the HE-LHC experiment with an integrated luminosity of $100\ \mathrm{fb}^{-1}$ has advantages over the HL-LHC (with the nominal luminosity of $3\ \mathrm{ab}^{-1}$) in terms of statistical sensitivity to high-mass

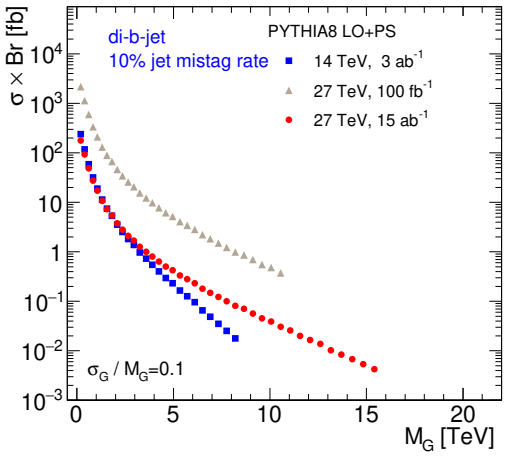

Fig. 6.4.4: Expected 95% C.L. upper limits obtained from the M_{jj} distribution for jets identified as b-jets. The limits are set on fiducial cross-section times the BR to two jets for a hypothetical BSM signal approximated by a Gaussian contribution to the dijet mass spectrum. The limits are obtained for the HL-LHC and HE-LHC energies.

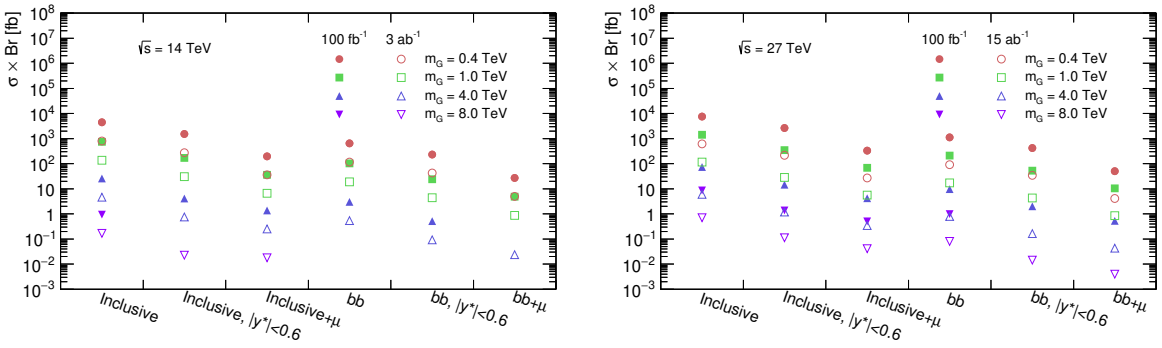

Fig. 6.4.5: Comparisons of the 95% C.L. upper limits obtained from the M_{jj} distribution for the HL-LHC at 14 TeV (left) and the HE-LHC at 27 TeV (right). The limits for the masses 0.4 TeV, 1 TeV, 4 TeV and 8 TeV are shown for 100 fb^{-1}, 3 ab^{-1} and 15 ab^{-1} for different channels with different selections.

states. When using the nominal integrated luminosity of 15 ab^{-1} for HE-LHC, the HE-LHC provides a factor of two larger reach for dijet masses compared to the HL-LHC with the nominal luminosity.

Figure 6.4.4 shows the 95% C.L. upper limits obtained from the M_{jj} distribution for events where both leading jets were identified as $b-$jets. As for the previous simulation based on inclusive jets, the physics reach of the HE-LHC with the nominal luminosity is a factor two larger than that of the HL-LHC.

Figure 6.4.5 shows the comparisons of the limits for dijet and muon associated dijet channels with inclusive or b-tagging selections for the 14 TeV and 27 TeV collision energies. In addition to the inclusive jet case, we also calculated the upper limits after applying the rapidity difference requirement $|y^*| < 0.6$ between two jets [727] in order to enhance the sensitivity to heavy BSM particles decaying to jets.

The studies discussed [721] have also shown that searches for signals in dijets invariant masses require well-understood estimates for the M_{jj} background shape. An example of such challenging background shape is shown in Fig. 6.4.2. A data-driven determination of the shape background at the HL-LHC and HE-LHC should be performed with the relative statistical precision of 0.01% per data point for $M_{jj} < 1$ TeV. Currently, it is difficult to achieve such precision using the available tools used for the

LHC run 2 data.

In conclusion, it was illustrated that the HE-LHC provides substantial improvements for searches of new physics in dijet invariant masses, compared to searches at the HL-LHC. Even for a rather modest $100\ \mathrm{fb}^{-1}$ luminosity of the HE-LHC project, the simulations show that the mass reach for dijet searches is about 50% larger than that from the HL-LHC with the nominal luminosity of $3\ \mathrm{ab}^{-1}$. It was also shown that the HE-LHC project with the nominal luminosity of $15\ \mathrm{ab}^{-1}$ will extend the HL-LHC mass reach by a factor two. The reported limits can be used for exclusions of BSM resonances decaying that decay to form two jets in inclusive dijet events, events with di-b-jets, and events with associated muons. Note that the actual exclusion ranges significantly depend on expected cross-sections and BRs of BSM models for the HL-LHC and HE-LHC collision energies.

6.4.3 Dissecting heavy diphoton resonances at HL- and HE-LHC

Contributors: B. Allanach, D. Bhatia, A. Iyer

We examine the phenomenology of the production of a heavy resonance X, which decays via other new on-shell particles n into multi- (*i.e.* three or more) photon final states. In the limit that n has a much smaller mass than X, the multi-photon final state may dominantly appear as a two photon final state because the γs from the n decay are highly collinear and remain unresolved. We discuss how to discriminate this scenario from $X \to \gamma\gamma$: rather than discarding non-isolated photons, it is better instead to relax the isolation criterion and instead form photon jet substructure variables. The spins of X and n leave their imprint upon the distribution of pseudorapidity gap $\Delta\eta$ between the apparent two photon states. In some models, the heavy resonance X may decay into nn or $n\gamma$, where n is an additional light particle, may further decay into photons leading to a multi-photon[17] final state. Examples of such models include hidden valley models [346, 728], the NMSSM [528] or Higgs portal scenarios [729]. Describing angles in terms of the pseudorapidity η and the azimuthal angle around the beam ϕ, the angular separation between two photons may be quantified by $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$. Neglecting its mass, the opening angle between the two photons coming from a highly boosted on-shell n is

$$\Delta R = \frac{m_n}{\sqrt{z(1-z)}p_T(n)}, \tag{6.4.7}$$

purely from kinematics (this was calculated already in the context of boosted Higgs to $b\bar{b}$ decays [502]), where z and $(1-z)$ are the momentum fractions of the photons[18]. Thus,

$$\Delta R = \frac{m_n}{M_X}\frac{2\cosh\eta(n)}{\sqrt{z(1-z)}}. \tag{6.4.8}$$

In the limit $m_n/M_X \to 0$, $\Delta R \to 0$ and the two photons from n are collinear, appearing as one photon; thus several possible interpretations can be ascribed to an apparent diphoton signal.

We assume that any couplings of new particles such as the X (and the n, to be introduced later) to Higgs fields or $W^{\pm}, Z^0$ bosons are negligible. Eq. (6.4.9) gives an effective field theoretic interaction Lagrangian for the coupling of X to a pair of photons, when X is a scalar (first line) or a graviton (second line).

$$\begin{aligned}
\mathcal{L}^{int}_{X=\text{spin }0} &= -\eta_{GX}\frac{1}{4}G^a_{\mu\nu}G^{\mu\nu a}X - \eta_{\gamma X}\frac{1}{4}F_{\mu\nu}F^{\mu\nu}X, \\
\mathcal{L}^{int}_{X=\text{spin }2} &= -\eta_{T\psi X}T^{\alpha\beta}_{fermion}X_{\alpha\beta} - \eta_{TGX}T^{\alpha\beta}_{gluon}X_{\alpha\beta} - \eta_{T\gamma X}T^{\alpha\beta}_{photon}X_{\alpha\beta}.
\end{aligned} \tag{6.4.9}$$

where $T^{\alpha\beta}_i$ is the stress-energy tensor for the field i and the η_j are effective couplings of mass dimension -1. $F_{\mu\nu}$ is the field strength tensor of the photon (this may be obtained in a SM invariant way from a

[17] In the present paper, whenever we refer to multi-photon final states, we refer to three or more photons.

[18] The decay is strongly peaked towards the minimum opening angle $\Delta R = 2m_n/p_T$ [730].

Model	Process
$S2$	$pp \to S \to \gamma\gamma$
$S4$	$pp \to S \to nn \to \gamma\gamma + \gamma\gamma$
$V3$	$pp \to Z' \to n\gamma \to \gamma + \gamma\gamma$
$G2_{ff}$	$q\bar{q} \to G \to \gamma\gamma$
$G4_{gg}$	$gg \to G \to nn \to \gamma\gamma + \gamma\gamma$
$G4_{ff}$	$\bar{q}q \to G \to nn \to \gamma\gamma + \gamma\gamma$

Table 6.4.2: Cases to discriminate with a scalar n and a heavy resonance which is: scalar (S), spin 1 (Z') or spin 2 (G). We have listed the main signal processes to discriminate between in the second column, ignoring any proton remnants. The notation used for a given model is Xk: $X = S, V, G$ labels the spin of the resonance and k denotes the number of signal photons at the parton level in the final state.

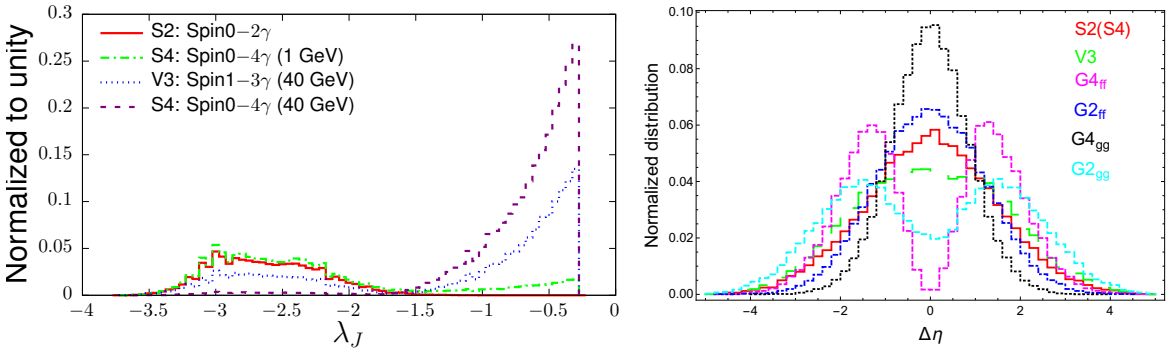

Fig. 6.4.6: Left: distribution of λ_J variable for various signal hypotheses. m_n is noted in parentheses in the legend for the relevant cases. Right: signal $\Delta\eta$ distribution for various different spin combinations at $\sqrt{s} = 27$ TeV, $m_X = 2.5$ TeV. The cases S2 and S4 are practically indistinguishable by eye and so we only plot one histogram for them.

coupling involving the field strength tensor of the hypercharge gauge boson), whereas $G^a_{\mu\nu}$ is the field strength tensor of a gluon of adjoint colour index $a \in \{1, \ldots, 8\}$. As noted earlier, the direct decay of a vector boson into two photons is forbidden by the Landau-Yang theorem [731, 732].

Although we assume that n is electrically neutral, it may decay to two photons through a loop-level process (as is the case for the SM Higgs boson, for instance). Alternatively, if X is a spin 1 particle, it could be produced by quarks in the proton and then decay into $n\gamma$. The Lagrangian terms would be

$$\mathcal{L}^{int}_{X=\text{spin }1,n} = -(\lambda_{\bar{q}Xq}\bar{q}_R\gamma_\mu X^\mu q_R + \lambda_{\bar{Q}XQ}\bar{Q}_L\gamma_\mu X^\mu Q_L + H.c.) - \frac{1}{4}\eta_{nX\gamma} n\tilde{X}_{\mu\nu}F^{\mu\nu}, \qquad (6.4.10)$$

where λ_i are dimensionless couplings, q_R is a right-handed quark, Q_L is a left-handed quark doublet and $\tilde{X}_{\mu\nu} = \partial_\mu X_\nu - \partial_\mu X_\nu$. The decay $X_{spin=1} \to n\gamma$ would have to be a loop-level process, as explicitly exemplified in Ref. [730], since electromagnetic gauge invariance forbids it at tree level. The possible different spins involved in multi-photon production processes, along with our nomenclature for them, are listed in Table 6.4.2. The first tool for model discrimination is the photon sub-jet variable $\lambda_J = \log(1 - p_{T_L}/p_{T_J})$, where P_{T_L} denotes the transverse momentum of the leading photon sub-jet whilst p_{T_J} is the transverse momentum of the whole photon jet. Double pronged photon jets have a peak at $\lambda_J = -0.3$. This may be observed when the signal is multi-photon and m_n is not too small, as Fig. 6.4.6 (left) shows.

Here, we neglect backgrounds and only focus on the signal. This is a good approximation for heavy resonances where backgrounds die off exponentially with invariant mass of the apparent diphoton pair, provided that the signal cross-section is large enough. The signal cross-section is of course set by the size of the couplings in Eq.s (6.4.9) and (6.4.10), which may be adjusted as required. Here, we

Table 6.4.4: Spin discrimination for case B: $N_R = \mathcal{L}\sigma_{tot}^{(X)}$, the expected number of total signal events required to be produced to discriminate against the 'true' row model versus a column model by a factor of 20 at the 14 TeV LHC for $m_n = 10$ GeV.

consider one of the cases in Table 6.4.2 at a time, with cross-sections of all other cases set to zero.

If there is a sizeable peak at $\lambda_J = -0.3$, the model possibilities are $S4, V3, G4_{gg}$ and $G4_{ff}$. Further to this, $V3$ may be further discriminated owing to its double peak structure: at ~ -3 and at -0.3. We call this case A. If there is no sizeable peak, we can either have $S2$ or m_n very small. This latter case we call case B.

After categorisation into case A or B, we can use the fact that each case in Table 6.4.2 corresponds to a different distribution in $\Delta\eta$, the difference in pseudorapidity between the two initially identified photons. We plot the $\Delta\eta$ distributions for the different spin cases in Fig. 6.4.6 (right). We calculate N_R, the expected number of signal events required to disfavour a hypothesis H_S over another hypothesis H_T to an odds factor of $R = 20$ from the $\Delta\eta$ distributions in the discretised Kullback-Leibler method proposed in Ref. [733]. From Tables 6.4.3 and 6.4.4, we see that our estimate of the required number of signal events to discriminate two signal hypotheses does not change much between the HL-LHC and the HE-LHC. For identical input parameters, we would expect the number of signal events to be higher at the higher energies, meaning that spins can be more effectively discriminated to smaller production cross-sections at the HE-LHC.

6.4.4 Prospects for diboson resonances at the HL- and HE-LHC

Contributors: R. Les, V. Cavaliere, T. Nitta, K. Terashi, ATLAS

Prospects are presented [734] for the search for resonances decaying to diboson (WW or WZ, collectively called VV where $V = W$ or Z) in the semileptonic channel where one W-boson decays leptonically and the other W or Z-boson decays to quarks ($\ell\nu qq$ channel). The results include sensitivity for such new resonances based on an integrated luminosity of $300\,\mathrm{fb}^{-1}$or $3\,\mathrm{ab}^{-1}$of pp collisions at $\sqrt{s} = 14\,\mathrm{TeV}$ using the ATLAS upgraded detector. Searches in other semileptonic and fully hadronic decay channels are expected to have similar sensitivities at high masses, as observed in the ATLAS searches with Run-2 data. The analysis is based on event selection and classification similar to those used in the Run-1 and Run-2 ATLAS searches.

The prospect for resonance searches presented in this article are interpreted in the context of three different models: a heavy vector triplet (HVT) [735], a RS model and a narrow heavy scalar resonance. The parameters of these models are chosen such that along the whole generated mass range, the resonance widths are less than 6% of the mass value, which is smaller than the detector resolution. The main background sources are W bosons produced in association with jets (W+jets), with significant contributions from top-quark production (both $t\bar{t}$ pair and single-top), non-resonant vector-boson pair production (ZZ, WZ and WW) and Z bosons produced in association with jets (Z+jets). Background originating from multi-jet processes are expected to be negligible due to the event selection requirements.

Small- and Large-R jets (denoted by j and J) are used in the analysis, reconstructed with the anti-k_t algorithm and radius 0.4 and 1.0 respectively. It is assumed that the performance of a future W/Z-boson tagger at the HL-LHC conditions will have similar, if not better, performance as existing boson taggers.

Events are required to have exactly one lepton satisfying the selection criteria. It is assumed that the effect of trigger thresholds is negligible for the selected leptons with p_T studied in this note. Events are further required to contain a hadronically-decaying W/Z candidate, reconstructed either from two small-R jets, defined as the resolved channel, or from one large-R jet, designated the boosted channel. The missing transverse energy $E_{\mathrm{T}}^{\mathrm{miss}}$ has to be greater than $60\,\mathrm{GeV}$, which suppresses multijet background to a negligible level. By constraining the $E_{\mathrm{T}}^{\mathrm{miss}}$ + lepton system to be consistent with the W mass, the z component of the neutrino momentum can be reconstructed by solving a quadratic equation. The smallest solution is chosen and in the case where the solution is imaginary, only the real part is taken.

The presence of narrow resonances is searched for in the distribution of reconstructed diboson mass using the signal shapes extracted from simulation of benchmark models. The invariant mass of the diboson system ($m(WV)$) is reconstructed from the leptonic W candidate and hadronic W/Z candidate, the latter of which is obtained from two small-R jets in the resolved channel ($m(\ell\nu jj)$) or large-R jet in the boosted channel ($m(\ell\nu J)$). The background shape and normalisation are obtained from MC simulation with dedicated control regions to constrain systematic uncertainties of the background modelling and normalisation. The search is divided into two orthogonal categories to identify the $\mathrm{ggF}/\mathrm{q\bar{q}}$ and VBF production modes by identifying additional forward jets. If an event passes the VBF category selection for the additional forward jets (defined below) it is categorised as a VBF candidate event, otherwise as a $\mathrm{ggF}/\mathrm{q\bar{q}}$ candidate event. Events are then processed by a merged-jet selection then a two resolved-jet selection if they fail the merged selection. This prioritisation strategy provides the optimum signal sensitivity as it favours the merged selection which contains less background contributions. Examples of the final distributions can be seen in Fig. 6.4.7 for the merged $\mathrm{ggF}/\mathrm{q\bar{q}}$ and VBF signal region.

The results are extracted by performing a simultaneous binned maximum-likelihood fit to the $m(WV)$ distributions in the signal regions and the W+jets and $t\bar{t}$ control regions.

The fit includes five background contributions, corresponding to W+jets, $t\bar{t}$, single-top, Z+jets, and diboson. Systematic uncertainties are taken into account as constrained nuisance parameters with

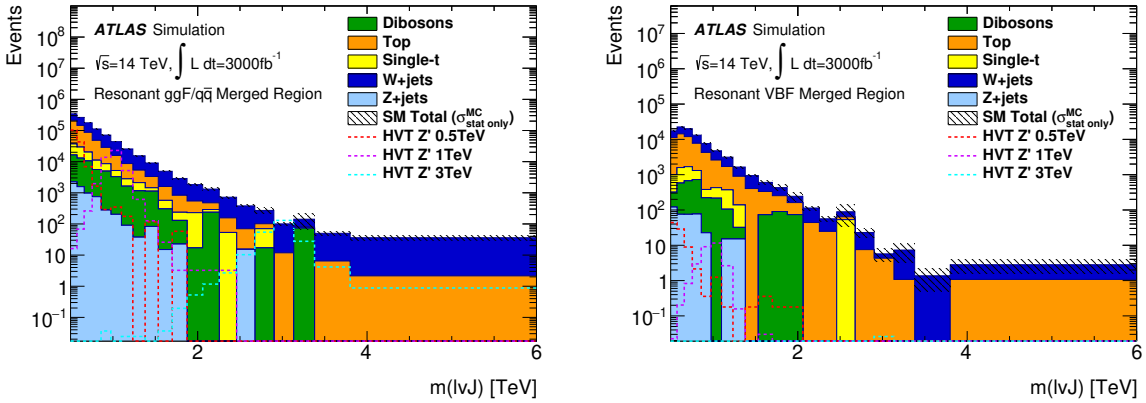

Fig. 6.4.7: Left: final $m(\ell\nu J)$ distribution in the merged signal region for the $\mathrm{ggF/q\bar{q}}$ search. Right: final $m(\ell\nu J)$ distributions in the merged signal region for the VBF search. Background distributions are separated into production type. HVT signals are superimposed as dashed curves where appropriate.

Gaussian or log-normal distributions. For each source of systematic uncertainty, the correlations across bins of $m(WV)$ distributions and between different kinematic regions, as well as those between signal and background, are taken into account. The main background modelling systematics, namely the W+jets and $t\bar{t}$ shape uncertainties, are constrained by the corresponding control regions and are treated as uncorrelated among the resolved and merged signal regions.

The expected upper limits are set on the signal cross section times BR as a function of the signal mass. For the HVT W' and Z' the limits are estimated to be 4.3 TeV with $\mathcal{L} = 300$ fb^{-1} and 4.9 TeV with $\mathcal{L} = 3$ ab^{-1} of pp collisions, using the same detector configuration and pileup conditions. For the Bulk graviton the expected limits are estimated as 2.8 and 3.3 TeV at $\mathcal{L} = 300$ fb^{-1} and $\mathcal{L} = 3$ ab^{-1}. The values at $\mathcal{L} = 3$ ab^{-1} show an expected increase to the sensitivity of the search to the benchmark signals by ~ 1 TeV with respect to existing limits in this channel in Run-2.

Figure 6.4.8 (left) shows one of the upper limit plots for the $\mathrm{ggF/q\bar{q}}$ category at $\mathcal{L} = 3$ ab^{-1}. A line showing the theoretical cross section for the HVT Z' decaying into WW via $\mathrm{ggF/q\bar{q}}$ production at each mass is superimposed and indicates the mass reach of the search. In the circumstance that HL-LHC sees an excess, the expected sensitivity can also be characterised. The discovery significance is defined as the luminosity required to see a 5σ effect of the signal. Figure 6.4.8 (right) shows the expected discovery significance for the resonant search. The signal significance is the quadratic sum of $s/\sqrt{s+b}$, for each bin of the final discriminant distribution at that luminosity, $s(b)$ representing the number of signal(background) events in the bin. In addition to the expected values, dashed curves shows the expected values for a future W/Z-tagger which has a 50% increase in signal efficiency and a further factor of two in background rejection. These values are representative of improvements seen in a recent diboson resonance search in the fully-hadronic $VV \to qqqq$ analysis by using track-calo clusters as opposed to locally-calibrated topologically-clustered calorimeter jets. Other possible improvements in W/Z-tagging in the HL-LHC era can originate from usage of more advanced machine-learning techniques to discriminate against the background contribution and better understanding of jet substructure variables with measurements at higher integrated luminosities.

Resonance search at HE-LHC

The prospect analysis [736] at HE-LHC mimics the analysis at HL-LHC but the DELPHES simulation is used. Results are interpreted in the context of the heavy vector triplet (HVT) model [735]. The major backgrounds W+jets and $t\bar{t}$ production are simulated with MADGRAPH and AMC@NLO respectively, interfaced with Pythia. Z+jets, single top and diboson contribution are not simulated and are expected to contribute at most 10% to the total background.

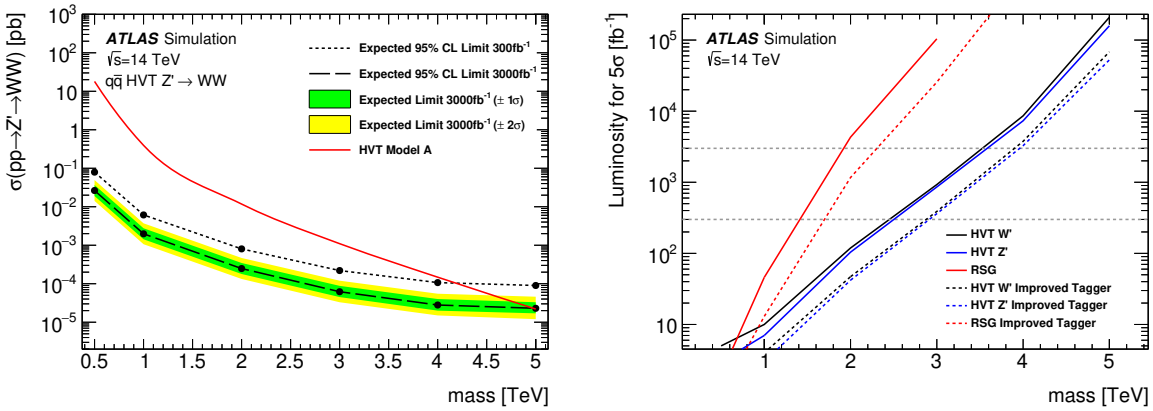

Fig. 6.4.8: Left: 95% C.L. upper limit for the HVT Z' via $\mathrm{ggF/q\bar{q}}$ production. Right: expected luminosity required to observe a 5σ signal significance for the HVT W' (black), HVT Z' (blue) and G_{RS} (red). The solid curves shows the sensitivity using the current W/Z-tagger and the dashed curves for a future tagger that has a 50% increased signal efficiency and a factor two increased rejection of background.

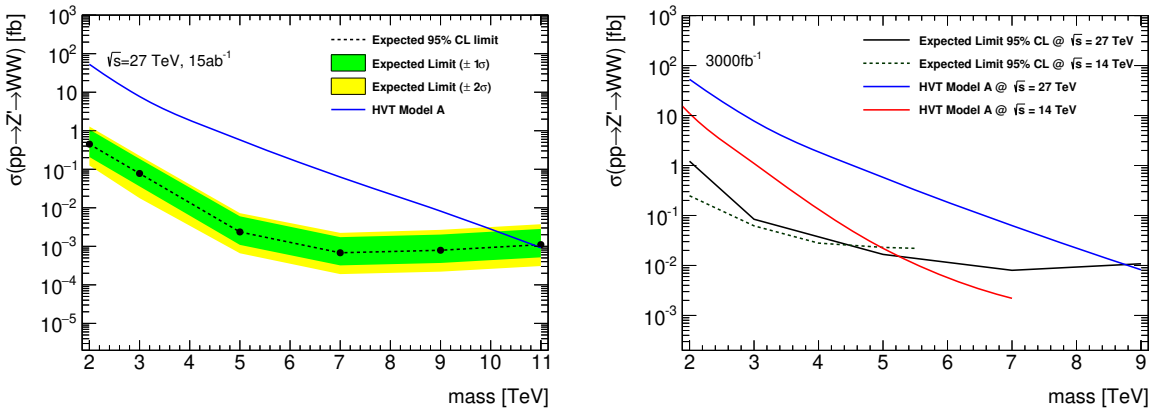

Fig. 6.4.9: 95% C.L. upper limit for the HVT Z' via $\mathrm{ggF/q\bar{q}}$ production for the HE-LHC (left) and HL-LHC (right).

The analysis sensitivities to the resonance signals are extracted by performing a simultaneous binned maximum-likelihood fit to the m_{WW} distributions as in the HL-LHC in the signal regions and the W+jets and $t\bar{t}$ control regions. The signal region and control regions are defined in the same way.

The expected upper limits set on the signal cross section times BR as a function of the signal mass are shown in Fig. 6.4.9 at 27 TeV and compared to the limits obtained for HL-LHC . Based on the Z' production cross section from the HVT signal model the exclusion mass reach is extracted to be 9 and 11 TeV for integrated luminosities of 3 and 15 ab^{-1}at 27 TeV, using DELPHES simulation of a potential detector configuration under no pileup condition.

6.4.5 Prospects for Boosted Object Tagging with Timing Layers at HL-LHC

Contributors: M. D. Klimek

Both CMS and ATLAS are studying new timing detectors to be installed for the high luminosity phase of the LHC. The primary motivation for these new detectors is to aid in mitigating the increased level of pileup that comes along with the increased luminosity. The $\mathcal{O}(30\ \mathrm{ps})$ timing resolution will permit individual proton-proton interactions within a single bunch crossing to be temporally resolved. Beyond pileup mitigation, these detectors may be useful for novel kinds of searches. For example, it has

been proposed in Ref. [737] that they could be used to set limits on long-lived particles. In this section, we point out that this level of timing precision provides the capability of temporally resolving jets for the first time. Currently, jet substructure techniques play a major role in the search for BSM physics. These exploit correlations in momentum and angular distribution of jet constituents to distinguish standard QCD jets from other objects. The capabilities of the new timing layers open up the possibility of extending jet substructure techniques to the time domain. In this section, we will introduce the relevant concepts and suggest that time domain jet substructure can play a complementary role to existing techniques in the search of boosted resonances at the HL-LHC.

Of the various physics objects that are reconstructed by the LHC experiments, jets are unique in that they are collections of particles. The individual jet constituents have some spread in velocity and therefore arrive at the detector over some finite span of time. On dimensional grounds, we can estimate that the typical scale of Lorentz boosts of the jet constituents is $\gamma = E/m \sim E_j/n\Lambda_{\mathrm{QCD}}$, where E_j is the jet energy, n is the hadron multiplicity of the jet, and Λ_{QCD} sets the typical hadron mass. The corresponding scale of the spread in arrival times at a detector a distance R from the interaction point is then of order $\delta t \sim R\delta v \sim R\gamma^{-2}$. For $R \sim 1$ m, $E_j \sim 100$ GeV, $n \sim 10$, and $\Lambda_{\mathrm{QCD}} \sim 1$ GeV, we have $\delta t \sim 100$ ps. Thus we see that at typical LHC energies, the proposed timing detectors with $\mathcal{O}(30\ \mathrm{ps})$ resolution should be sensitive to the temporal structure of jets.

We note that this effect is entirely due to the hadronisation process. Any time differences inherent to the perturbative parton shower should be of order $\Lambda_{\mathrm{QCD}}^{-1}$ and will be far below the resolution of the timing detectors. (In practice, the distance from the interaction point to the timing detector will have some dependence on pseudorapidity η. Because the showering process produces radiation in a cone around the original parton direction, the various jet constituents will then have slightly different distances to travel to the detector. However, for reasonably central jets, this will be a small effect.) If, in the hadronisation process, jet constituents are produced with rapidities y distributed according to $dN/dy = f(y)$, then it is easy to verify that at a detector a distance R in any direction from the interaction point, they will arrive distributed in time according to

$$\frac{dN}{dt} = \frac{cRf(y(t))}{(ct)^2 - R^2}, \tag{6.4.11}$$

with $ct > R$, where c is the speed of light and $y(t) = \operatorname{arctanh}(R/ct)$. Although it is not possible to calculate $f(y)$ from first principles, we note that for any reasonably well-behaved $f(y)$ the arrival time distribution will indicate a burst of jet constituents arriving promptly with a tail extending out to later times.

The hadronisation process is treated phenomenologically by a number of models, and we can verify that this behaviour is borne out. For example, the simplest form of the Lund string hadronisation model [738] predicts $f(y) =$ constant. PYTHIA implements a more complete version of the Lund model, and we use it to verify the predictions of the preceding paragraphs. We generated a sample of 50 GeV quark jets from e^+e^- annihilation in PYTHIA 8, and computed the arrival times of all charged hadrons in each jet at a distance of 1 m from the interaction point. A histogram with 100 ps bin size of the averaged arrival time profile is shown in Fig. 6.4.10. We can see that the PYTHIA output displays the expected behaviour, and we verify that the typical width of the profile is indeed $\mathcal{O}(100\ \mathrm{ps})$.

A study of the rapidity distribution of jet constituents from arrival time profile of QCD jets could provide additional data with which to tune our models of hadronisation. However, we will now argue that this information also provides a novel method for distinguishing normal QCD jets from jets produced by boosted objects. As described in the preceding paragraphs, in a typical jet we expect most hadrons to arrive together and a few to arrive at later times. Note that under a boost, the ordering of the jet constituents in velocity or rapidity is unchanged. Consider a massive particle that decays in its rest frame producing a jet pointing along the negative x axis. The particles in the tail of its velocity distribution have velocities along the x direction that are less negative than the rest of the jet. Now consider the same massive particle but with a large boost in the positive x direction so that this jet is boosted forward into

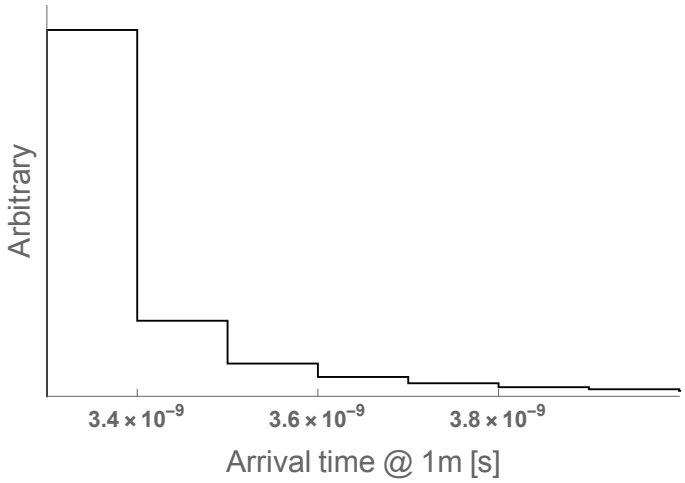

Fig. 6.4.10: Average arrival time profile at $1\ \mathrm{m}$ for charged hadrons in $50\ \mathrm{GeV}$ quark jets from e^+e^- annihilation as simulated by PYTHIA 8.

the positive direction as well. Despite the change in direction, the ordering of the velocities in the jet is the same. The velocities of all jet constituents are now positive, and the tail of the distribution is more positive. We see that if a jet is sufficiently boosted, the tail of its hadron distribution can arrive at the detector first.

In order to quantify this effect, we make use of a simple diagnostic that can distinguish the boosted from the unboosted jets based on their arrival time profiles. Recall that for an unboosted jet, we expect the majority of the charged hadrons to arrive in close temporal proximity with a few arriving later, whereas for a sufficiently boosted jet, one or more charged hadrons may arrive before most of the others. Let t_i and p_i be the arrival times and momenta of the charged hadrons in a jet and $\bar{t}$ be the median charged hadron arrival time. We define the diagnostic function

$$D_\tau = \frac{\sum p_i \Theta(t_i - \bar{t} - \tau)}{\sum p_i}. \tag{6.4.12}$$

The parameter τ should be a value of order the time resolution of the detector. For an unboosted jet, the median arrival time will be in the prompt burst of hadrons. For an appropriate value of τ, none of these hadrons nor any that arrive later will satisfy the theta function, and we will obtain $D_\tau = 0$. However, for boosted jets, some hadrons from the boosted tail may arrive before the main burst. Because the median will still be in the main burst, the early hadrons can satisfy the theta function, in which case we will find $D_\tau > 0$.

To verify this behaviour, we generate two samples of jets in PYTHIA 8. The first is a sample of $500\ \mathrm{GeV}$ quark jets from e^+e^- annihilation. For comparison, we also generate a similar sample of $50\ \mathrm{GeV}$ jets, but then boost them by $v = 0.98$. This is comparable to jets that would be observed from Z decay, where the Z has been produced in the decay of a $1\ \mathrm{TeV}$ diboson resonance. We choose a conservative value of $\tau = 200\ \mathrm{ps}$, which is several times the expected timing detector resolution. In the first sample, we find that our diagnostic is zero in all but 1% of events. However, for the boosted jet sample, we obtain non-zero values in 25% of events.

The actual operating environment of the HL-LHC will present additional challenges coming from the noisy hadronic environment. Jet contamination from pileup and underlying event radiation could mimic the early arrival of the tail of a boosted jet. The information from the timing layers will be used to mitigate pileup and jet grooming techniques can be used to remove stray radiation from the jets before their temporal characteristic are analysed. The timing substructure information can then be combined with existing jet substructure techniques to increase the efficiency for tagging boosted objects, in turn

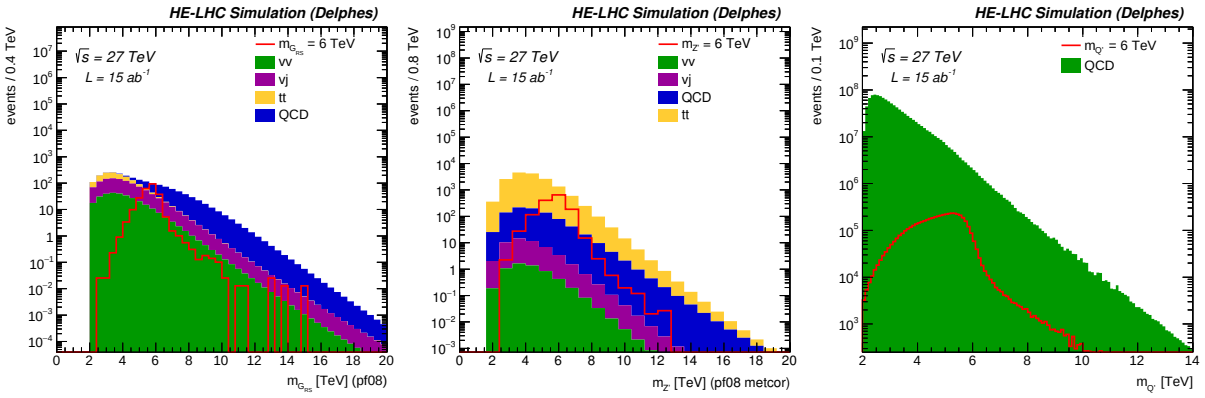

Fig. 6.4.11: Invariant mass distribution of the two selected jets for the full selection for a 6 TeV signal for the three benchmark analyses $G_{RS} \to WW$ (left), $Z' \to t\bar{t}$ (centre) and $Q' \to jj$ (right)

improving the reach of BSM searches. During an HE-LHC phase, even higher boosts can be expected, demanding effective techniques for boosted object tagging. Further details are presented in Ref. [739].

6.4.6 High mass resonance searches at HE-LHC using hadronic final states

Contributors: C. Helsens, D. Jamin, M. Selvaggi

The presence of new resonant states [472,479,740–746] decaying to two highly boosted particles decaying hadronically could be observed as an excess in the invariant mass spectrum of two jets over the large SM background. In this section we present the reach at the HE-LHC for three distinct hadronic signatures: $Z' \to t\bar{t}$, $G_{RS} \to WW$ and $Q' \to jj$. For the $Z' \to t\bar{t}$ decay mode the SSM $Z'_{\rm SSM}$ [672] and a leptophobic $Z'_{\rm TC2}$ [645,747] have been considered as benchmarks Z'models. For the $G_{RS} \to WW$ and $Q' \to jj$ decay modes, a Randall-Sundrum graviton [472] and excited heavy quarks [394,748] have been taken as a benchmarks respectively.

The decay products of the heavy resonances are typically in the multi-TeV regime and their reconstruction imposes stringent requirements on the detector design. Precise jet energy resolution requires full longitudinal shower containment. Highly boosted W bosons and top quarks decay into highly collimated jets that need to be disentangled from standard QCD jets by characterising their substructure. Thus, in order to achieve high sensitivity excellent granularity is needed both in the tracking detectors and in the calorimeters.

Signal events were generated at LO with PYTHIA 8.230 [68]. The considered SM backgrounds are dijet (QCD), top pairs ($t\bar{t}$), VV and $V+$ jets where $V = W/Z$, and were generated at LO using MADGRAPH5_aMC@NLO [67]. A conservative constant k-factor of 2 is applied to all the background processes to account for possibly large higher order corrections. The detector simulation was performed with DELPHES [33] assuming an HE-LHC generic detector [699].

An important ingredient of the $Z' \to t\bar{t}$ and $G_{RS} \to WW$ searches is the identification of hadronically decaying boosted tops and W bosons. To this end, a tagger using jet substructure observables was developed to discriminate W and top jets against QCD jets. It was found that jets using tracking only information (*track-jets*) feature better angular resolution compared to pure calorimeter based jets. Therefore, track-jets are the optimal choice to build jet substructure observables. The boosted top tagger is built from the following jet substructure observables: the soft-dropped jet mass [504] and N-subjettiness [75] variables $\tau_{1,2,3}$ and their ratios τ_2/τ_1 and τ_3/τ_2. In addition, the W-jet versus QCD-jet tagger also uses an "isolation-like" variable that exploits the absence of high $p_{\rm T}$ final state-radiation (FSR) in the vicinity of the W decay products. Following the strategy defined in Ref. [26], we call these variables $E_{\rm F}(\mathrm{n}, \alpha)$ and define them as:

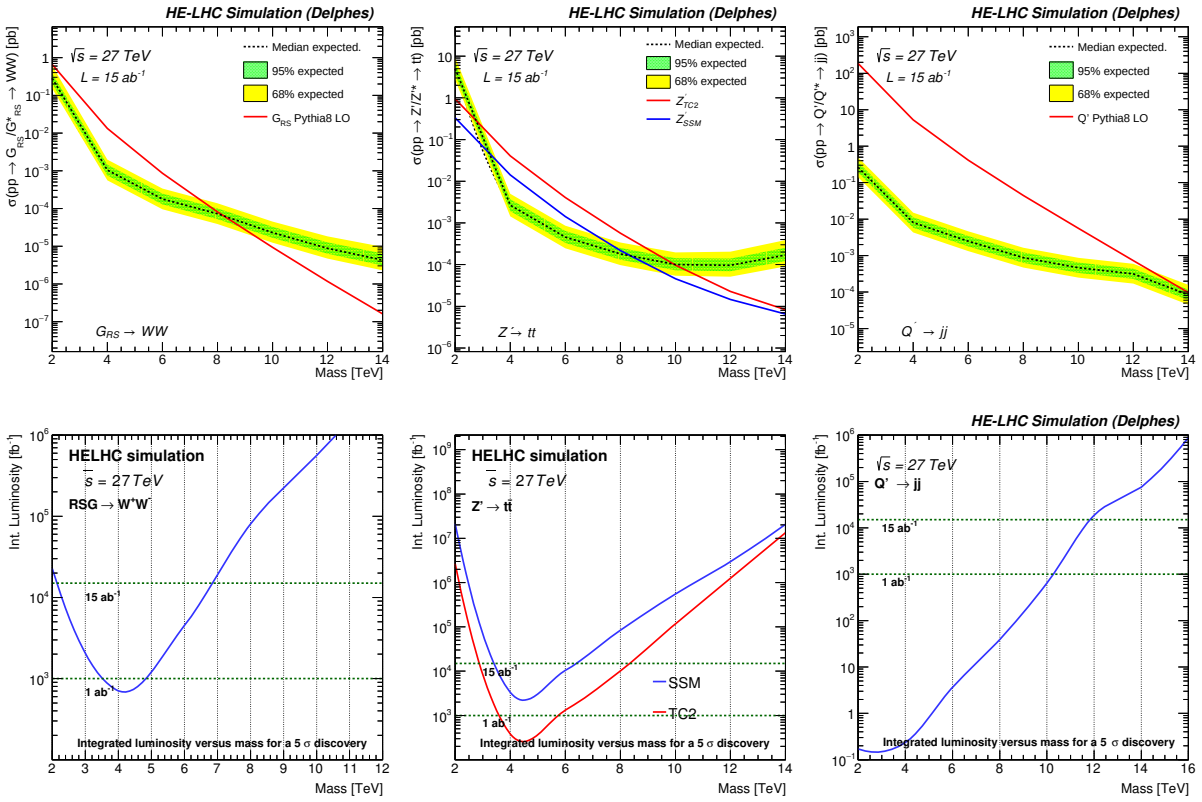

Fig. 6.4.12: Top: exclusion limit at 95% C.L. versus heavy resonance mass for the three benchmark models: $G_{RS} \to WW$ (left), $Z' \to t\bar{t}$ (middle), and $Q' \to jj$ (right). Bottom: integrated luminosity needed for a 5σ discovery as a function of the heavy resonance mass for the three benchmark models.

$$E_{\mathrm{F}}(\mathrm{n},\alpha) = \frac{\sum\limits_{\frac{n-1}{5}\alpha<\Delta R(k,jet)<\frac{n}{5}\alpha} p_{\mathrm{T}}^{(k)}}{\sum\limits_{\Delta R(k,jet)<\alpha} p_{\mathrm{T}}^{(k)}} \tag{6.4.13}$$

We choose $\alpha = 0.05$, construct 5 variables $E_{\mathrm{F}}(\mathrm{n},\alpha)$with $n = 1..5$ and use them as input to the multivariate tagger. The W tagging performance has significantly better performance than the top-tagging due to the use of the energy-flow variables. We choose our working points with a top and W tagging efficiencies of $\epsilon_S^{\mathrm{top}} = 60\%$ and $\epsilon_S^{\mathrm{W}} = 90\%$ corresponding respectively to a background efficiency of $\epsilon_B^{\mathrm{top}} = \epsilon_B^{\mathrm{W}} = 10\%$.

The event selection proceeds as follows: we require two jets with $p_{\mathrm{T}} > 1$ TeV, $|\eta| < 3$ and a small rapidity gap $\Delta\eta < 1.5$ between the two high p_{T} jets. For the $Z' \to t\bar{t}$ and $G_{RS} \to WW$ searches, the rapidity gap selection is relaxed to $\Delta\eta < 2.4$, both jets are required to be respectively top or W-tagged, and, to further reject background QCD jets, we require for both jets a large soft-dropped mass $m_{\mathrm{SD}} > 40$ GeV. Finally, for the $Z' \to t\bar{t}$ search alone, we require that both selected jets must also be b-tagged. Since no lepton veto is applied, there is also some acceptance for leptonic decays. The sensitivity to semi-leptonic $t\bar{t}$ decays is enhanced by adding the $\vec{p_{\mathrm{T}}}^{\mathrm{miss}}$ vector to the closest jet 4-momentum (among the two leading jets). The invariant mass of the two selected jets is used as a discriminant and is shown for the three benchmark analyses in Fig. 6.4.11.

Hypothesis testing is performed using a modified frequentist method based on a profile likelihood fit that takes into account the systematic uncertainties (mostly the background normalisations) as nuisance parameters. The expected exclusion limit at 95% C.L. and discovery reach at 5σ are shown in

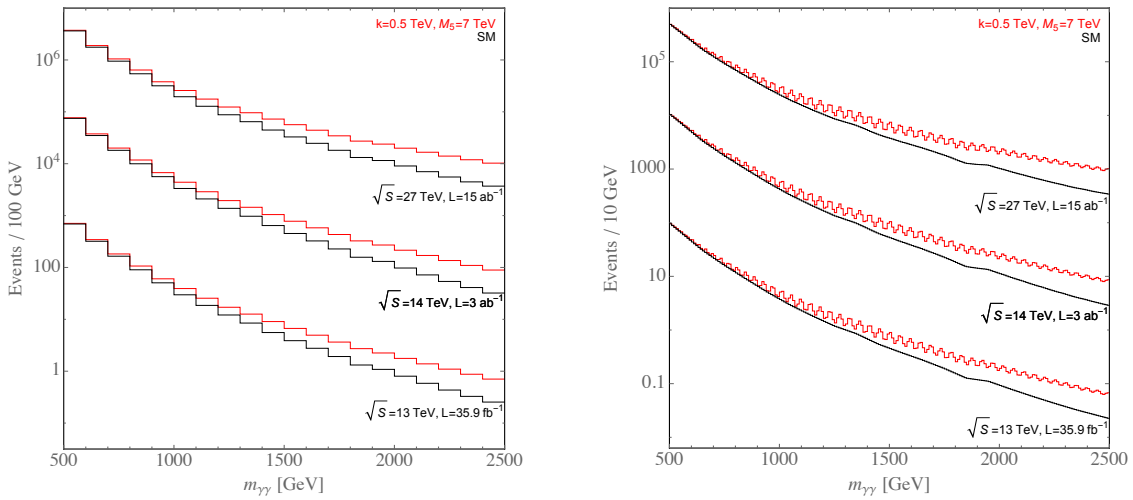

Fig. 6.4.13: Event rates for current integrated luminosity, HL-LHC, and HE-LHC, for the choice $k = 0.5$ TeV and $M_5 = 7$ TeV, which is a parameter point currently on the 95% exclusion contour of a recent CMS analysis [749]. Left: events are shown for a bin width of 100 GeV, as in Ref. [749]. Right: events are shown for a bin width of 10 GeV, which is close to the current experimental resolution, and reveals the oscillating nature of the signal arising due to the closely spaced resonances.

Fig. 6.4.12 (top and bottom) for the various scenarios that have been considered. At $\sqrt{s} = 27$ TeV, and with an integrated luminosity $\mathcal{L} = 15$ ab^{-1}, it is possible to discover a G_{RS} up to $m_G \approx 7$ TeV, and to exclude $m_G \lesssim 8$ TeV. For the $Z' \to t\bar{t}$ search the exclusion reach is $m_{Z'} \lesssim 10(8.5)$ TeV and it is possible to discover it up to $m_{Z'} \approx 8(6.5)$ TeV for the TC2 and SSM models respectively. Finally, for the excited quark model, the exclusion reach is $m_{Q'} \lesssim 14$ TeV and the discovery reach is $m_{Q'} \approx 12$ TeV.

6.4.7 On the power (spectrum) of HL/HE-LHC

Contributors: G. Giudice, Y. Kats, M. McCullough, R. Torre, A. Urbano

Typical searches for heavy new physics beyond the SM focus on particular forms of kinematic features in differential event distributions, such as isolated resonant structures, edges, and fat tails, to name a few. However the space of theoretically consistent BSM signatures extends well beyond these classic signatures.

Recently, in Ref. [750], it was suggested that new physics signatures could give rise to peculiar oscillating patterns in collider data. These signatures may be revealed as a resonance, however rather than being a resonance in the invariant mass distribution within some SM final state, this resonance would show up in Fourier space, after performing a Fourier transform on the relevant collider data.

The particular model studied in Ref. [750], which provides a theoretically robust example of such a signature, is the 'Linear Dilaton Model' which is known to be connected to continuum limit of 'Clockwork' models. We will refer to all classes of models of this form as CW/LD. The CW/LD models can all give rise to various forms of oscillating patterns within SM final states. In particular, the LD model predicts closely packed resonances, starting at some threshold determined by a parameter 'k' which is related to an extra-dimensional geometry. These resonances are predicted to have mass splittings at the $\mathcal{O}(\text{few}\%)$ level. Such mass splittings are still greater than the detector energy resolution in some high-resolution final states, such as $\gamma\gamma$ and l^+l^-.

Motivated by this, in Ref. [750] a detailed proposal for a class of collider searches in Fourier space was discussed. In this contribution we provide a simple extension of this proposal to estimate the expected reach of the HL-LHC and HE-LHC. The analysis is basic and has not been systematically optimised, thus the search reach based on the Fourier space analysis presented here should be considered

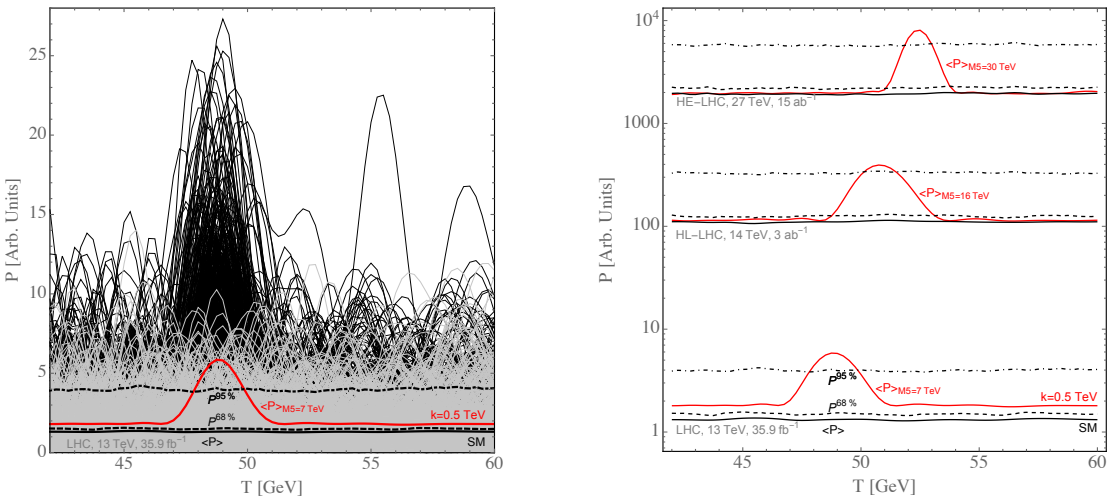

Fig. 6.4.14: Left: example power spectra for 1000 fake experiments at the LHC. The individual SM lines are shown in grey, alongside the mean and confidence intervals. The power with signal ($k = 500$ GeV, $M_5 = 7$ TeV) included is shown in black, alongside the mean in red. Right: the power spectrum, defined in [750], for current integrated luminosity of 35.9 fb^{-1}, HL-LHC, and HE-LHC, for $k = 0.5$ TeV and a variety of values of M_5. The red lines show the average power in the presence of signal and background. The significance of the peak in the power spectrum at $T \approx 50$ GeV, which corresponds to $T = 1/R$, is clearly seen for higher energy and integrated luminosity colliders.

as a preliminary estimate, however it is likely that a dedicated study could perform better.

In Fig. 6.4.13 we show the spectrum of events in the diphoton final state expected for two choices of binning, to reveal the oscillating nature of the signal. The spectrum is calculated for the EBEB selections of the recent analysis [749]. The SM events are taken from the NNLO prediction calculated in Ref. [749]. In Ref. [749] the normalisation of the NNLO prediction is determined by fitting to the data, which is dominated by the low energy events. To obtain the corresponding prediction at 14 TeV and 27 TeV the SM events are rescaled by the ratio of $q\bar{q}$ PDFs at the same $m_{\gamma\gamma}$, relative to 13 TeV. We adopt the diphoton energy resolution detailed in Ref. [750].

Signal events are generated and passed through the acceptance curves for the EBEB category shown in Ref. [749] and we find good agreement with Ref. [749] for the same signal parameters shown in Figure 5 of Ref. [749]. Similarly to the SM events, 14 TeV and 27 TeV predictions are obtained by reweighting according to the PDF ratio.

In Fig. 6.4.13 the oscillatory pattern due to the multiple closely-spaced resonances is clear. We now move to Fourier space, which is suited to searching for such oscillating patterns. We adopt an analogous diphoton 'Power' to the function detailed in Ref. [750], with the modification that, rather than integrating over bins, a discrete Fourier transform, which sums over bin heights at the midpoint energy, is employed. A second modification is that rather than subtracting a fitted curve to find the residuals, we subtract the NNLO prediction detailed in Ref. [749], where the systematics related to the overall normalisation are removed by floating the distribution and fitting to the data.

The resulting power spectrum is illustrated in Fig. 6.4.14. Figure 6.4.14 (right) was obtained by generating 5000 sets of fake experiments, where the number of events in each bin is generated from a Poisson distribution, for both the SM only and SM + signal hypotheses, before subtracting the SM prediction. The curves for $\langle P \rangle$, $P^{68\%}$, and $P^{95\%}$ represent the mean value of $P(T)$ at a given value of T, over all fake experiments, and also the corresponding upper limits at a given C.L. derived from the distributions. The average value, when signal is included, is also shown for a variety of M_5 values.

In each case, the peak in Fourier space is clearly visible and approaches the $P^{95\%}$ line. We will not attempt a robust statistical analysis here, which would require a thorough treatment of systematics in

a likelihood ratio test. Rather, we will focus on the comparison between different colliders. Clearly, if the current LHC data can exclude a parameter point in the ballpark of $k = 0.5$ TeV and $M_5 \approx 7$ TeV, then at the HL-LHC one should be sensitive to $M_5 \approx 16$ TeV, and at the HE-LHC $M_5 \approx 30$ TeV. Furthermore, since the statistics are much higher at these colliders one would presumably benefit from widening the range of $m_{\gamma\gamma}$ considered, thus we expect the reach to exceed these values in a dedicated analysis.

To summarise, in this contribution we have estimated the reach of the HL-LHC and HE-LHC for detecting oscillating patterns in BSM contributions to the differential diphoton spectrum. Such searches have not yet been performed at the LHC and they provide a new target in the search for BSM physics. This estimate is performed in the context of the linear dilaton model, as described in Ref. [750].

We have found that for a warping parameter of $k = 500$ GeV, which sets the mass scale of the first KK graviton resonance, if current limits on the extra-dimensional Planck scale are at the level of $M_5 \approx 7$ TeV, then with HL-LHC they should extend considerably, to around $M_5 \approx 16$ TeV, and at HE-LHC further still, to $M_5 \approx 30$ TeV.

7 Conclusions and Outlook

The LHC is performing superbly and has already moved on from discovering the Higgs boson to accurately measuring its properties. As yet there are no clear deviations from the SM, in Higgs measurements or elsewhere. Nonetheless, with only a fraction of the $150\ \mathrm{fb}^{-1}$ recorded data so far analysed, it is possible that surprises await, or that some of the existing small deviations grow. It is also possible that the new physics has small production cross sections either because it is weakly coupled to the initial state at the LHC, or that it is heavy, or both. Weakly coupled states within kinematic reach of the LHC may require increased data sets to uncover, such as the $3\ \mathrm{ab}^{-1}$ of the HL-LHC each for ATLAS and CMS, and up to $300\ \mathrm{fb}^{-1}$ for the Upgrade II of LHCb. Heavy states instead might require both increased centre-of-mass energy and increased luminosity, such as the 27 TeV and $15\ \mathrm{ab}^{-1}$ of the HE-LHC.

The HL- and HE-LHC will both offer new possibilities to test many BSM scenarios, motivated by long-standing problems such as EW Naturalness, dark matter, the flavour problem, neutrino masses, the strong CP problem, and baryogenesis. All these new physics manifestations predict the existence of new particles, which can be searched for at HL-LHC, profiting from the much larger statistics and slightly higher energy, and at the HE-LHC, profiting from the much larger statistics and much higher energy. In both cases the searches will also benefit from detector upgrades. Careful attention has been paid to the impact of these upgrades and the assessment of the future systematic uncertainties, especially for HL-LHC where concrete proposals for the ATLAS, CMS and LHCb experiments exist.

This document contains numerous studies of the increased reach for many BSM scenarios that can be explored at the HL- and HE-LHC options. As well as determining the reach in sensitivity, several studies analyse the ability for HL- and HE-LHC to characterise potential discoveries and distinguish between possible BSM explanations. Rather than give a complete summary of all prospect analyses in this report, we instead provide representative examples of the scope of the BSM searches for the HL-LHC and HE-LHC. Broadly speaking, in most BSM scenarios, we expect the HL-LHC will increase the present reach in mass and coupling by $20-50\%$ and potentially discover new physics that is currently unconstrained. The reach of the HE-LHC is generically more than double that of the HL-LHC. In Fig. 7.1 we present a summary of the results of SUSY searches (both prompt and long-lived) for sparticles produced via strong- or electroweak interactions, as described in detail in Section 2. Figure 7.2 shows a summary of most of the resonance searches (both single and pair production) presented in Sections 5 and 6.

HL-LHC

Supersymmetry

The extension of the kinematic reach for supersymmetry searches at the HL-LHC is reflected foremost in the sensitivity to EW states, including sleptons, but also for gluinos and squarks. Studies under various hypothesis were made, including prompt and long-lived SUSY particle decays. Wino-like chargino pair production processes are studied considering dilepton final states. Masses up to 840 (660) GeV can be excluded (discovered) for charginos decaying as $\tilde{\chi}_1^{\pm} \to W^{(*)}\tilde{\chi}_1^0$, in R-parity conserving scenarios with $\tilde{\chi}_1^0$ as the lightest supersymmetric particle. The results extend by about 500 GeV the mass reach obtained with $80\ \mathrm{fb}^{-1}$ of 13 TeV pp collisions, and extend beyond the LEP limit by almost an order of magnitude in case of massless neutralinos. Compressed SUSY spectra are theoretically well motivated but are among the most challenging scenarios experimentally, and are barely covered by the Run-2 analyses. HL-LHC searches for low momentum leptons will be sensitive to $\tilde{\chi}^{\pm}$ masses up to 350 GeV for $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) \approx 5$ GeV, and to mass splittings between 0.8 and 50 GeV, thus bringing significant new reach to Higgsino models. Similar search techniques can also be used to target pair produced $\tilde{e}$ and $\tilde{\mu}$ in compressed scenarios. If $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) < 1$ GeV, charginos can decay after the inner layers of the pixel detectors.

Dedicated searches for sleptons, characterised by the presence of at least one hadronically-

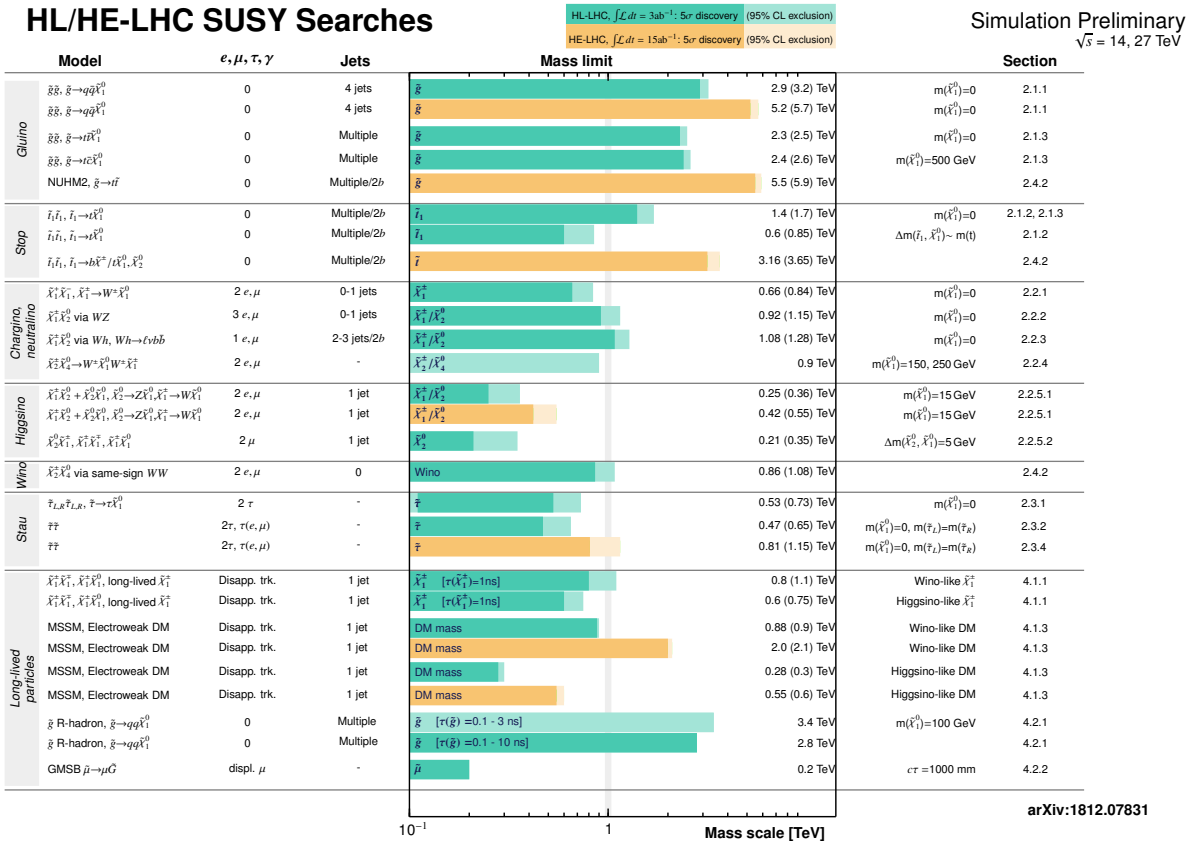

Fig. 7.1: A summary of the expected mass reach for 5σ discovery and 95% C.L. exclusion at the HL/HE-LHC, as presented in Section 2.

decaying τ and missing E_T, will be sensitive to *currently unconstrained* pair-produced $\tilde{\tau}$: exclusion (discovery) for $m_{\tilde{\tau}}$ up to around 700 (500) GeV can be achieved under realistic assumptions of performance and systematic uncertainties.

In the strong SUSY sector, HL-LHC will probe gluino masses up to 3.2 TeV, with discovery reach around 3 TeV, in R-parity conserving scenarios and under a variety of assumptions on the $\tilde{g}$ prompt decay mode. This is about $0.8 - 1$ TeV above the Run-2 $\tilde{g}$ mass reach for 80 fb^{-1}. Pair-production of top squarks has been studied assuming $\tilde{t}_1 \to t\tilde{\chi}_1^0$ and fully hadronic final states with large missing E_T. Top squarks can be discovered (excluded) up to masses of 1.25 (1.7) TeV for massless neutralinos, *i.e.* $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \gg m_t$, under realistic uncertainty assumptions. This extends by about 700 GeV the reach of Run-2 for 80 fb^{-1}. The reach in $m_{\tilde{t}}$ degrades for larger $\tilde{\chi}_1^0$ masses. If $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \sim m_t$, the discovery (exclusion) reach is 650 (850) GeV.

Dark Matter and Dark Sectors

Compressed SUSY scenarios, as well as other DM models, can be targeted using signatures such as mono-jet, mono-photon and vector-boson-fusion production. Mono-photon and VBF events allow targeting an EW fermionic triplet (minimal DM), equivalent to a wino-like signature in SUSY, for which there is no sensitivity in Run-2 searches with 36 fb^{-1}. Masses of the $\tilde{\chi}_1^0$ up to 310 (130) GeV can be excluded by the mono-photon (VBF) channel, with improvements possible, reducing the theoretical uncertainties. Projections for searches for a mono-Z signature, with $Z \to \ell^+\ell^-$ recoiling against missing E_T, have been interpreted in terms of models with a spin-1 mediator, and models with two Higgs doublets and an additional pseudoscalar mediator a coupling to DM (2HDMa). The exclusion is expected for mediator masses up to 1.5 TeV, and for DM and pseudoscalar masses up to 600 GeV, a

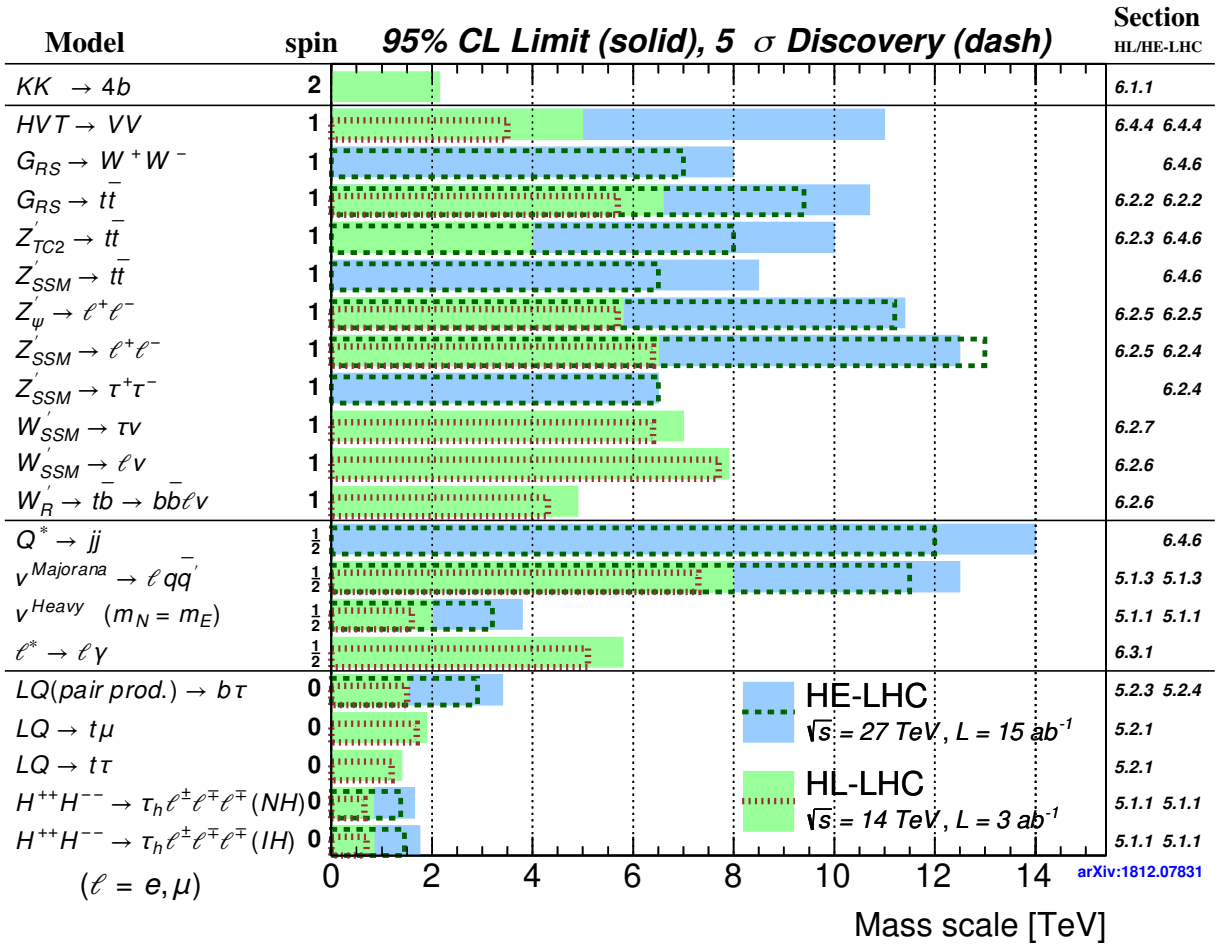

Fig. 7.2: A summary of the expected mass reach for 5σ discovery and 95% C.L. exclusion at the HL/HE-LHC, as presented in Sections 5 and 6.

factor of ~ 3 better than the 36 fb^{-1} Run-2 constraints. The case of 2HDMa models is complemented by 4-top final states, searched in events with two same-charge leptons, or with at least three leptons. While searches using 36 fb^{-1} Run-2 data have limited sensitivity considering the most favourable signal scenarios (*e.g.* $\tan\beta = 0.5$), HL-LHC will probe possible evidence of a signal with $\tan\beta = 1$, $m_H = 600$ GeVand mixing angle of $\sin\theta = 0.35$, assuming m_a masses between 400 GeV and 1 TeV, and will allow exclusion for all 200 GeV $< \mathrm{m_a} <$ 1 TeV. For DM produced in association with bottom or top quarks, where a (pseudo)scalar mediator decays to a DM pair, the HL-LHC will improve the sensitivity to mediator masses by a factor of $3-8$ relative to the Run-2 searches with 36 fb^{-1}.

A compelling scenario in the search for portals between the visible and dark sectors is that of the dark photon A'. Prospects for an inclusive search for dark photons decaying into muon or electron pairs indicate that the HL-LHC could cover a large fraction of the theoretically favoured $\epsilon - m_{A'}$ space, where ϵ is the kinetic mixing between the photon and the dark photon and $m_{A'}$ the dark photon mass.

Resonances

Several studies of resonance searches, in a variety of final states, have been performed and were presented here. A right-handed gauge boson with SM couplings, decaying as $W_R \to bt(\to b\ell\nu)$, can be excluded (discovered) for masses up to 4.9 (4.3) TeV, 1.8 TeV larger than the 36 fb^{-1} Run-2 result. For a sequential SM W' boson in $\ell\nu$ final states ($\ell = e, \mu$), the mass reach improves by more than 2 TeV

w.r.t. Run-2 ($80\,\mathrm{fb}^{-1}$) reach, and by more than 1 TeV w.r.t. $300\,\mathrm{fb}^{-1}$. The HL-LHC bound will be $M_{W'} = 7.9$ TeV, with discovery potential up to $M_{W'} = 7.7$ TeV. Projections for searches of SSM Z' bosons in the dilepton final state predict exclusion (discovery) up to masses of 6.5 (6.4) TeV. The $36\,\mathrm{fb}^{-1}$ Run-2 exclusion is 4.5 TeV, expected to grow to 5.4 TeV after $300\,\mathrm{fb}^{-1}$. Using top-tagging techniques, a Randall–Sundrum Kaluza–Klein gluon decaying to $t\bar{t}$ is expected to be excluded up to 6.6 TeV and discovered up to 5.7 TeV, extending by over 2 TeV the $36\,\mathrm{fb}^{-1}$ bounds.

Models related to the apparent flavour anomalies in B decays suggest the presence of heavy resonances, either Z' or leptoquarks (LQ), coupling to second and/or third generation SM fermions. The HL-LHC will be able to cover a significant portion of the parameter space allowed by flavour constraints, with an exclusion reach up to 4 TeV for the Z', depending on the structure and size of the Z' couplings. Pair produced scalar LQs coupling to μ (τ) and b-quarks, on the other hand, can be excluded up to masses of 2.5 (1.5) TeV, depending on assumptions on couplings. Finally, prospect studies for third generation LQ in the $t\mu$ and $t\tau$ channels deliver mass limits (discovery potential) increased by 500 (400) GeV with respect to $36\,\mathrm{fb}^{-1}$, with prospect discovery in the $t\mu$ channel up to 1.7 TeV.

Long-lived particles

In addition to the significant expansion of expected luminosity, new detector upgrades will enable searches in the long-lived particle regime. Muons displaced from the beamline, such as found in SUSY models with $\tilde{\mu}$ lifetimes of $c\tau > 25\,\mathrm{cm}$, can be excluded at 95% C.L.. New fast timing detectors will also be sensitive to displaced photon signatures arising from LLP in the $0.1 < c\tau < 300\,\mathrm{cm}$ range.

Prospect studies for disappearing tracks searches using simplified models of $\tilde{\chi}^{\pm}$ production lead to exclusions of chargino masses up to $m(\tilde{\chi}_1^{\pm}) = 750$ GeV (1100 GeV) for lifetimes of 1 ns for the higgsino (wino) hypothesis. When considering the lifetime predicted by theory, masses up to 300 GeV and 830 GeV can be excluded in higgsino and wino models, respectively. This improves the $36\,\mathrm{fb}^{-1}$ Run-2 mass reach by a factor of 2-3. The discovery reach is reduced to 160 GeV and 500 GeV respectively, due to the loss in acceptance at low lifetime (0.2 ns), but sensitivity is expected to be recovered with dedicated optimisations.

Several studies are available also for long-lived $\tilde{g}$. As an example, we expect a 1 TeV extension of the $36\,\mathrm{fb}^{-1}$ Run-2 mass reach, for models with $\tilde{g}$ lifetimes $\tau > 0.1$ ns, and an exclusion of $m_{\tilde{g}}$ up to $3.4 - 3.5$ TeV. Finally, the signature of long-lived dark photons decaying to displaced muons can be reconstructed with dedicated algorithms and is sensitive to very small coupling $\epsilon^2 \sim 10^{-14}$ for masses of the dark photons between 10 and 35 GeV. Complementarities in long-lived particle searches and enhancements in sensitivity might be achieved if new proposals of detectors and experiments such as Mathusla, FASER, Codex-B, MilliQan and LHeC are realised in parallel to the HL-LHC.

HE-LHC

Supersymmetry

The increase in energy from 14 TeV to 27 TeV leads to a large increase in the production cross section of heavy coloured states, a 3.5 TeV gluino has nearly a 400-fold increase in production cross section. For supersymmetric spectra without compression the HE-LHC has sensitivity to gluinos up to masses of 6 TeV and discovery potential of 5.5 TeV. The corresponding numbers for stop squarks are 3.5 TeV and 3 TeV, respectively. These results allow to put in perspective the question to what extent classes of "natural" supersymmetric models are within the reach of HE-LHC and can be discovered or excluded conclusively. Examples of specific model scenarios were studied during the Workshop: while HL-LHC can only cover part of the parameter space of the models considered, HE-LHC covers it entirely. The HE-LHC would allow for a 5σ discovery of most natural SUSY models via the observation of both gluinos and stops.

If the coloured states are close in mass to the lightest supersymmetric particle (LSP), the amount

of missing transverse momentum ($E_{\mathrm{T}}^{\mathrm{miss}}$) in the event is decreased. The typical multijet + $E_{\mathrm{T}}^{\mathrm{miss}}$ SUSY searches are less sensitive and must be replaced with monojet-like analyses. Prospect studies show that if for example the gluino-LSP mass splitting is held at $10\ \mathrm{GeV}$, gluino masses can be excluded up to $2.6\ \mathrm{TeV}$. If the lightest coloured state is the stop, and the $\tilde{t}$-LSP splitting is such that final states include very off-shell W and b-jets, $\tilde{t}$ masses up to about $1\ \mathrm{TeV}$ could be excluded, extending the HL-LHC reach by about a factor of two.

The electroweakino sector of supersymmetry presents a particular challenge for hadronic machines. If the LSP is pure higgsino or wino, there is a very small neutralino-chargino mass splitting ($\sim\ 340\ \mathrm{MeV}$, $\sim\ 160\ \mathrm{MeV}$ respectively) and the chargino has a correspondingly long lifetime ($c\tau\ \sim 5,1\ \mathrm{cm}$ respectively). The $E_{\mathrm{T}}^{\mathrm{miss}}$ is again small unless the pair produced electroweakinos recoil against an ISR jet. Taking into account contributions from both chargino and neutralino production the monojet search will deliver a sensitivity for exclusion (discovery) of winos up to $\sim 600\ \mathrm{GeV}$ ($300\ \mathrm{GeV}$) and higgsinos up to $\sim\ 400\ \mathrm{GeV}$ ($150\ \mathrm{GeV}$). Taking advantage of the long lifetime of the charginos allows searches to be done for disappearing charged tracks. Considering a detector similar to the ones available for HL-LHC, winos below $\sim 1800\ \mathrm{GeV}$ ($1500\ \mathrm{GeV}$) can be excluded (discovered), while the equivalent masses for Higgsinos are $\sim 500\ \mathrm{GeV}$ ($450\ \mathrm{GeV}$).

While these results come short of covering the full range of masses for electroweakinos to be a thermal relic and account for all of DM, the mass range accessible to HE-LHC greatly extends the HL-LHC potential and can be complementary to the indirect detection probes using gamma rays from dwarf-spheroidal galaxies.

Dark Matter

Monojet searches, as well as monophoton and vector-boson-fusion production searches, might be sensitive to generic weakly interactive dark matter candidates beyond compressed SUSY scenarios. Analyses of the reach of the HE-LHC under various assumptions of the structure of the DM-SM coupling have been carried out. Models characterised by the presence of an extended Higgs sector, with Higgs doublets mixing with an additional scalar or pseudoscalar mediator that couples to DM have been studied assuming associate production of DM with a pair of top quarks.

Using leptonic decays of the tops, a fit to the distribution of the opening angle between the two leptons can help distinguish signal from SM processes, after other background-suppressing selections. Assuming the DM is lighter than half the mediator mass, a scalar or pseudoscalar mediator can be ruled out at 95% C.L. up to $900\ \mathrm{GeV}$ using this technique, a factor of 2 higher in mass compared to the HL-LHC bounds.

If a dark sector exists and contains heavy coloured particles, $\mathcal{Q}$, nearly degenerate with the DM and decaying to DM and SM coloured particles, a monojet topology could be again the most sensitive. The rate and shape of the monojet distribution depend upon the mass, spin and colour representation of $\mathcal{Q}$. Fermionic colour triplet $\mathcal{Q}$ could be discovered up to $1.1\ \mathrm{TeV}$ at the HE-LHC, a fermionic octet will be ruled out if lighter than $1.8\ \mathrm{TeV}$, and a scalar colour triplet almost degenerate in mass to the DM could be probed up to masses of $600\ \mathrm{GeV}$. Should an excess be observed identifying the spin and colour representation, NNLO precision will be needed for the predictions of the SM backgrounds. Analyses of double-ratios of cross sections at varying p_T could be utilised to partially cancel uncertainties.

Resonances

Searches for heavy resonances will greatly benefit from the increased partonic energy of a $27\ \mathrm{TeV}$ machine. If the resonance is narrow the search can be data driven but if the resonance is wide it will require a precise understanding of the backgrounds, which presents a formidable challenge. The HE-LHC can expect to approximately double the mass reach on dijet resonances of the HL-LHC. For instance, the reach for an excited quark decaying to dijets will be $14\ \mathrm{TeV}$.

Dilepton resonances, *e.g.* Z', are present in many gauge extensions of the SM. The exact reach in any model depends upon the coupling to light quarks and BR to charged leptons. A Z' whose couplings to SM quarks and leptons are as in the SM, a so called sequential Z'_{SSM}, will be discoverable in the dilepton channel up to ~ 13 TeV. In the di-tau channel the reconstruction is harder, reducing the reach to ~ 6 TeV. In the di-top channel a Z'_{SSM} will be discovered up to 6 TeV and excluded up to 8 TeV. It is an interesting question to ask: if a resonance is discovered can we determine the nature of the model? Considering a 6 TeV Z' decaying into e, μ, t, b, q final states, it is sufficient to consider three observables ($\sigma \cdot B$, the forward-backward asymmetry, and the rapidity asymmetry) to distinguish between six Z' models in most cases.

Gauge extensions of the SM also often contain new heavy charged vector bosons, W'. One promising search channel for these new particles is the WZ final state. More generally BSM models can contain resonances decaying to di-bosons WZ/WW. Searching for a RS graviton G_{RS} resonance in WW final states exploiting the all-hadronic signature presents a considerable challenge and requires dedicated identification of boosted W-jets. The estimated reach is ~ 8 TeV, almost a factor of two increase with respect to the HL-LHC. Diboson searches in $WW \to \ell\nu qq$ final states are sensitive also to heavy vector triplet (HVT) model produced via $\mathrm{ggF/q\bar{q}}$. HVT $Z^{'}$ masses up to 11 TeV can be excluded by HE-LHC, extending the HL-LHC reach by about 6 TeV.

Searches for top partners decaying to a top and a W boson in the same-sign dilepton signature can lead to discovery up to more than 2 TeV, with the possibility to discriminate left- and right-handed couplings at the 2σ level in all the accessible discovery range.

Models related to the generation of the observed pattern of neutrino masses and mixings offer a variety of signatures that could profit from the high energy available at HE-LHC. For instance, searches for lepton flavour violating (LFV) final states with two opposite-sign different-flavour leptons and two jets arising from the production of a heavy pseudo-Dirac neutrino and a SM lepton could test heavy neutrino masses in seesaw models up to more than 1 TeV. In left-right symmetric models, a right-handed heavy W_R boson decaying to a Majorana neutrinos can be discovered with 5 ab^{-1} up to ~ 10.5 TeV and excluded up to masses of around ~ 16 TeV with an integrated luminosity of 15 ab^{-1}. This increases the reach of HL-LHC by about 10 TeV. Doubly charged scalars in type-II seesaw models, can also be searched for in multi-lepton signatures, with a reach in the 1.5 TeV region. Heavy leptons in type-III seesaw models, giving rise to final states with two leptons, jets and b-jets can be excluded (discovered) up to 3.8 (3.2) TeV. For comparison, the exclusion reach for the HL-LHC is about 1.6 TeV.

Finally, models related to observed flavour anomalies in neutral-current B decays, suggest the presence of heavy resonances, either Z' or leptoquarks, coupling to muons and b-quarks. The HE-LHC will be able to cover an ample region of the parameter space allowed by flavour constraints, with an exclusion (discovery) reach up to 10 (7) TeV for the Z', depending on the assumptions on the Z' couplings structure and size. Pair produced leptoquarks, on the other hand, can be excluded up to masses of 4.2 TeV, again depending on assumptions on couplings. These masses are typically a factor of 2 to 2.5 higher than the HL-LHC sensitivity.

8 Acknowledgements

We would like to thank the LHC experimental Collaborations and the WLCG for their essential support. We are especially grateful for the efforts by the computing, generator and validation groups who were instrumental for the creation of large simulation samples. We thank the detector upgrade groups as well as the physics and performance groups for their input. Not least, we thank the many colleagues who have provided useful comments on the analyses. The research of A. Aboubrahim and P. Nath was supported in part by NSF Grant PHY-1620575. The research of J. Kalinowski and W. Kotlarski was supported in part by the National Science Centre, Poland, HARMONIA project under contract UMO-2015/18/M/ST2/00518 (2016-2019). The work of T. Han, S. Mukhopadhyay, and X. Wangwas supported in part by the U.S. Department of Energy under grant No. DE-FG02- 95ER40896 and by the PITT PACC. T. Han also acknowledges the hospitality of the Aspen Center for Physics, which is supported by National Science Foundation grant PHY-1607611. The work of S. Chekanov, J. Childers, J. Proudfoot, R. Wang, and D. Frizzell has been created by UChicago Argonne, LLC, Operator of Argonne National Laboratory ("Argonne"). Argonne, a U.S. Department of Energy Office of Science laboratory, is operated under Contract No. DE-AC02-06CH11357. It was also made possible by an allocation of computing time through the ASCR Leadership Computing Challenge (ALCC) program and used resources of the National Energy Research Scientific Computing Center, a DOE Office of Science User Facility supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. The work of B. Allanach, D. Bhatia, B. Gripaios, A. Iyer, and T. Tevong You has been partially supported by STFC consolidated grants ST/L000385/1, ST/P000681/1. The work of M. Klasen has been supported by the BMBF under contract 05H15PMCCA and the DFG through the Research Training Network 2149 "Strong and weak interactions - from hadrons to dark matter". T. Jezo was supported by the Swiss National Science Foundation (SNF) under contracts BSCGI0-157722 and CRSII2-160814. The work of F. Sala is partly supported by a PIER Seed Project funding (Project ID PIF-2017-72). The work of M. Heikinheimo has been supported by the Academy of Finland, Grant NO. 31013 G. Cacciapaglia is supported by Institut Franco-Suedois (project Tör) and the Labex-LIO (Lyon Institute of Origins) under grant ANR-10-LABX-66, FRAMA (FR3127, Fédération de Recherche "André Marie Ampère"). G. Ferretti is supported by The Knut and Alice Wallenberg Foundation and the Lars Hierta Memorial Foundation. T. Flacke is supported by the IBS under the project code, IBS-R018-D1. H. Serodio is supported by the ERC under the European Union's Horizon 2020 research and innovation programme (grant agreement No 668679). D. Camargo and F. S. Queiroz acknowledge financial support from MEC and UFRN. F. S. Queiroz also acknowledges the ICTP-SAIFR FAPESP grant 2016/01343-7 for additional financial support. S. Moretti is supported in part by the NExT Institute and acknowledges partial financial support from the STFC Consolidated Grant ST/L000296/1 and STFC CG ST/P000711/1, and the H2020-MSCA-RISE-2014 grant no. 645722 (NonMinimal-Higgs).

Abstract

Motivated by the success of the flavour physics programme carried out over the last decade at the Large Hadron Collider (LHC), we characterize in detail the physics potential of its High-Luminosity and High-Energy upgrades in this domain of physics. We document the extraordinary breadth of the HL/HE-LHC programme enabled by a putative Upgrade II of the dedicated flavour physics experiment LHCb and the evolution of the established flavour physics role of the ATLAS and CMS general purpose experiments. We connect the dedicated flavour physics programme to studies of the top quark, Higgs boson, and direct high-p_T searches for new particles and force carriers. We discuss the complementarity of their discovery potential for physics beyond the Standard Model, affirming the necessity to fully exploit the LHC's flavour physics potential throughout its upgrade eras.

1 Introduction

The past decade has witnessed a highly successful programme of flavour physics at the LHC, building on and greatly expanding the pioneering work at the Tevatron's CDF and DØ. The unprecedented breadth and precision of the physics results produced by the LHC's dedicated flavour physics experiment, LHCb, has been complemented by crucial measurements at ATLAS and CMS. Together, they have probed the Standard Model at energy scales complementary to the direct LHC searches, and proven that it is possible to carry out a broad programme of precision flavour physics in such a challenging hadronic environment. This document offers a glimpse of the future – the potential for flavour physics in the High-Luminosity phase of the Large Hadron Collider (HL-LHC) and its possible upgrade to a 27 TeV proton collider, the High-Energy LHC (HE-LHC). The landscape of flavour physics is considered and theoretical arguments are presented for measurements with higher precision and of qualitatively new observables. The prospective experimental sensitivities for the HL-LHC assume 3000 fb^{-1} recorded by ATLAS and CMS, and 300 fb^{-1} recorded by a proposed Upgrade II of LHCb.

The main points, detailed in the subsequent sections, are:

- The flavour physics programme at the LHC comprises many different probes: the weak decays of beauty, charm, strange and top quarks, as well as of the τ lepton and the Higgs;
- CP violation and Flavour Changing Neutral Currents (FCNCs) are sensitive probes of short-distance physics, within the Standard Model (SM) and beyond (BSM);
- Flavour physics probes scales much greater than 1 TeV, with the sensitivity often limited by statistics and not by theory;
- For most FCNC processes, a New Physics (NP) contribution at 20% of the SM is still allowed, so there is plenty of discovery potential;
- Spectroscopy and flavour changing transitions serve as laboratories for a better understanding of nonperturbative Quantum Chromodynamics (QCD);
- Some of the several tensions between flavour physics data and the SM may soon become decisive;
- Precision tests of the SM flavour sector will improve by orders of magnitude including Charged Lepton Flavour Violating transitions (CLFV);
- Flavour physics will teach us about physics at shorter distances, complementary to the high-$p_{\rm T}$ physics programme, whether NP is seen or not, and could point to the next energy scale to explore.

1.1 Theoretical considerations

Authors (TH): G. Isidori, Z. Ligeti.

As a community, we are now in a strikingly different position than we were a decade ago, before the LHC turned on. Already before the start of the LHC it was clear from unitarity considerations that the LHC experiments were basically guaranteed to uncover the origin of the electroweak symmetry breaking, i.e., the breaking of the $SU(2)_L \times U(1)_Y$ gauge symmetry to the $U(1)$ of electromagnetism. The discovery of the Higgs boson by ATLAS and CMS in 2012 was a triumph, confirming these expectations. Since then we have learned that the properties of the Higgs boson are in increasing agreement with the SM. Coupled with the lack of direct signals of BSM particles so far, this increasingly points to a mass gap between the SM particle spectrum and the BSM one.

After completion of the first phase of the LHC programme, the field entered into a more uncertain, yet possibly more exciting exploratory era. We are still faced by a number of key open questions, e.g., the need for dark matter and how to generate the baryon asymmetry. We thus do know that BSM physics must exist. However, we do not know which experiments, at what energy scale, and probing which aspects of our understanding of nature, may provide the first unambiguous evidence for BSM phenomena. The phenomenological successes of the SM, in conjunction with being a renormalizable quantum field theory,

means that there is no clear guidance where to search for clues on how to extend the SM. [1] This calls for a diversified programme of BSM searches, with no stone left unturned. A deeper study of the properties of the Higgs boson is one of the pillars of this programme, and will be the central focus of the HL-LHC. The same programme also offers unique opportunities for tremendous improvements in indirect NP searches via precision studies of low-energy flavour-changing observables. Here the expected increase in statistics may be even larger than in the Higgs sector. As explained below, this programme is complementary to both the high-$p_{\rm T}$ NP searches as well as to the indirect NP searches performed via the Higgs precision measurements. To show this, we first give a brief introduction to flavour physics, starting with the "flavour puzzle" and the general discussion of probing BSM through flavour transitions.

1.1.1 The flavour puzzle

Flavour is the label generically used to differentiate the 12 fermions which, according to the SM, are the basic constituents of matter. These particles can be grouped into 3 families, each containing two quarks and two leptons. The particles within a given family have different combinations of strong, weak, and electromagnetic charges. This in turn implies differing behaviors under the SM interactions. Across the three families the particle content is identical except for the masses. That is, the second and third family are copies of the first family, with the same SM quantum numbers for the copies of particles across generations, but with different masses. Ordinary matter consists of particles of the first family: the up and down quarks that form atomic nuclei, as well as the electrons and the corresponding neutrinos. The question why there are three almost identical replicas of quarks and leptons as well as the origin of their different mass matrices are among the big open questions in fundamental physics, often referred to as the "SM flavour puzzle".

Within the SM, the hierarchy of fermion masses originates from the hierarchy in the strengths of interactions between the fermions and the Higgs field, namely from the structure of the Yukawa couplings. However, this prescription does not provide any explanation for the origin of the large hierarchies observed among fermion masses. Putting aside the special case of neutrinos, there are five orders of magnitudes between the mass of an electron and a top quark. Similarly, we do not know what determines the peculiar and rather different mixing structure in the quark and lepton mass matrices observed through the misalignment of mass and weak-interaction eigenstates in flavour space. We do know experimentally, that the Higgs field is responsible for the bulk of the heaviest quark and lepton masses: the top and bottom quarks and the tau leptons. The generation of at least some of the quark masses and mixing angles is thus connected to the Higgs sector. This suggests a possible connection between the flavour puzzle and the electroweak hierarchy puzzle, another big open question pointing toward some form of new physics.

1.1.2 Model-independent considerations

The above puzzling aspects make flavour physics, i.e., the precision study of flavour-changing processes in the quark and lepton sector, a very interesting window on possible physics beyond the SM. We do not know if there is an energy scale at which the flavour structure observed assumes a simpler form, i.e., we do not know if the masses and mixing angles, as observed at low energies, can be predicted in terms of a reduced number of more fundamental parameters in a theory valid at some high scale. On the other hand, precision measurements of flavour-changing transitions may probe such scales, even if they are well above the LHC center-of-mass energy.

This statement can be made quantitative by considering the SM as a low-energy effective theory that is valid up to a cut-off scale Λ, taken to be bigger than the electroweak scale $v = (\sqrt{2}\,G_F)^{-1/2} \approx$

[1] The only clearly established exception are neutrino masses which require non-renormalizable operators (or new degrees of freedom) and seem to point toward a very high scale of new physics that is not accessible in practice. However, the existence of a high new scale connected to neutrino mass generation does not prevent other BSM physics to appear at lower scales.

246 GeV. According to such an assumption of heavy NP, the amplitudes describing a flavour changing transition of a fermion ψ_i to a fermion ψ_j can be cast into the following general form

$$\mathcal{A}(\psi_i \to \psi_j + X) = \mathcal{A}_0 \left(\frac{c_{\rm SM}}{v^2} + \frac{c_{\rm NP}}{\Lambda^2} \right). \tag{1}$$

Since in many cases $c_{\rm SM} \ll 1$, NP effects can have a large impact even if $\Lambda \gg v$. For instance, in the quark sector the reason that often $c_{\rm SM} \ll 1$ stems from the facts that:

(i) $c_{\rm SM}$ can be proportional to small entries of the Cabibbo-Kobayashi-Maskawa (CKM) matrix and/or to small SM Yukawa couplings;

(ii) $c_{\rm SM}$ may include a loop factor $1/(16\pi^2)$, if the corresponding transition is forbidden at tree level, as is the case for flavour-changing neutral-current (FCNC) transitions or meson-antimeson mixing transitions.

As a result, these low-energy processes can probe indirectly, via quantum effects, scales of order $v/\sqrt{c_{\rm SM}}$. These can easily exceed those directly reachable via production of on-shell states in current and planned accelerators. As an explicit example, in the case of $B-\bar{B}$ mixing, $\sqrt{c_{\rm SM}} \sim |V_{td}|/(4\pi) \sim 10^{-3}$, hence this observable can probe NP scales up to 10^3 TeV in models with $c_{\rm NP} \sim 1$.

The precise values of the NP scale probed at present vary over a wide range, depending on the specific observable and the specific NP model ($c_{\rm NP}$ can span a large range, too). However, the form of Eq. (1) does allow us to predict how the bounds will improve with increasing datasets. For the observables that are SM dominated, are already observed, and whose uncertainties are dominated by statistics, the corresponding bound on Λ scales as $N^{1/4}$, where N is the relative increase in the number of events. The same scaling occurs for forbidden or highly suppressed SM processes, i.e., in the limit $c_{\rm SM} \ll c_{\rm NP}$, if the search is not background dominated. Thus, with two orders of magnitude increase in statistics one can probe scales roughly 3 times higher than at present. This is well above the increase in NP scale probed in on-shell heavy particle searches at high-$p_{\rm T}$ that can be achieved at fixed collider energy by a similar increase in statistics.

While theoretical uncertainties are often important, there are enough measurements which are known not to be limited by theoretical uncertainties. Improved experimental results will therefore directly translate to better NP sensitivity. There are also several cases of observables sensitive to NP where the theoretical uncertainties are mainly of parametric nature (e.g., our ability to precisely compute $c_{\rm SM}$ is dominated by the knowledge of CKM elements, quark masses, etc.). For such cases, we can expect significant increase in precision with higher statistics thanks to the improvement in the reduction of parametric uncertainties. This also highlights the importance of a broad flavour physics programme where the focus is not only on rare or CP violating processes "most likely" affected by NP but also on core SM measurements which help to reduce the theoretical uncertainties.

1.1.3 Current anomalies and historical comments

Due to the generic sensitivity to high scales, flavour physics has historically played a major role in developing and understanding the Standard Model. Flavour physics measurements signalled the presence of "new" particles well before these were directly observed (this was the case for charm and top quarks from $K_L \to \mu^+\mu^-$ decays and K-meson mixing, and from B-meson mixing, respectively). With the completion of the SM, and the increasingly precise tests that the SM predictions have successfully passed, one may draw the naive conclusion that the discovery potential of precision experiments has declined in the last decades. However, the opposite is true. First of all, a qualitative change in our understanding has been achieved during that time. Before the asymmetric B factory experiments, BaBar and Belle, it was not known whether the SM accounted for the dominant or just a small part of CP violation observed in kaon mixing. We now know that the bulk of it is due to the SM Kobayashi-Maskawa mechanism. However, even after decades of progress, for most FCNC amplitudes the NP is still allowed to contribute at $\sim 20\%$ of the SM contribution.

The great improvements in precision for several flavour-changing processes achieved in the last 20 years, both at experimental and theoretical levels, represent a very important advancement of the field. We learned that either NP is much heavier than the electroweak scale, or, if it is not far above the electroweak scale as required by most solutions of the hierarchy puzzle, it must have a highly nontrivial flavour structure that is able to mimic the strong suppression of FCNC transitions in the SM. The latter statement has often been oversimplified, assuming that there is little hope to observe significant deviations from the SM in flavour physics. The anomalies recently observed in semileptonic B decays clearly demonstrated a genuine discovery potential, regardless of whether or not their significance increase with improved measurements.

Recent measurements, both in charged-current and in neutral-current semileptonic B decays, hint at a violation of one of the key predictions of the SM – the universality of interactions for leptons of different generations (in the limit where their masses can be neglected). These anomalies represent the strongest tensions with the SM predictions currently observed in laboratory experiments. The statistical significance of the anomalies is not high enough to claim a discovery but the situation is very interesting. More precise measurements of some of these observables, in particular the lepton flavour universality violating ratios $R_{K^{(*)}} = \Gamma(B \to K^{(*)}\mu^+\mu^-)/\Gamma(B \to K^{(*)}e^+e^-)$ and $R(D^{(*)}) = \Gamma(B \to D^{(*)}\tau\bar{\nu})/\Gamma(B \to D^{(*)}l\bar{\nu})$, where $l = e,\ \mu$, could establish the presence of NP even with modest improvements in statistics. At the current central values for these anomalies, analyzing all of the Run 1 and Run 2 data could already establish a discrepancy with the SM expectation in a single observable with $5\,\sigma$ significance.

Whether or not these anomalies will gain significance to become unambiguous signals of physics beyond the SM, they have clearly exemplified the discovery potential of flavour-physics observables and enlarged our horizon regarding possible BSM scenarios. Before the appearance of these anomalies, lepton flavour universality (LFU) was an implicit assumption adopted by the vast majority of BSM scenarios proposed . It is now better appreciated that LFU is an accidental property of the SM. It is well tested in transitions involving only the first two generations of quarks and leptons, while it is rather poorly tested in processes involving the third generation (and may indeed be violated at a detectable level in B decays). A deeper scrutiny of this SM property has highlighted the interest in a large variety of observables, with small theoretical uncertainties, which would strongly benefit from more statistics. Similarly, it has often (though not always) been taken for granted that NP effects in tree-level dominated processes, such as those affecting $R(D^{(*)})$, are negligible, while it is now clear that there are many NP scenarios where this assumption does not hold. This observation has important phenomenological consequences and signals the limitation of a significant fraction of current NP analyses. Last but not least, theoretical models addressing the anomalies have highlighted the interest of BSM constructions containing heavy leptoquark fields – a class of NP models that was not popular until a few years ago.

The current central values of $R_{K^{(*)}}$ and, especially, $R(D^{(*)})$ imply that NP needs to be at a fairly low scale: below few tens of TeV in the former, and a few TeV in the latter case. This can be easily understood given that the NP effects need to give $\mathcal{O}(10\% - 20\%)$ corrections to the amplitudes which are one-loop and tree level in the SM, respectively. Models addressing the anomalies are therefore a perfect laboratory to explore the interplay between indirect NP searches from flavour observables and direct searches at high-$p_{\rm T}$. Interestingly enough, even in the low-scale models addressing $R(D^{(*)})$, with or without $R_{K^{(*)}}$, there exist ample regions of parameter space that are able to explain the anomalies and that are at the same time consistent with the null results of NP searches performed so far at high $p_{\rm T}$.

1.1.4 Connections to lepton flavour violation

The CLFV processes, such as $\tau \to 3\mu$, are essential parts of the flavour-physics programme. CLFV amplitudes can also be decomposed as in Eq. (1), with the advantage that in this case $c_{\rm SM}$ vanish. If the SM is extended to describe neutrino masses, non-zero predictions arise but are suppressed by m_ν^2/m_W^2.

The predicted CLFV rates are thus many orders of magnitudes below the detection reach of any present or planned facility. As a consequence the searches for CLFV are very clean and powerful ways to search for physics beyond the SM.

Any attempt to solve the flavour puzzle with new dynamics not far from the TeV scale, such that the observed hierarchies in the Yukawa couplings are accounted for by the new dynamics, naturally leads to CLFV rates not far from the present bounds. The recent LFU anomalies have strengthened the case further. Many models explaining these anomalies predict CLFV at a detectable level, in many cases just below the current bounds. Of noteworthy interest, triggered by the recent anomalies, are processes that violate both quark and lepton flavour, such as $B \to K\tau\mu$. There is a large variety of observables of this type that, together with purely leptonic observables, form a large and very promising sub-field of NP probes. Such searches can be organized in a large matrix, with the row and column indices determined by lepton and quark flavours, which is largely unexplored at present. For any NP model that may populate entries in this matrix, there is a large complementarity between the HL-LHC experiments, Belle-II, and dedicated experiments at muon beams searching for $\mu \to e$ conversion, $\mu \to e\gamma$, and $\mu \to 3e$, as well as with the flavour diagonal probes such as the measurements of the $(g-2)$ of the muon and the electron, or the searches for electric dipole moment of the electron.

1.1.5 Connections with the hierarchy problem and complementarity with high-p_{T} searches

BSM models proposed to address the electroweak hierarchy problem, such as supersymmetric models or composite Higgs models, predict new particles around the TeV scale. For all these models, flavour physics imposes very stringent bounds, requiring a flavour structure not far from that in the SM. This was the main rationale underlying the hypothesis of Minimal flavour Violation (MFV). The MFV hypothesis is an ansatz for the flavour structure of NP that assumes that the SM Yukawa couplings are the only sources of flavour non-degeneracy even beyond the SM. This requirement is nowadays partially relaxed by the absence of direct signals of NP in high-p_{T} experiments, allowing non-trivial modifications from the strict MFV. This example illustrates nicely the importance of flavour physics in reconstructing the structure of any NP model addressing the electroweak hierarchy problem. But it also reveals its complementarity with the high-p_{T} experiments, where improved direct bounds relax the flavour structure requirements.

If there are new particles which couple to the SM quarks or leptons, then, in general, there are corresponding new flavour parameters. Measuring them would be very important in order to understand the structure of NP. This has been studied in great detail in the context of Supersymmetry (SUSY) (alignment mechanism of the soft-breaking terms) and in composite models (partial-compositeness mechanism). In the specific case of low energy supersymmetry, the squark and slepton couplings may yield measurable effects in FCNC processes and CP violating observables and may give rise to detectable CLFV transitions. Observable CP violation is also possible in neutral currents and in electric dipole moments, for which the SM predictions are below the near future experimental sensitivities. The supersymmetric flavour problems, namely the observation that TeV-scale SUSY models with generic parameters are excluded by FCNC and CP violation measurements, can be alleviated in several scenarios: (i) universal squark masses (e.g., gauge mediation); (ii) quark–squark alignment, (e.g., horizontal symmetry); (iii) very heavy squarks (e.g., split SUSY). All viable models incorporate some of these ingredients. Conversely, if SUSY is discovered, mapping out its flavour structure, with the help of future more precise flavour tests, may help answer questions about even higher scales, the mechanism of SUSY breaking and the way it is communicated to the Minimal Supersymmetric Standard Model (MSSM), etc.

1.1.6 Nonperturbative QCD and its role in flavour physics

Of special interest are the theoretical uncertainties due to our incomplete understanding of QCD dynamics at low energies. In order to extract information on short-distance physics from weak decays of

hadrons, knowledge of nonperturbative matrix elements, encoded in decay constants and form factors, is usually needed. Refinements in the effective-field-theory (EFTs) approaches exploiting heavy-quark and/or low-energy perturbative expansions and, especially, major progress in lattice QCD calculations seen in the last decade, make possible a full exploitation of the BSM flavour physics programme. Some of the hadronic uncertainties have already reached the per-mille level, e.g., the theoretical precision in the calculation of nonperturbative quantities crucial for the extraction of the CKM matrix element $|V_{us}|$, and many more are at the percent level, for instance, the theory prediction for the rare FCNC decay $B_q \to \mu^+\mu^-$.

On the other hand, there are many other transitions that would benefit from further theoretical breakthroughs. In the past, large increases in available data always triggered new theory developments, and better understanding of the domain of applicability and accuracy of existing theoretical tools. It can be anticipated that these fruitful cross-fertilizations will continue to occur in the HL-LHC era between flavour physics experiments and theory. While there is a substantial suite of measurements whose interpretations will not be limited by hadronic uncertainties, the experimental programme can still benefit a lot from theoretical improvements. For many observables, lattice QCD improvements are important. The anticipated improvements in experimental precision also pose interesting challenges for lattice QCD, to robustly address isospin violating and electromagnetic effects in flavour observables. For many nonleptonic decays, relevant for CP violation, lattice QCD is unlikely to make a big impact. Nevertheless, developing new methods based on effective theories and testing existing approaches can be expected to improve the theoretical understanding of many observables, further enhancing the sensitivity of the experimental programme to possible BSM phenomena.

Understanding the nonperturbative structure of QCD of course has significant scientific merit per se, independent of the searches for NP. A very active area of research that will benefit from the flavour programme at HL/HE-LHC is hadron spectroscopy. A plethora of new states, many of which were unexpected or show intriguing features, have been discovered at the B-factories, Tevatron and the LHC. The increase of data samples at the HL-LHC will make it possible to discover many more of these states and chart their quantum numbers and properties. Accommodating them into our theoretical understanding of the nonperturbative regime of QCD will be a major challenge for the next decades.

1.1.7 Unexpected discoveries

It goes without saying that it is impossible to predict truly unexpected future discoveries. However, it cannot be emphasized enough that the large increase in datasets has the potential to revolutionize the field by unexpected discoveries and trigger entirely new areas of experimentation. It should be obvious that exact and approximate conservation laws should be tested as precisely as possible, especially when the experimental sensitivity can substantially increase. Recall that the discovery of CP violation itself was unexpected, in an experiment whose primary goal was checking an anomalous kaon regeneration result. New particles with surprising properties were in fact discovered at each of BaBar, Belle, and LHCb, respectively: the discoveries of the $D_{sJ}(2317)$ meson with a mass much below expectations, the discovery of the unexpectedly narrow charmonium-like state $X(3872)$ and the $Z(4430)$, and the discovery of pentaquarks. Thus, beside the "classical" searches for flavour-violating processes mentioned so far, both in quark and lepton sectors, other searches like those related to dark sectors in many channels or BSM searches not yet conceived will all form important parts of the flavour physics programme in the HL-LHC era.

1.2 Experimental considerations and the breadth of flavour physics

At the end of the HL-LHC the useful datasets will have increased by a factor of order 30–100 compared to the present ones. However, due to improvements in detector capabilities and changing running conditions, robust estimates of sensitivity improvements are complicated tasks discussed in details in the next

sections. At LHCb, in most analyses, one may expect faster improvements in the results than simply scaling with collected total luminosity, due to improvements in detector capabilities in the upcoming upgrades. At ATLAS and CMS the large number of interactions per bunch crossing during the HL-LHC will be a challenge. However, the upgraded detectors will have higher granularity and timing information to mitigate pileup effects [1,2]. It is important to pursue as broad a programme as possible, since several key channels are expected to remain competitive with LHC.

In many cases Belle-II and tau-charm factories such as BES III will provide competition and cross-checks of LHCb results. However, especially in the very low rate modes, such as $B_d \to \mu^+\mu^-$, it is ATLAS and CMS and not Belle-II which are expected to best compete with LHCb. If there are anomalies in B_s, and especially in Λ_b decays, they can only be cross-checked at the LHC experiments.

As mentioned above, our ignorance about BSM physics requires a diversified programme that, even within the flavour-physics domain, calls for a large set of complementary measurements. To properly identify the BSM model, if deviations are observed, measuring its imprint on different observables is very important, as stressed, e.g., in Ref. [3]. These measurements cannot all be performed at a single facility. There is full complementarity and many potential synergies in case some BSM signal emerges, among different b-hadron decays ($B_{u,d}$, B_s, Λ_b, etc.), CP violating and rare processes involving charm and kaons, as well as possible FCNC transitions with top-quark. For instance, the measurements of theoretically precisely known $s \to d\nu\nu$ FCNC transitions are expected from NA62 and KOTO, and will be directly complementary to the results from the flavour programme at the LHC. Such measurements of different flavour transitions are important to determine the BSM flavour structure, while measurements of the same quark level transition, but with different hadronic initial and final states determine the chiral structure of the BSM model.

1.2.1 Key experimental capabilities at ATLAS and CMS

The upgraded high-luminosity LHC (HL-LHC) will deliver to the CMS and ATLAS experiments proton-proton collisions at a center-of-mass energy of 14 TeV for a total integrated luminosity of about 3000 fb^{-1}. This goal will be achieved through a high instantaneous luminosity which implies up to 200 proton-proton interactions per bunch-crossing. In this regime, the experimental sensitivity to new physics is enhanced and complemented by flavour physics measurements, with sensitivities in specific modes (e.g., $B_{s,d} \to \mu\mu$, $B_s^0 \to J/\psi\phi$, $B^0 \to K^{*0}\mu\mu$) comparable to those of dedicated experiments. The ability of general purpose detectors to make precision heavy flavour measurements has been clearly demonstrated by the results from Run-1 and Run-2 data. HL-LHC can be a unique test bench for B physics studies in ATLAS and CMS: $\sim 10^{15}$ $b\bar{b}$ pairs will be produced for the integrated luminosity goal.

ATLAS and CMS will exploit this potential thanks to some projected Phase-2 upgrades which promise good detection capability at low momenta, good pileup effect mitigation and even, in some cases, an improved performance. Examples are the new inner trackers, improvements of the muon systems, topological trigger capabilities, and the possibility to use tracking in the early stages of the trigger chain [1,2].

The high integrated luminosity expected will allow ATLAS and CMS to study some rare processes at a precision never attained before. The excellent tracking and muon identification performances are highlighted by a number of benchmark channels, $B_{s,d} \to \mu\mu$, $B^0 \to K^{*0}\mu\mu$, $B_s \to J/\psi\phi$, and $\tau \to 3\mu$, that are used for projections. Precision measurements at the level of 5% to 10% for the $B_s^0 \to \mu^+\mu^-$ branching fraction, are expected, along with the observation of the $B^0 \to \mu^+\mu^-$ decay with more than 5σ, and a measurement of the $B_s^0 \to \mu^+\mu^-$ effective lifetime with a 3% statistical precision. The sensitivity to the CP-violating phase ϕ_s in the $B_s^0 \to J/\psi\phi$ mode is estimated to be at the level of $\sim$ 5 mrad, i.e., a factor of ~ 20 better than the corresponding Run-1 analyses values (a factor of ~ 5 with respect to the current combination of $b \to \bar{c}cs$ measurements). The uncertainty on the angular variable P_5' in $B^0 \to K^{*0}\mu^+\mu^-$ as a function of the dimuon squared invariant mass (q^2) is expected to improve

by a factor of 15 with respect to the published Run-1 measurements. With the HL-LHC high statistics the $B^0 \to K^{*0}\mu^+\mu^-$ analysis can be performed in narrow bins of q^2 to reach a more precise determination of the angular observables. Finally, the $\tau \to 3\mu$ decay is expected to be probed down to $\mathcal{O}(10^{-9})$.

The lack of particle-ID detectors is bound to limit the investigation of fully hadronic final states at ATLAS and CMS. Nevertheless, some capability is retained through the early use of tracking in the trigger selection. The $B_s \to \phi\phi \to 4K$ decay is an example of a hadronic final state that would benefit from the tracking performance at trigger level and the ϕ resonance signature. Furthermore, the precision time information from the timing detector [4] will bring new and unique capabilities to the detectors in the heavy flavour sector.

The heavy flavour programme at ATLAS and CMS requires dedicated low-$p_{\rm T}$ triggers, in contention for bandwidth with high-$p_{\rm T}$ measurements and searches. The physics scenario at the time of HL-LHC will motivate the optimal trigger bandwidth allocation for low-$p_{\rm T}$ studies. Indeed, considering the tenfold increase in the High Level Trigger rates and pileup mitigation, it could be conceivable to think of analysis dedicated streams to be performed with the whole 3000 fb^{-1} statistics or in dedicated runs, with minimal impact on the high-$p_{\rm T}$ physics. Still unexplored options, such as 40MHz data scouting, will be also studied. Furthermore, the high-$p_{\rm T}$ searches in ATLAS and CMS will allow for a programme of measurements which are complementary to the low-$p_{\rm T}$ flavour investigations and will help to build a coherent theoretical picture.

1.2.2 Key experimental capabilities at LHCb

The Upgrade II of LHCb will enable a very wide range of flavour observables to be determined with unprecedented precision, which will give the experiment sensitivity to NP scales several orders of magnitude above those accessible to direct searches. The expected uncertainties for a few key measurements with 300 fb^{-1} are presented in Table 1. The future LHCb estimates are all based on extrapolations from current measurements, and take no account of detector improvements apart from an approximate factor two increase in efficiency for hadronic modes, arising from the full software trigger that will be deployed from Run 3 onwards. Three principal arguments motivate the Upgrade II of LHCb, and the full exploitation of the HL-LHC for flavour physics.

1. There is a host of measurements of *theoretically clean* observables, such as the CP-violating phase γ, the lepton-universality ratios R_K, R_{K^*} etc., or the ratio of branching fractions $R \equiv \mathcal{B}(B^0 \to \mu^+\mu^-)/\mathcal{B}(B^0_s \to \mu^+\mu^-)$, where knowledge will still be statistically limited after Run 4. The same conclusion applies for other observables such as ϕ_s and $\sin 2\beta$, where strategies exist to monitor and control possible Penguin pollution. The HL-LHC and the capabilities of LHCb Upgrade II offer a unique opportunity to take another stride forward in precision for these quantities. Advances in lattice-QCD calculations will also motivate better measurements of other critical observables, e.g. $|V_{ub}|/|V_{cb}|$.
   The anticipated impact of the improved knowledge of Unitarity Triangle parameters can be seen in Fig. 1, which shows the evolving constraints in the $\bar{\rho} - \bar{\eta}$ plane from LHCb inputs and lattice-QCD calculations, alone. The increased sensitivity will allow for extremely precise tests of the CKM paradigm. In particular, it will permit the tree-level observables, which provide SM benchmarks, to be assessed against those with loop contributions, which are more susceptible to NP. In practice, this already very powerful ensemble of constraints will be augmented by complementary measurements from Belle-II, particularly in the case of $|V_{ub}|/|V_{cb}|$.
   The increasing precision of observables from measurements of statistically-limited FCNC processes will provide significant improvements in sensitivity to the scale of NP. As an example, Table 2 shows the expected improvement with integrated luminosity in the knowledge of the Wilson coefficients C_9 (vector current) and C'_{10} (right-handed axial-vector current), and the corresponding 90% exclusion limits to the NP scale Λ under various scenarios. The reach for generic NP at

Table 1: Summary of prospects for future measurements of selected flavour observables for LHCb. The projected LHCb sensitivities take no account of potential detector improvements, apart from in the trigger. See subsequent chapters for definitions.

tree-level in Upgrade II is found to exceed 100 TeV.

2. It will be essential to *widen the set of observables under study* beyond those accessible at the current LHCb experiment or its first upgrade, *e.g.* by including additional important measurements involving $b \to s\ell^+\ell^-$, $b \to d\ell^+\ell^-$ and $b \to c\ell^-\bar{\nu}_l$ decays. Improving our knowledge of the flavour sector both through better measurements and through new observables will be essential in searching for and then characterising NP in the HL-LHC era.
3. Due to its ability to reconstruct and analyze all collisions in real-time and the statistical power of the HL-LHC dataset, LHCb Upgrade II will be able to collect a unique dataset for hadronic spectroscopy. This will enable not only the precise understanding of higher-excited states of mesons and baryons, but also a detailed and broad understanding of multiquark systems, containing (or not) multiple heavy quarks, and other yet-to-be-discovered exotic states of matter. While not directly sensitive to BSM effects, these measurements will play an important role in sharpening our understanding of QCD at the energy scales relevant for flavour physics, and hence make an important contribution to the accurate interpretation of any BSM anomalies observed.

The intention to operate a flavour-physics experiment at luminosities of $10^{34}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$ is already an

Table 2: Uncertainty on Wilson coefficients and 90% exclusion limits on NP scales Λ for different data samples. The C_9 analysis is based on the ratio of branching fractions R_K and R_{K^*} in the range $1 < q^2 < 6\,\mathrm{GeV}^2/c^4$. The C'_{10} analysis exploits the angular observables S_i from the decay $B^0 \to K^{*0}\mu^+\mu^-$ in the ranges $1 < q^2 < 6\,\mathrm{GeV}^2/c^4$ and $15 < q^2 < 19\,\mathrm{GeV}^2/c^4$. The limits on the scale of NP, Λ_{NP}, are given for the following scenarios: tree-level generic, tree-level minimum flavour violation, loop-level generic and loop-level minimal flavour violation. More information on the fits may be found in [22].

Integrated Luminosity	$3\,\mathrm{fb}^{-1}$	$23\,\mathrm{fb}^{-1}$	$300\,\mathrm{fb}^{-1}$
R_K and R_{K^*} measurements			
$\sigma(C_9)$	0.44	0.12	0.03
$\Lambda^{\text{tree generic}}$ [TeV]	40	80	155
$\Lambda^{\text{tree MFV}}$ [TeV]	8	16	31
$\Lambda^{\text{loop generic}}$ [TeV]	3	6	12
$\Lambda^{\text{loop MFV}}$ [TeV]	0.7	1.3	2.5

$\sigma^{\text{stat}}(S_i)$	0.034–0.058	0.009–0.016	0.003–0.004
$\sigma(C'_{10})$	0.31	0.15	0.06
$\Lambda^{\text{tree generic}}$ [TeV]	50	75	115
$\Lambda^{\text{tree MFV}}$ [TeV]	10	15	23
$\Lambda^{\text{loop generic}}$ [TeV]	4	6	9
$\Lambda^{\text{loop MFV}}$ [TeV]	0.8	1.2	1.9

ambitious one, but the planned improvements to the detector's capabilities will extend the physics gains still further. These gains are not included in Table 1 as full simulations have not yet been performed, but a summary of the expected benefits can be found in [22]. It is intended to take first steps towards some of these detector enhancements already in LS3, before the start of the HL-LHC, thereby improving the performance of the first LHCb upgrade, and laying the foundations for Upgrade II. Finally, it must be emphasised that the raw gain in sample sizes during the HL-LHC era will have great consequences for the physics reach, irrespective of any detector improvements. The energy scale probed by virtual loops in flavour observables will rise by a factor of up to 1.9 with respect to the pre-HL-LHC era, with a corresponding gain in discovery potential similar to what will apply for direct searches if the beam energy is doubled, as proposed for the HE-LHC.

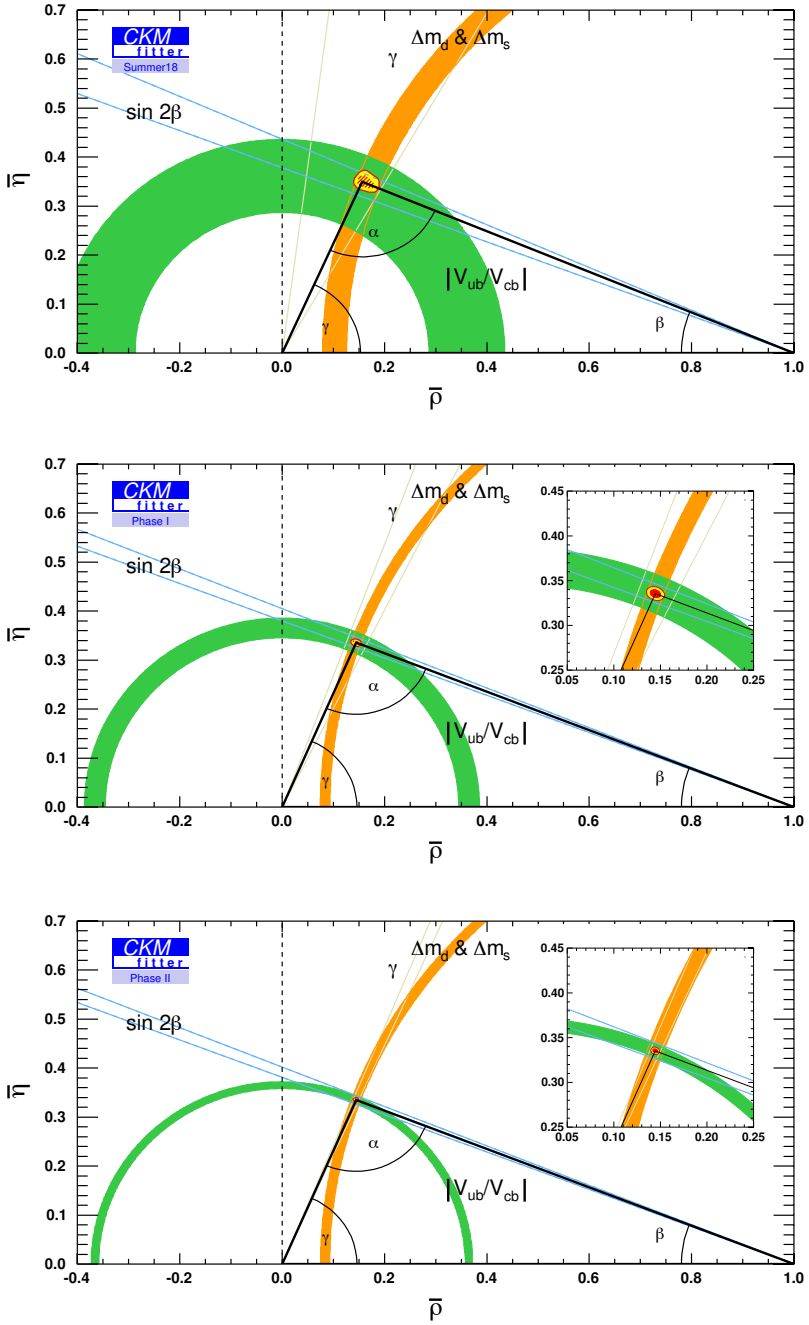

Fig. 1: Evolving constraints in the $\bar{\rho} - \bar{\eta}$ plane from LHCb measurements and lattice QCD calculations, alone, with current inputs (2018), and the anticipated improvements from the data accumulated by 2025 ($23\,\text{fb}^{-1}$) and 2035 ($300\,\text{fb}^{-1}$). More information on the fits may be found in Sec. 2 and [22].

2 Testing the CKM unitarity and related observables

Authors (TH): Jérôme Charles, Marco Ciuchini, Olivier Deschamps, Sébastien Descotes-Genon, Luca Silvestrini, Vincenzo Vagnoni.

In the SM, the weak charged-current transitions mix quarks of different generations, which is encoded in the unitary Cabibbo-Kobayashi-Maskawa (CKM) matrix [23, 24]. The SM does not predict the values of the weak flavour-couplings, and so all matrix elements must be measured experimentally. However, the unitary nature of the CKM matrix, and the assumptions of the SM, impose relations between the elements that are often expressed graphically in the complex plane as the so-called unitarity triangle. Overconstraining the apex of this unitarity triangle from tree- and loop-level quark mixing processes is therefore a powerful way to probe for virtual BSM effects at mass scales complementary or superior to those which can be directly searched for at the HL-LHC. As we shall see below, in many cases such indirect probes of BSM physics will not be limited by either experimental or theoretical systematics in the HL-LHC era.

2.1 Structure of the CKM matrix

The part of the SM Lagrangian which is relevant for describing quark mixing is

$$\mathcal{L}_{W^\pm} = -\frac{g}{\sqrt{2}} \left(V_{\rm CKM}\right)_{ij} \left(\overline{u}_i \gamma^\mu \tfrac{(1-\gamma_5)}{2} d_j\right) W^+_\mu + \text{h.c.}, \tag{2}$$

where g is the electroweak coupling constant, and $V_{\rm CKM}$ the unitary CKM matrix,

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix}. \tag{3}$$

The CKM matrix induces flavour-changing transitions inside and between generations in the charged currents at tree level ($W^\pm$ interaction). By contrast, there are no flavour-changing transitions in the neutral currents at tree level.

Experimentally, a strong hierarchy is observed among the CKM matrix elements: transitions within the same generation are characterised by $V_{\rm CKM}$ elements of $\mathcal{O}(1)$, whereas there is a suppression of $\mathcal{O}(10^{-1})$ between 1st and 2nd generations, $\mathcal{O}(10^{-2})$ between 2nd and 3rd and $\mathcal{O}(10^{-3})$ between 1st and 3rd. This hierarchy is expressed by defining the four phase convention–independent quantities,

$$\lambda^2 = \frac{|V_{us}|^2}{|V_{ud}|^2 + |V_{us}|^2}, \qquad A^2\lambda^4 = \frac{|V_{cb}|^2}{|V_{ud}|^2 + |V_{us}|^2}, \qquad \bar\rho + i\bar\eta = -\frac{V_{ud}V^*_{ub}}{V_{cd}V^*_{cb}}. \tag{4}$$

The four independent quantities, λ, A, $\bar\rho$, $\bar\eta$, fully determine the CKM matrix in the SM.

The CKM matrix can be expanded in powers of the small parameter λ (which corresponds to the Cabibbo parameter $\sin\theta_C \simeq 0.22$) [25] by exploiting the unitarity of $V_{\rm CKM}$. This expansion yields the following parametrisation, valid up to $\mathcal{O}\left(\lambda^6\right)$,

$$V_{\rm CKM} = \begin{pmatrix} 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4 & \lambda & A\lambda^3\left(\bar\rho - i\bar\eta\right) \\ -\lambda + \frac{1}{2}A^2\lambda^5\left[1 - 2(\bar\rho + i\bar\eta)\right] & 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4(1 + 4A^2) & A\lambda^2 \\ A\lambda^3\left[1 - (\bar\rho + i\bar\eta)\right] & -A\lambda^2 + \frac{1}{2}A\lambda^4\left[1 - 2(\bar\rho + i\bar\eta)\right] & 1 - \frac{1}{2}A^2\lambda^4 \end{pmatrix}. \tag{5}$$

The CKM matrix is complex, i.e., it contains a phase that cannot be rotated away, if $\bar\eta \neq 0$. Furthermore, CP is violated, if and only if $\bar\eta$ differs from zero.

Orthogonality relations can be written involving two columns or two rows of the unitary CKM matrix, and they can be represented as triangles in the complex plane. It is standard to focus on the following orthogonality relation,

$$V_{ud}V^*_{ub} + V_{cd}V^*_{cb} + V_{td}V^*_{tb} = 0, \tag{6}$$

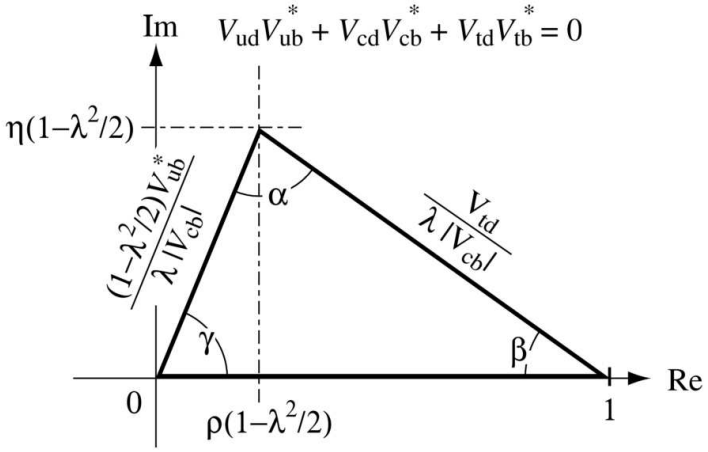

Fig. 2: The standard CKM unitarity triangle. The parameters ρ and η are defined as $\rho + i\eta = \left(\bar{\rho} + i\bar{\eta}\right)\left(1 - \lambda^2/2 + O(\lambda^4)\right)$, with $\bar{\rho}, \bar{\eta}$ defined in (4).

as the three products of CKM elements are of similar size, $\mathcal{O}(\lambda^3)$. Fig. 2 shows the standard unitarity triangle (UT), obtained from Eq. (6) by rescaling the three terms in the orthogonality relation by $V_{cd}V_{cb}^*$.

The apex of the UT is at $(\bar{\rho}, \bar{\eta})$, while the angles are related to the CKM matrix elements as

$$\alpha = \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right), \qquad \beta = \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right), \qquad \gamma \equiv \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right). \tag{7}$$

2.2 Current status of the constraints

2.2.1 $|V_{ud}|, |V_{us}|, |V_{cd}|, |V_{cs}|$

Accurate constraints on the first and second rows and columns of the CKM matrix come from leptonic decays, $\pi \to e\nu$, $K \to e\nu$, $K \to \mu\nu$, $\tau \to \pi\nu_\tau$, $\tau \to K\nu_\tau$, $D \to \mu\nu$, $D_s \to \mu\nu$, and from semileptonic decays, $K \to \pi e\nu$, $D \to \pi e\nu$, $D_s \to K e\nu$. The extraction of CKM matrix elements requires knowledge of hadronic inputs (decay constants for the leptonic decays, normalisations of the form factors at $q^2 = 0$ for the semileptonic decays) and electromagnetic/isospin corrections when available (i.e., for kaon and pion decays) [26]. Another prominent input for the $|V_{ud}|$ determination comes from the consideration of the superallowed β decays of 20 different nuclei [27–29], which provides a very accurate constraint on $|V_{ud}|$. There are also other constraints, but less powerful due to experimental uncertainties and/or theoretical systematics that are difficult to assess.

2.2.2 $|V_{cb}|$ and $|V_{ub}|$

Tree-level semileptonic decays of beauty mesons and baryons allow for the extraction of $|V_{cb}|$ and $|V_{ub}|$. The current determination is dominated by the B-factories data on B decays and by the measurement of $|V_{ub}|/|V_{cb}|$ from baryonic decays at LHCb. For B decays, both inclusive and exclusive semileptonic decays have been used to extract $|V_{cb}|$ and $|V_{ub}|$. The two approaches have different sources of theoretical uncertainties: inclusive analyses rely on quark-hadron duality, involve hadronic matrix elements in subleading powers of the heavy quark expansion and, for $|V_{ub}|$, on additional hadronic quantities called shape functions; exclusive analyses require the knowledge of the relevant form factors over the entire kinematic range, a very difficult task for lattice QCD. Currently, the HFLAV averages for inclusive and exclusive determinations of $|V_{cb}|$ and $|V_{ub}|$ disagree at the 3σ level. While recently the choice of the parameterization of the form factor dependence on the recoil for $B \to D^*$ decays has been shown to have a large impact on the extracted value of $|V_{cb}|$ [30–32], the situation is still rather unclear.

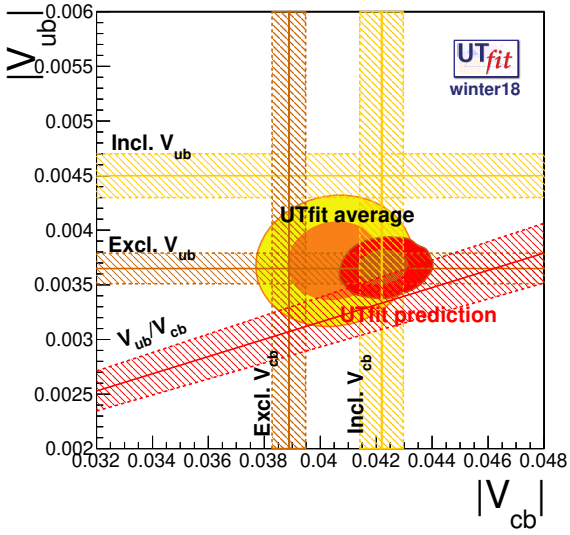

Fig. 3: Measurements of $|V_{cb}|$ and $|V_{ub}|$ from exclusive and inclusive B decays (vertical and horizontal bands) and from $\Lambda_b^0 \to p\mu^-\overline{\nu}_\mu$ and $\Lambda_b^0 \to \Lambda_c^+\mu^-\overline{\nu}_\mu$ (diagonal band), skeptical average and indirect determination of $|V_{cb}|$ and $|V_{ub}|$.

One way to deal with this, followed by the UTFit collaboration, is to assume that the uncertainty of each determination of $|V_{cb}|$ and $|V_{ub}|$ might have been underestimated, and perform a "skeptic combination" of all available data following the method of Ref. [33], which is equivalent to the PDG prescription in one dimension, and is a straightforward generalization to the two-dimensional case of $|V_{cb}|$ and $|V_{ub}|$. The result is reported in Fig. 3, where in addition to the average we also plot the "indirect determination" obtained from all the other flavour observables. The numerical results of the skeptic average are $|V_{cb}| = 0.0405 \pm 0.0011$, $|V_{ub}| = 0.00374 \pm 0.00023$, with correlation $\rho = 0.09$. CKMfitter collaboration uses instead the exclusive value for V_{cb} from $B \to D^*\ell\nu$ that was obtained using more model independent BGL parametrisation, and which is in agreement with both $B \to D\ell\nu$ and the inclusive extraction. This leads to the combined value $|V_{cb}| = (41.8 \pm 0.4(\text{exp}) \pm 0.6(\text{theory})) \cdot 10^{-3}$. For V_{ub} the CKMfitter collaboration performs an R-fit of inclusive and exclusive determinations to obtain $|V_{ub}| = (3.98 \pm 0.08(\text{exp}) \pm 0.22(\text{LQCD})) \cdot 10^{-3}$.

Lattice QCD determinations of the form factors in a large kinematic range are under way. It is expected that they will allow Belle-II to perform a much more parameterization-independent extraction of V_{cb} from exclusive decays, hopefully reconciling it with the inclusive one. Also for $|V_{ub}|$, the much larger statistics should allow to get an insight on the origin of the discrepancy between inclusive and exclusive determinations, and provide a consistent determination of $|V_{ub}|$.

2.2.3 Angle α

The constraints on the CKM angle α are derived from the isospin analysis of the charmless decay modes $B \to \pi\pi$, $B \to \rho\rho$ and $B \to \rho\pi$ [34–36]. This approach has the interesting feature of being almost free from hadronic uncertainties. Assuming isospin symmetry and neglecting the electroweak penguin contributions, the amplitudes of the isospin $SU(2)$-conjugated modes are related. The measured branching fractions and asymmetries in the $B^{\pm,0} \to (\pi\pi)^{\pm,0}$ and $B^{\pm,0} \to (\rho\rho)^{\pm,0}$ modes and the bilinear form factors in the Dalitz analysis of the neutral $B^0 \to (\rho\pi)^0 \to \pi^+\pi^-\pi^0$ decays thus provide enough observables to simultaneously extract the weak phase $\beta + \gamma = \pi - \alpha$ together with the hadronic tree and penguin contribution to each mode. The combination of the experimental data for the three decay modes above, mostly provided by the B-factories, gives the world-average value at 68% Confidence

Level (CL) [37]: $\alpha_{\rm dir} = (86.2^{+4.4}_{-4.0} \cup 178.4^{+3.9}_{-5.1})^\circ$. The experimental uncertainty is so far significantly larger than the theoretical uncertainty due to isospin $SU(2)$ breaking, which may affect the $\alpha_{\rm dir}$ determination at around 2°. The solution near 90° is in good agreement with the indirect determination obtained by the global fit of the flavour data [38].

A detailed analysis of the prospects for the CKM angle α has been performed in [37]. The global determination of α is dominated by the $B \to \rho\rho$ data, constraining α with about 5% uncertainty. Improving the measurements of the neutral modes, especially the colour-suppressed $B^0 \to \rho^0\rho^0$ decay, can have a sizeable impact. In the $B \to \pi\pi$ system any sizable improvement is driven by the increased accuracy in the measurement of the direct CP asymmetry in the colour-suppressed decay $B^0 \to \pi^0\pi^0$, potentially reachable through Dalitz decays $\pi^0 \to \gamma e^+ e^-$. However, all α measurements at subdegree precision must address isospin-breaking effects such as electroweak penguin contributions [37, 39].

2.2.4 Angle β

The CKM angle β is measured from the time-dependent CP asymmetry of $b \to c\bar{c}s$ decays, such as $B \to J/\psi K_S$. The decay amplitude, $A_{J/\psi K_S} = V_{cs}V_{cb}^* T + V_{us}V_{ub}^* P$, is dominated by the isoscalar tree-level amplitude T, while the subleading term P is both loop and doubly Cabibbo suppressed. Neglecting P, the time-dependent CP asymmetry, $a_t^{CP}(B \to J/\psi K_S) = \sin 2\beta \, \sin(\Delta m_B \, t)$, has a single oscillatory term, the amplitude of which gives experimental access to $\sin 2\beta$ (the fourfold ambiguity in β can be reduced through time-dependent transversity analysis of $B \to J/\psi K^*$, sensitive to $\cos 2\beta$). The $P = 0$ approximation is justified as long as the relative error on $\sin 2\beta$ is larger than the correction induced by the subleading term $\sim \lambda^2 P/T$. The present relative uncertainty on $\sin 2\beta$ from various charmonium states, including J/ψ / $\psi(2S)$ / χ_{c1} / η_c K_S, $J/\psi K_L$, $\psi(nS)K^0$, is about 2.4%. Double Cabibbo suppression amounts to 5% and $|P/T| < 1$ is expected. Yet the precise suppression due to P/T is unknown, likely ranging between some tens and a few percent, the latter estimate given by the perturbative estimate of the penguin amplitude. Thus, depending on the actual value of P/T, the subleading amplitude could be a limiting factor for the extraction of $\sin 2\beta$ already now or, in the opposite case, be safely neglected down to an experimental precision of few permille. In order to place a bound on the subleading amplitude, one can use $SU(3)$ flavour (or U-spin) related decays where the penguin contribution is not suppressed, such as $B_s \to J/\psi K_s$ or $B \to J/\psi\pi$ [40–45]. Measuring branching ratios and (time-dependent) CP asymmetries, it is possible to extract the correction to $\sin 2\beta$ induced by the subleading term and the corresponding uncertainty, due to the experimental errors and $SU(3)$-breaking effects. The latter, being proportional to a CKM suppressed amplitude, are expected to be at the permille level.

With present data, the typical shift in β is 0.5–1° with about 100% uncertainty, dominated by the experimental uncertainties. Improvements in the measurement of the time-dependent asymmetry in $B \to J/\psi K_S$ should therefore be accompanied by a corresponding improvement in the measurement of the control channels in order to keep the subleading amplitude under control and extract $\sin 2\beta$ with a subpercent precision. It is worth mentioning that a complemetary approach proposing a theoretical computation of the subleading amplitude using an OPE based on soft-collinear factorization in QCD can be found in Ref. [46]. Assuming that the subleading amplitude is kept under control, the uncertainty on the indirect determination of $\sin 2\beta$ from the UT analysis is expected to go from the present 4.5% down to 0.6%, providing an improved sensitivity to NP in the B–$\bar{B}$ mixing amplitude, as discussed further below.

2.2.5 Angle γ

The current best sensitivity is obtained from charged B decays into $\tilde{D}K^-$, $\tilde{D}^*K^-$, $\tilde{D}K^{*-}$, and $\tilde{D}K^-\pi^+\pi$ where $\tilde{D}$ is a D^0 or $\overline{D}^0$ meson decaying to the same final state. The D^0 is produced through the leading $b \to c$ transition, with the amplitude $\mathcal{A}_{b\to c} \propto \lambda^3$, and $\overline{D}^0$ in the CKM and colour-suppressed $b \to u$

transition, $\mathcal{A}_{b\to u} \propto \lambda^3\left(\bar{\eta}^2+\bar{\rho}^2\right)^{1/2} e^{i(\delta_B-\gamma)}$. Since D^0 and $\overline{D}^0$ decay to a common final state, the interference between the two tree amplitudes leads to observables that depend on the relative weak phase γ and results in different B^+ and B^- decay rates. The size of this interference also depends on the magnitude of the ratio of the two amplitudes, $r_B \equiv |\mathcal{A}_{b\to u}/\ \mathcal{A}_{b\to c}|$, and the relative strong phase δ_B. The value of r_B, which determines the size of the direct CP asymmetry, is predicted [47] to lie in the range 0.05–0.2. Experimental sensitivity to γ decreases with smaller r_B.

There are several different methods that exploit the above interference pattern: the Gronau-London-Wyler (GLW) method [48, 49] where the neutral D meson is reconstructed in a CP eigenstate; the Atwood-Dunietz-Soni (ADS) method [50–52] where the D^0 meson, associated with the $\mathcal{A}_{b\to c}$ amplitude, is required to decay to a doubly Cabibbo-suppressed decay (DCSD), while the $\overline{D}^0$ meson, associated with the $\mathcal{A}_{b\to u}$ amplitude, decays to a Cabibbo-favoured final state, such as $K^+\pi^-$; the Giri-Grossman-Soffer-Zupan (GGSZ) method [53] where the neutral D meson is reconstructed in self-conjugate three-body final state such as $K^0_S h^+ h^-$ (where $h = \pi$ or K). These γ extraction techniques rely on clean theoretical assumptions since the decay amplitudes are completely tree-level dominated, to an excellent approximation [54]. All variants are sensitive to the same B decay parameters and can therefore be combined in a single fit to extract the common weak phase γ, as well as the hadronic parameters associated with each method.

In addition to the above approaches, it is also possible to measure γ from time-dependent analyses of B^0 and B^0_s decays, as well as from decays of b-baryons. These methods offer significant additional sensitivity and are discussed further in Sec. 2.5.

2.2.6 Angle β_s

The angle $\beta_s = \arg\left(-V_{ts}V^*_{tb}/V_{cs}V^*_{cb}\right)$ belongs to the squeezed UT $\sum_{q_u} V^*_{q_u b}V_{q_u s} = 0$ instead of the usual $\sum_{q_u} V^*_{q_u b}V_{q_u d} = 0$. Given its reduced sensitivity to $\bar{\rho}$ and $\bar{\eta}$, it is not a strong constraint in the UT plane. On the other hand, the UT analysis provides a very precise indirect determination of its value that can be compared with the direct determination extracted from time-dependent transversality analysis of $B_s \to J/\psi\phi$. At present, we have $\beta_s^{\rm direct} = (0.60 \pm 0.88)^\circ$ and $\beta_s^{\rm UTA} = (1.06 \pm 0.03)^\circ$. The future uncertainties of the direct and indirect determinations are expected to be ± 0.01 and ± 0.007 respectively, allowing for a deeper investigation of BSM contributions to B_s–$\bar{B}_s$ mixing amplitude. It is worth noting that, similarly to the measurement of phase β, the shifts of a few degrees in the value of β_s extracted from the time-dependent analysis caused by the subleading amplitude P cannot be excluded. These shifts, however, now produce a much larger relative uncertainty, since β_s itself is doubly Cabibbo suppressed. Some control of doubly Cabibbo suppressed contributions is thus required to meaningfully extract β_s at the SM level. This can be achieved by using the $SU(3)_f$ related channels, with the additional caveat that ϕ is an (almost equal) admixture of $SU(3)_f$ octet and singlet, introducing an additional source of uncertainty.

2.2.7 $K - \bar{K}$ mixing

The CP-violating parameter ε_K, historically the first constraint in the UT plane, is becoming limited by long-distance contributions. In the last years, the improvements in the constraining power of ε_K have come from new determination of the bag parameter, B_K, on the lattice. Nowadays, the theoretical error on B_K is approaching percent level. The dominating uncertainty in the SM prediction of ε_K comes from the long-distance contributions, the best estimate of which has an error of 2% [55]. A breakthrough could come from developing ideas for computing these terms on the lattice, using recent techniques to cope with the non-local operators that were used to obtain predictions for a closely related quantity, Δm_K [56, 57].

2.2.8 $B_d - \bar{B}_d$ and $B_s - \bar{B}_s$ mixing

The dispersive and absorptive contributions to B_d and B_s mixing are described by 2×2 matrices, $M^q = M^{q\dagger}$ and $\Gamma^q = \Gamma^{q\dagger}$, respectively ($q = d, s$). They describe the quantum-mechanical evolution of the $B_q - \overline{B}_q$ system. Their diagonalisation defines the physical eigenstates $|B_H^q\rangle$ and $|B_L^q\rangle$ with masses M_H^q, M_L^q and decay rates Γ_H^q, Γ_L^q. One can reexpress these quantities in terms of three parameters: $|M_{12}^q|$, $|\Gamma_{12}^q|$ and the relative phase $\phi_q = \arg(-M_{12}^q/\Gamma_{12}^q)$. The SM prediction for the mass splitting, $\Delta m_q = M_H^q - M_L^q$, is dominated by boxes involving top quarks, and is given by

$$\Delta m_q = \frac{G_F^2}{6\pi^2} \eta_B m_{B_q} f_{B_q}^2 \hat{B}_q m_W^2 S(x_t) \left| V_{tq} V_{tb}^* \right|^2 , \tag{8}$$

with the Inami-Lim function $S(x_t)$ [58] evaluated at $x_t = \overline{m}_t^2/m_W^2$, while η_B encodes the perturbative QCD corrections, originally estimated at NLO in Ref. [59]. Using up-to-date α_s and the top-quark mass gives $\eta_B = 0.5510 \pm 0.0022$ [60]. The decay constant f_{B_q} and the so-called bag parameter, $\hat{B}_q$, parametrize the nonperturbative hadronic matrix elements.

The translation of the measured value for Δm_d into constraints on the CKM parameter combination $|V_{td}V_{tb}^*|^2$ is limited at present by uncertainties in the lattice QCD calculation of the hadronic parameters $f_{B_d}, \hat{B}_d$. The ratios f_{B_s}/f_{B_d} and $\hat{B}_s/\hat{B}_d$ are much better determined, so that $\Delta m_d/\Delta m_s$ gives a much better constraint in the $(\bar{\rho}, \bar{\eta})$ plane, see Fig. 4. The hadronic parameters, f_{B_s}, $\hat{B}_s$, as well as f_{B_s}/f_{B_d} and $\hat{B}_s/\hat{B}_d$, are set to have their errors significantly reduced by future lattice QCD computations, see Sec. 11.

2.3 Combined constraints on the CKM parameters

Due to its economical structure in terms of only four parameters the CKM matrix can be determined through many different quark transitions, both the $\Delta F = 1$ decays and the $\Delta F = 2$ neutral-meson mixing transitions. A consistent determination of the four CKM parameters from all these processes is a fundamental test of the Kobayashi-Maskawa mechanism. Extracting the information on the four CKM parameters from data poses both experimental and theoretical challenges. First of all, the SM depends on a number of other parameters, masses and couplings, which are not predicted within the SM, but rather need to also be determined experimentally. An additional difficulty relates to the presence of strong interactions, binding quarks into hadrons. This is responsible for most of the theoretical uncertainties in the determinations of CKM matrix elements.

2.3.1 Statistical approaches

The CKMfitter group determines the CKM parameters from a large set of flavour physics constraints using a standard χ^2-like frequentist approach, in addition to a specific (Rfit) scheme to treat theoretical uncertainties [61–63]. The set of experimental observables, denoted $\vec{\mathcal{O}}_{exp}$, is measured in terms of likelihoods that can be used to build a χ^2-like test statistic, $\chi^2(\vec{p}) = -2 \log \mathcal{L}(\vec{\mathcal{O}}_{exp} - \vec{\mathcal{O}}_{th}(\vec{p}))$, with $\vec{\mathcal{O}}_{th}(\vec{p})$ the theoretical values of the observables depending on N fixed parameters $\vec{p}$. The absolute minimum value of the test statistic, $\chi^2_{\rm min}$, quantifies the agreement of the data with the theoretical model, once converted into a p-value (interpreting $\chi^2(\vec{p})$ as a random variable distributed according to a χ^2 law). It is also possible to perform the metrology of specific parameters of the model, by considering the hadronic parameters $\vec{\mu}$ as "nuisance parameters" and defining the test statistic, $\Delta\chi^2(\alpha) = \min_{\vec{\mu}}[\chi^2(\alpha)] - \chi^2_{\rm min}$ [61, 64, 65]. Here, $\min_{\vec{\mu}}[\chi^2(\alpha)]$ is the value of χ^2, minimised with respect to the nuisance parameters for a fixed α value. This test statistic assesses how a given hypothesis on the true value of α agrees with the data, irrespective of the value of the nuisance parameters. Confidence intervals on α can be derived from the resulting p-value, which is computed assuming that $\Delta\chi^2(\alpha)$ is χ^2-distributed with one degree of

freedom,

$$p(\alpha) = \mathrm{Prob}(\Delta\chi^2(\alpha), N_{dof} = 1)\,, \qquad \mathrm{Prob}\Big(\Delta\chi^2, N_{dof}\Big) = \frac{\Gamma(N_{dof}/2, \Delta\chi^2/2)}{\Gamma(N_{dof}/2)}\,, \tag{9}$$

where $\Gamma(x)$ is the usual Euler factorial function, and $\Gamma(s,x)$ is the upper incomplete gamma function. Confidence intervals at a given confidence level (CL) are obtained by selecting the values of α with p-value larger than $1-$CL.

In addition to the frequentist statistical treatment outline above, the CKMfitter collaboration relies on a specific treatment of theoretical uncertainties (e.g., systematics due to uncertainties on hadronic matrix elements not scaling with the size of the sample). The current approach is the so-called Rfit [61, 64,65] model, where the theoretical parameter/observable is restricted to a range, without any possibility to exceed this range. Most of the systematic uncertainties come from lattice QCD. The CKMfitter collaboration follows the recommendations of the Flavour Lattice Averaging Group [66] and uses a specific procedure to perform the average of the lattice inputs based on the Rfit model combined with a linear addition of systematic uncertainties for the individual inputs [65].

The UTfit collaboration follows a Bayesian approach to combine the constraints in the UT plane. Bayesian statistics allows for a unified treatment of systematic and theoretical uncertainties in a scheme of "updating of knowledge" from prior to posterior distributions. Following Bayes' theorem, the unnormalized posterior probability density function (p.d.f.) for $\bar\rho$ and $\bar\eta$ (given the constraints) is,

$$f(\bar\rho, \bar\eta | \hat{\mathbf{c}}, \hat{\mathbf{f}}) \propto \mathcal{L}(\hat{\mathbf{c}} \,|\, \bar\rho, \bar\eta, \mathbf{f})\, f_0(\bar\rho, \bar\eta). \tag{10}$$

Here $\hat{\mathbf{c}} = \{c_1, c_2, \ldots, c_M\}$ is a set of measured constraints, whose theoretical expressions are given by functions $c_j(\bar\rho, \bar\eta; \mathbf{x})$ that depend on $\bar\rho$, $\bar\eta$, and a set of additional experimental and theoretical parameters $\mathbf{x} = \{x_1, x_2, \ldots, x_N\}$. The $f_0(\bar\rho, \bar\eta)$ is the prior p.d.f. for $\bar\rho$ and $\bar\eta$, assumed to be flat on the UT plane, and is multiplied by the effective overall likelihood,

$$\mathcal{L}(\hat{\mathbf{c}} \,|\, \bar\rho, \bar\eta, \mathbf{f}) = \int \prod_{j=1,\mathrm{M}} f_j(\hat{c}_j \,|\, \bar\rho, \bar\eta, \mathbf{x}) \prod_{i=1,\mathrm{N}} f_i(x_i)\, \mathrm{d}x_i\,. \tag{11}$$

The p.d.f. $f_i = \{f_1, f_2, \ldots, f_N\}$ are the prior distributions of the parameters, while $f_j(\hat{c}_j \,|\, \bar\rho, \bar\eta, \mathbf{x})$ are the conditional probabilities of $\hat{c}_j$ given $\bar\rho$, $\bar\eta$, and $\mathbf{x}$, that in the Gaussian approximation become

$$f_j(\hat{c}_j \,|\, \bar\rho, \bar\eta, \mathbf{x}) = \frac{1}{\sqrt{2\pi}\,\sigma(c_j)} \exp\left[-\frac{(c_j(\bar\rho, \bar\eta; \mathbf{x}) - \hat{c}_j)^2}{2\,\sigma^2(c_j)} \right]. \tag{12}$$

The integration in Eq. (11) is usually carried out using Monte Carlo methods. More details on the Bayesian approach of the UTfit collaboration can be found in Ref. [67].

2.3.2 Current combined constraints on the CKM parameters

From the SM global fit the CKMfitter collaboration finds for the four CKM parameters,

$$A = 0.8403^{\,+0.0056}_{\,-0.0201}, \quad \lambda = 0.224747^{\,+0.000254}_{\,-0.000059}, \quad \bar\rho = 0.1577^{\,+0.0096}_{\,-0.0074}, \quad \bar\eta = 0.3493^{\,+0.0095}_{\,-0.0071}. \tag{13}$$

The asymmetric errors come from the combination of several constraints containing both statistical and systematic uncertainties, so that the resulting χ^2 has a rather complicated asymmetric shape. The corresponding results are shown in Fig. 4. The fit shows a good overall consistency among the various constraints. The main pulls come from the kaon and charm sector, but nothing exceeds the 2-σ level, confirming the very good overall agreement of the various constraints involved here.

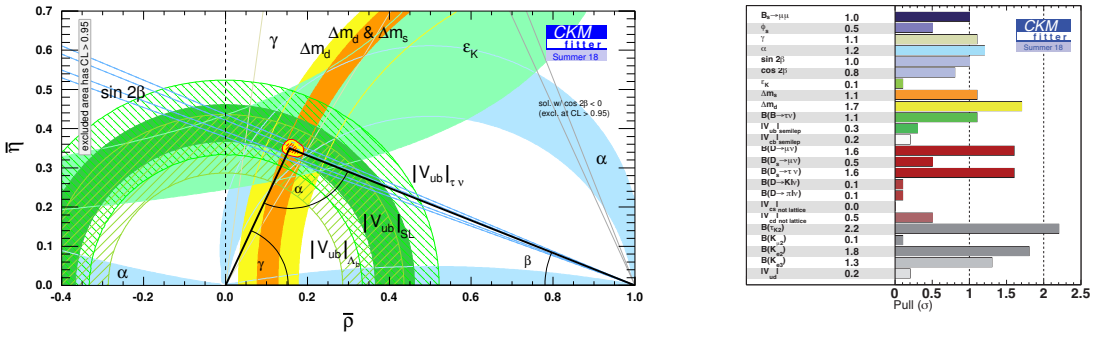

Fig. 4: Results for the CKMfitter global fit of the CKM parameters as of Summer 2018. See Ref. [38] for more detail.

Detailed input values as well as predictions for various CKM-related parameters and observables in the SM from the UTfit collaboration can be found in the Summer 2018 update page on the UTfit website [68]. The CKM matrix is determined as

$$V_{\rm CKM} = \begin{pmatrix} 0.97431(12) & 0.22514(55) & 0.00365(10)e^{-i66.8(2.0)^\circ} \\ -0.22500(54)e^{i0.0351(10)^\circ} & 0.97344(12)e^{-i0.00188(5)^\circ} & 0.04241(65) \\ 0.00869(14)e^{-i22.2(0.6)^\circ} & -0.04124(56)e^{i1.056(32)^\circ} & 0.999112(24) \end{pmatrix} . \quad (14)$$

while the Wolfenstein parameters are,

$$A = 0.826\pm, 0.012, \quad \lambda = 0.2255 \pm 0.0005, \quad \bar{\rho} = 0.148 \pm 0.013, \quad \bar{\eta} = 0.348 \pm 0.010, \quad (15)$$

in good agreement with the CKMfitter determination in (13).

2.4 Theoretical prospects

2.4.1 Lattice extrapolations

Advancement in the lattice QCD determination of hadronic matrix elements, used in the extraction of CKM elements, need to go hand in hand with the improved experimental precision. The projections on the expected errors for the most important hadronic matrix elements are discussed in detail in Sec. 11 with the main results collected in Table 41.

The accuracy of the projections below will also require an improvement in the understanding of electromagnetic corrections, which for the moment are only partially addressed in theoretical predictions. Further details on the inclusion of QED corrections in lattice predictions are discussed in Sec. 11.

2.4.2 Other theoretical issues

The determination of γ has negligible theoretical errors. In contrast, extractions of β and β_s from $b \to c\bar{c}s$ transitions receive small theoretical uncertainty from penguin diagrams. For present data the penguin contributions in $b \to c\bar{c}s$ are assumed to be negligible. However, they may compete with the statistical errors in the future. Techniques to estimate the penguin contributions from data on SU(3)-related channels are described in Sec. 2.5.10. An independent, more theory-driven, cross-check of the SU(3) approach was suggested in Ref. [46] – to use Operator Product Expansion to calculate the penguin-to-tree ratio. It is important to note that the penguin contributions in various $b \to c\bar{c}s$ channels are different, so that with increased precision of the measurements one cannot anymore average $\sin 2\beta$ from

$B \to J/\psi K_S, B \to \eta_c K_S, \ldots$, without first correcting for the penguin contributions on a channel by channel basis.

In the determination of α, the small penguin contributions are avoided using isospin symmetry. The associated theory error on α due to isospin breaking has been estimated to be at sub degree level [37]. It is neglected at present, but will need to be taken into account in significantly larger statistics samples.

An open issue is the (in)compatibility of the inclusive and exclusive determinations of $|V_{cb}|$ and $|V_{ub}|$, where a $\sim 3\sigma$ discrepancy has been observed ever since the first precise measurements. Recently, the $|V_{cb}|$ discrepancy was shown to depend significantly on the choice of the form factor parametrisation, and on the hypotheses made about the underlying heavy quark symmetry [31, 32]. Relaxing these choices leads to an exclusive determination of $|V_{cb}|$ that is in good agreement with the inclusive one, but with unexpectedly large corrections to the heavy quark symmetry predictions [69], unless one employs additional theoretical information, as shown in Ref. [70]. Lattice calculations should soon settle the matter. As for $|V_{ub}|$ no satisfying explanation of the discrepancy has been found so far. In the future more precise exclusive measurements by LHCb and Belle-II, and more precise inclusive analysis by Belle-II, should shed light on this topic by investigating whether or not it could be an experimental effect.

2.5 Experimental prospects

2.5.1 $|V_{ub}|$ and $|V_{cb}|$ from semileptonic decays

LHCb is well suited to measuring ratios of $b \to u\ell\nu$ to $b \to c\ell\nu$ decay rates, in which the unknown b production cross sections, and to some extent also efficiency corrections, cancel. LHCb reported the first study of the $\Lambda_b^0 \to p\mu^-\overline{\nu}_\mu$ and $\Lambda_b^0 \to \Lambda_c^+\mu^-\overline{\nu}_\mu$ decays with Run 1 data, which resulted in a determination of $|V_{ub}|/|V_{cb}|$ [14], exploiting precise lattice QCD calculations of the decay form factors [71, 72].

LHCb Upgrade II presents an exciting opportunity for new measurements of this type. An excellent example is an analogous analysis of $B_s^0 \to K^-\mu^+\nu_\mu$ and $B_s^0 \to D_s^-\mu^+\nu_\mu$ decays. The relatively large spectator s quark mass allows the form factors of these decays to be computed with lattice QCD to higher precision than decays of other b hadrons. There are also good prospects to extend the approach of [14], with a single q^2 bin, to perform a differential measurement in many fine bins of q^2 [73], which clearly demands substantially larger sample sizes. Furthermore, there are several reasons to expect that, compared to the study of Λ_b^0 decays [14], far larger luminosities are required for the ultimate precision with B_s^0 decays. Firstly, the $B_s^0 \to K^-\mu^+\nu_\mu$ signal rate is roughly one order of magnitude smaller compared to $\Lambda_b^0 \to p\mu^-\overline{\nu}_\mu$. Secondly, the $B_s^0 \to K^-\mu^+\nu_\mu$ decay is subject to backgrounds from all b meson species, whereas $\Lambda_b^0 \to p\mu^-\overline{\nu}_\mu$ is primarily contaminated by other Λ_b^0 decays. Thirdly, the $B_s^0 \to K^-\mu^+\nu_\mu$ decay rate is further suppressed with respect to $\Lambda_b^0 \to p\mu^-\overline{\nu}_\mu$ at the higher q^2 values at which the lattice QCD uncertainties are smallest.

LHCb Upgrade II should also include several potential gains in the detector performance which are highly relevant to the reconstruction of decays like $B_s^0 \to K^-\mu^+\nu_\mu$. The key variable which distinguishes the signal from background processes is the *corrected mass*, which depends on the reconstructed line-of-flight between the primary vertex (PV) and the B_s^0 decay vertex. It is the resolution on this direction which dominates the corrected mass resolution. The removal, or further thinning, of the RF foil is therefore a very appealing prospect, since this would reduce the multiple scattering contribution to the corrected mass resolution. Fig. 5 shows the potential gain in effective luminosity that can be achieved by reducing the RF foil thickness. This analysis only considers the effect of the improved corrected mass resolution, while further improvements are expected in the selection efficiency, purity and q^2 resolution.

The dominant systematic uncertainty in the Λ_b^0 analysis [14] (material budget and its effect on the charged hadron reconstruction efficiency) can be tightly constrained with new methods, the performance of which will be greatly enhanced by any reduction in the RF foil. The lattice QCD form factors are most precise at large q^2 values, which correspond to low momentum kaons that are not efficiently identified with the RICH approach of the current detector. The low momentum particle identification (PID) per-

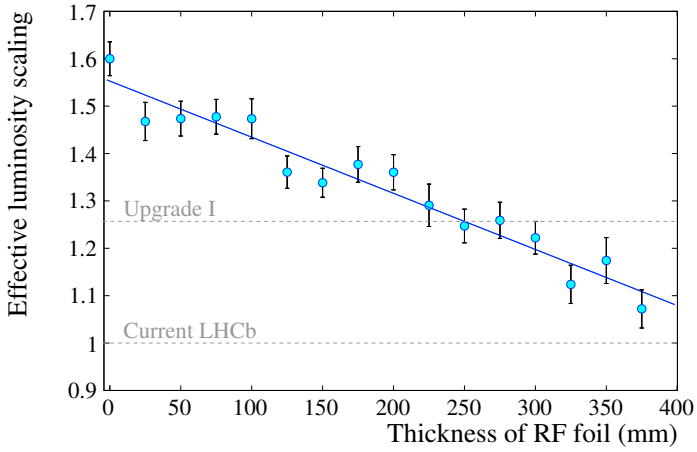

Fig. 5: The factor by which the effective luminosity in LHCb would be increased in an analysis of $B_s^0 \to K^-\mu^+\nu_\mu$ decays, as a function of the thickness of the RF foil. This factor is defined to be with respect to the vertex resolution of the current detector. It is determined using pseudo experiments in which the $B_s^0 \to K^-\mu^+\nu_\mu$ signal yield is extracted through a likelihood fit to the corrected mass distribution. The other parameters affecting the vertex resolution are assumed to be the same as in the upgraded LHCb detector, which will have a baseline foil thickness of 250 μm.

formance of the proposed TORCH detector would greatly enhance our capabilities with $B_s^0 \to K^-\mu^+\nu_\mu$ decays at high q^2.

The combination of these detector improvements with the LHCb Upgrade II data set is expected to reduce the experimental systematic uncertainties on $|V_{ub}|/|V_{cb}|$ to the 0.5% level. External branching ratio uncertainties will also be greatly reduced at the BESIII experiment. For example, $\mathcal{B}(D_s^+ \to K^+K^-\pi^+)$ will be determined at the 1% level, translating to a $\sim 0.5\%$ uncertainty on $|V_{ub}|/|V_{cb}|$. Combined with the differential shape information of the signals and continued improvements to the lattice calculations this will lead to a $|V_{ub}|/|V_{cb}|$ measurement uncertainty of less than 1% with the LHCb Upgrade II data set.

LHCb Upgrade II will allow several currently inaccessible decays, not least those of the rarely produced B_c^+ mesons, to be studied in detail. A prime example is the decay $B_c^+ \to D^0\mu^+\nu_\mu$, which is potentially very clean from a theory point of view, once lattice QCD calculations of the form factor become available. Approximately 30,000 reconstructed candidates can be expected with the 300 fb^{-1} LHCb Upgrade II data set, which could lead to a competitive measurement of $|V_{ub}|$ in this, currently unexplored, system. Purely leptonic decays, such as $B^+ \to \mu^+\mu^-\mu^+\nu_\mu$, will also become competitive, with similar signal yields, and can provide information on the B-meson light cone distribution amplitude, which is a crucial input to the widely used theoretical tool of QCD factorisation [74, 75].

The standalone determination of $|V_{cb}|$ will also be increasingly important when other measurements get more precise, as it will become the limiting factor in many SM predictions such as the branching fraction of $B_s^0 \to \mu^+\mu^-$ [76], as well as $K \to \pi\nu\bar{\nu}$, and for ϵ_K. The current uncertainty is inflated due to the disagreement between measurements from inclusive and exclusive final states and currently appears to critically depend on the parametrisation used to fit the form factors [31, 32]. LHCb has already performed a measurement of the differential rate of the decay $\Lambda_b^0 \to \Lambda_c^+\mu\nu$, allowing a determination of the form factors of that decay [77]. A first determination of the absolute value of $|V_{cb}|$, exploiting theoretical predictions for the ratios of semileptonic decay widths between different b hadron species [78], is in progress. The LHCb Upgrade II data set would provide large samples of exclusive $b \to c\ell\nu$ decays, with the full range of b hadron species, with which very precise shape measurements could be performed,

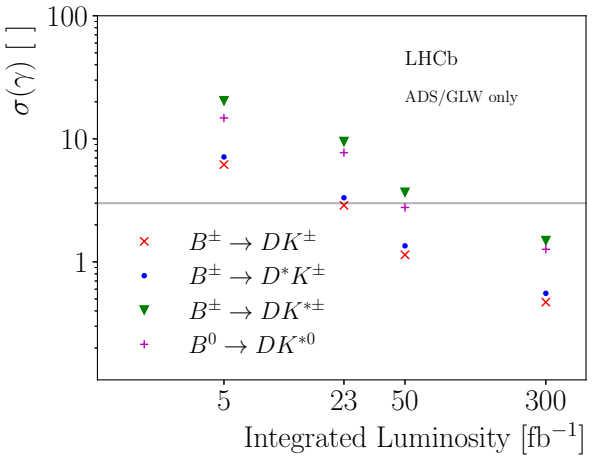

Fig. 6: Extrapolation of γ sensitivity from the ADS/GLW analyses at LHCb, ignoring disfavoured ambiguities. The expected Belle-II precision on γ at an integrated luminosity of 50 ab^{-1} is shown by the horizontal grey line.

as a crucial ingredient to reach the ultimate precision on $|V_{cb}|$.

2.5.2 Time-integrated tree-level measurements of γ

LHCb has observed and studied two-body ADS/GLW modes during Run 1 and Run 2 [79, 80]; all ADS/GLW asymmetries are statistically limited. The systematic uncertainties are small and arise predominantly from sources that will naturally decrease with increasing data, notably knowledge of instrumentation asymmetries. Methods for measuring and correcting for the B-meson production asymmetry and the $K^\pm/\pi^\pm$ reconstruction asymmetries are established using calibration samples; such samples will continue to be collected. The dominant systematic uncertainties for GLW decays are due to background contributions from $\Lambda_b^0 \to \Lambda_c^+ K^-$ decays and charmless decays, while the dominant uncertainty for ADS decays arises from the $B_s^0 \to \overline{D}^0 K^- \pi^+$ background. All will be better determined with dedicated studies as the sample size increases.

LHCb is expanding the ADS/GLW technique to the other $B \to DK$ decays, which share the same quark-level transition. An analysis of GLW observables in $B^\pm \to D^{*0}K^\pm$ decays has been developed for the case where the D^{*0} vector meson is not fully reconstructed [80]. This partial reconstruction has larger background uncertainties but these will improve with more data as dedicated studies of the background are performed. Furthermore, ADS/GLW analyses have been developed and published in quasi-two-body modes, $B^\pm \to DK^{*\pm}$ [81] and $B^0 \to DK^{*0}$ [82]. As in the case of $B^\pm \to D^{(*)0}K^\pm$ decays, these modes have no limiting systematic and they will make competitive contributions with the Upgrade II data sets.

Under the assumption that systematic uncertainties decrease in parallel with the statistical uncertainties as $\propto 1/\sqrt{\mathcal{L}}$, the future precision on γ is predicted in Fig. 6. Fig. 6 uses central values and uncertainties in the published analyses of $B^\pm \to DK^\pm$, $B^\pm \to DK^{*\pm}$ and $B^0 \to DK^{*0}$ decays. For $B^\pm \to D^{*0}K^\pm$ both the partial and full reconstruction techniques are used in this study albeit with unpublished central values and uncertainties.

For the GGSZ family of measurements, the model-independent method is expected to be the baseline for LHCb Upgrade II , and its uncertainty is currently statistically dominated. Although systematic uncertainties will already become significant compared to the statistical uncertainty in Run 3, studies performed so far give confidence that the systematic uncertainties will generally scale with the statistical reach well into the Upgrade II period. An example of the bin definitions and expected per-bin asymme-

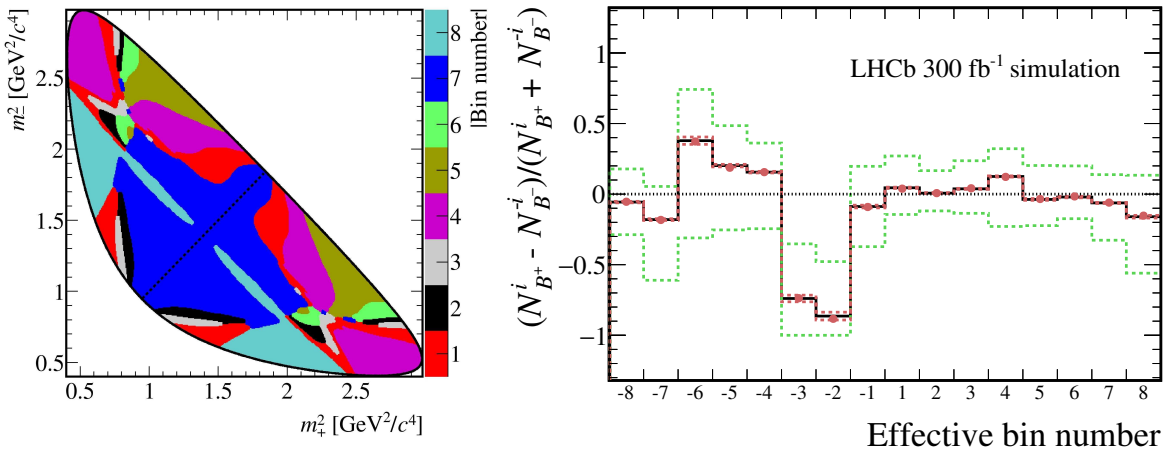

Fig. 7: (Left) Bin definitions for $D \to K^0_S\pi^+\pi^-$ as a function of m^2_- and m^2_+, the invariant masses squared of the $K^0_S h^-$ and $K^0_S h^+$. (Right) Asymmetry between yields for $B^\pm \to DK^\pm$ decays, with $D \to K^0_S\pi^+\pi^-$ in bin i (for B^+) and $-i$ (for B^-). The data points are obtained from simulation with the expected sample size at 300 fb^{-1}, assuming the current performance of the LHCb experiment. The black histogram shows the predicted asymmetry based on the current world average values of γ and relevant hadronic parameters, the red dots show the result of a single pseudoexperiment, while the red bands show the expected uncertainties from an ensemble. The green bands show the corresponding uncertainties with the current LHCb data set.

tries in LHCb Upgrade II can be seen in Fig. 7.

The largest systematic uncertainty is due to the precision of the external strong-phase inputs coming from the CLEO-c data which currently contribute approximately 2° to the overall uncertainty on γ [83]. The impact of this uncertainty on GGSZ measurements is estimated in Fig. 8 which compares a $\sqrt{N}$ improvement with the expected yield increase and the projected uncertainty if the current external information on c_i and s_i is not improved. It can be seen that this starts to approach a limit originating from the fixed size of the quantum-correlated charm input from CLEO-c. This contribution will naturally decrease with larger $B^\pm \to D^0K^\pm$ samples, however, as the B decays themselves also have sensitivity to c_i and s_i. Studies performed using pseudoexperiments with different size quantum correlated D samples and LHCb B data suggest that the optimal sensitivity is only reached when the size of the input D sample is at least as big as the overall B sample. More precise measurements with data already recorded by the BESIII experiment will be able to reduce the external contribution to the uncertainty by around 50% but analysis of future larger data sets with BESIII and at LHCb will be vital in order to avoid the external input compromising the ultimate sensitivity to γ.

The current second largest source of systematic uncertainty comes from the knowledge of the distribution of D decays over the Dalitz plane in the flavour-specific B final state, with reconstruction and efficiency effects incorporated. These are determined with a flavour-specific control decay mode $B^0 \to D^{*\pm}\mu^\mp\nu_\mu X$, where the D^{*-} decays to $\overline{D}^0\pi^-$ and X represents any unreconstructed particles. The ultimate systematic uncertainty is particularly sensitive to data-simulation agreement and size of simulated samples because of a need to model unavoidable differences in the signal and control modes. Fast simulation techniques which are being deployed and further developed at LHCb will therefore be crucial for keeping up with the large data samples, while a fully software-based trigger will allow for a better alignment of the signal and control channel selections compared to today. Uncertainties from sources such as low mass backgrounds can be expected to remain subdominant with higher statistics, as further studies will give better understanding to their rates and shapes. Some additional complications

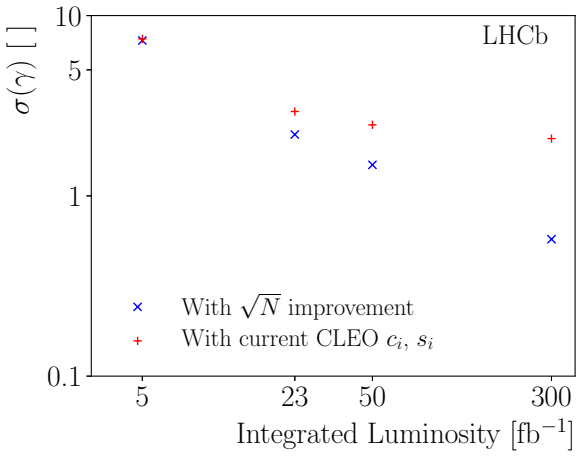

Fig. 8: Expected evolution of γ sensitivity with (red crosses) current CLEO inputs and with (blue x-marks) $\sqrt{N}$ improvements on their uncertainty.

will present themselves as the yields will eventually be high enough that it will become necessary to take into account effects induced from asymmetries in the K^0_S system, and eventually through mixing in the D^0 system. However these are tractable problems, and studies have already been done to understand when these effects will become important.

There are many prospects for adding orthogonal information on γ by applying the ADS/GLW and GGSZ techniques to modes that have an additional π^0. The first use of π^0 mesons in an LHCb γ analysis occurred with the Run 1 ADS/GLW analysis of $B^\pm \to DK^\pm$ decays with $D \to K\pi\pi^0$, $KK\pi^0, \pi\pi\pi^0$ final states [84]. The $K\pi\pi^0$ and $\pi\pi\pi^0$ modes have branching fractions 3 and 10 times larger than their two-body equivalents. However, the π^0 reconstruction+selection efficiency in these decays is low, around 3% with the current calorimeter. Also the analysis is complicated by a combinatorial background arising from random π^0 association. Improvements to the Upgrade II calorimeter granularity and energy resolution will therefore be crucial in achieving the ultimate sensitivity with these modes, especially by improving the resolution of merged π^0, their separation for photons, and improving the π^0 mass resolution.

An important mode under development for the upgrade era is $B^\pm \to D^{*0}K^\pm$ decays, with $D^{*0} \to D^0\pi^0$ and $D^{*0} \to D^0\gamma$ decays. These twin modes provide an excellent sensitivity to γ as an exact phase difference between the two D^{*0} modes can be exploited [85]. For this case, the efficient distinction of π^0 and γ calorimeter objects is critical as the two D^{*0} modes exhibit opposite CP asymmetries. The initial studies show small, but clean signals. As long as the fully and partially reconstructed data sets are kept statistically independent, the final sensitivity from $B^\pm \to D^{*0}K^\pm$ decays will be around 0.5° as seen in Fig. 6.

A GGSZ-like analysis of $B^\pm \to D[\to K^0_s\pi\pi\pi^0]K^\pm$ decays has recently been proposed for Belle II, where a sensitivity approaching that of the $D \to K^0_s\pi\pi$ GGSZ analysis is expected [86]. With improved π^0 efficiency, LHCb Upgrade II can exploit this mode competitively. Lastly, higher π^0 efficiency will merit the analysis of $B^\pm \to DK^{*\pm}[\to K^\pm\pi^0]$ decays. The π^0 reconstruction efficiency is typically a factor 3-4 lower than that of the K^0_S so the $K^0_S\pi^\pm$ mode is preferred. However the $B^\pm \to DK^\pm\pi^0$ Dalitz analysis for γ should share many advantages of the isospin-conjugate decays $B^0 \to DK^+\pi^-$ analysis (discussed next) but with reduced B^0_s feed down and large asymmetries in the ADS-like region of the Dalitz space.

Analogously to the neutral modes, a variety of high-multiplicity B and D modes are already being established and will play an important role in a future determination of γ. The most developed multi-body B decay channel is $B^0 \to DK^+\pi^-$ decays, where the D meson is found in an ADS/GLW-like

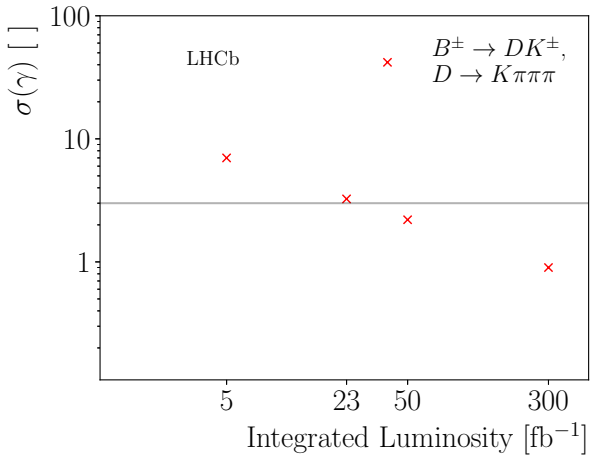

Fig. 9: Projected sensitivity to γ from a binned analysis of $B^\pm \to D[\to \pi K\pi\pi]K^\pm$ decays. The expected Belle-II precision on γ at an integrated luminosity of 50 ab^{-1} is shown by the horizontal grey line.

($K\pi$, KK, $\pi\pi$, $K3\pi$, ...) or GGSZ-like ($K^0_S\pi\pi$, $K^0_S KK$, ...) final states. These modes are less abundant than the equivalent $B^\pm$ modes but the fact that both the $b \to c\bar{u}s$ and $b \to u\bar{c}s$ transitions proceed by colour-suppressed amplitudes means the GLW asymmetries can be very large. Furthermore, understanding the pattern of asymmetry across the B^0 Dalitz plane quashes the trigonometric ambiguities. This analysis has been established with the KK and $\pi\pi$ modes using Run 1 data in Ref. [87] after the development of the $B^0 \to \overline{D}^0 K^+\pi^-$ amplitude model [88]. Although the statistical sensitivity to CP violation using Run 1 data alone was not significant, the method remains promising for future analysis given the high value of r_B in this mode (~ 0.25). The extension to $B^0 \to D[\to K^0_S\pi^+\pi^-]K^+\pi^-$ decays is of particular importance as it allows for a so-called "double Dalitz" model-independent analysis to be performed [89, 90]. Extrapolating yields from a Run 1 $B^0 \to D^0 K^{*0}$ analysis to a dataset corresponding to an integrated luminosity of 23 fb^{-1}, sensitivity studies indicate that a precision on γ of 3° can be expected [91], thus by extension, a sub-degree precision is expected for Upgrade II. Another high-multiplicity mode that holds promise is $B^\pm \to DK^\pm\pi^+\pi^-$, which has been studied with Run 1 data with two-body D decays [92], though due to the unknown Dalitz structure of the B decay a much larger dataset is needed to fully exploit this mode.

Another exciting extension to the standard ADS technique uses $B^\pm \to D[\to \pi K\pi\pi]K^\pm$ decays where the five-dimensional (5D) Dalitz volume of the D decay is split into bins. Excellent sensitivity to γ is achieved as long as the D-system parameters (r_D, δ_D, κ) in each bin are known. An optimal binning scheme is soon to be defined from the amplitude analysis of the suppressed and favoured $D^0 \to \pi K\pi\pi$ and $D^0 \to K\pi\pi\pi$ decays [93]. The expected sensitivity is shown in Fig. 9. An additional irreducible uncertainty from the D system measurements of $< 1^\circ$ is expected.

Other multibody D decays are under development with reciprocal charm-system measurements underway: a $B^\pm \to D[\to 4\pi]K^\pm$ analysis can build on the D-system knowledge gathered in Ref. [94]; an ADS analysis of $B^\pm \to D[\to K^0_S K\pi]K^\pm$ decays has been demonstrated with Run 1 [95]; and work on $B^\pm \to D[\to KK\pi\pi]K^\pm$ decays is envisaged.

2.5.3 Time-integrated loop-level measurements of γ

There are numerous methods that allow the extraction of CKM information by combining amplitude measurements made in different decay channels, in particular the $B^0_{(s)} \to K^0_S h^+h^-$, $B^0_{(s)} \to h^+h^-\pi^0$, and $B^+ \to h^+h^+h^-$ families. Some such methods exploit the interference between various $K^*\pi$ or ρK con-

tributions, which can be related using isospin symmetry [96–101]. Constructing such relations enables the determination of the angle γ, up to corrections for contributions from electroweak penguins. These methods are particularly promising when using decays such as $B_s^0 \to K_S^0\pi^+\pi^-$ and $B_s^0 \to K^-\pi^+\pi^0$, since here the electroweak penguin contributions are expected to be negligible. Other methods use the whole Dalitz plot amplitude and relate numerous decays via flavour symmetries [102–104] or exploit interference between the charmless decays and those that proceed via intermediate charmonium states such as $B^+ \to \chi_{c0}\pi^+$ [105, 106].

Extrapolating the observed yields in Ref. [107] to the data sample expected to be collected at the end of LHCb Upgrade II gives signal yields of between 1.2 and 36 million depending on the $B^+ \to h^+h^+h^-$ final state. These can be compared to an extrapolation of the yields obtained by the B factories [108, 109] to the expected 50 ab^{-1} sample to be collected by Belle II, which gives approximately 47,000 to 660,000 events for the same range of modes. The far larger yields, combined with the much better signal to background ratios, mean that LHCb will continue to dominate the precision in these modes.

Amplitude analyses cannot benefit from cancellations of systematic effects to the same degree as the binned measurements of asymmetries performed in Ref. [107], and are more likely to become systematically limited. On the other hand, the extremely large $B^+ \to h^+h^+h^-$ signal samples will allow new information to be extracted. In particular, by performing coupled-channel analyses of these decay modes, contributions from $\pi^+\pi^- \leftrightarrow K^+K^-$ rescattering processes can be better understood and constrained. The development of such new, improved models will also be of enormous benefit to analyses of many other decay modes, such as the closely related $B \to K_S^0h^+h^-$ and $B \to h^+h^-\pi^0$ families. This will help to reduce the corresponding uncertainty on the CKM phases that can be determined from those channels.

2.5.4 Time-dependent measurements of γ

Using Run 1 data, LHCb has determined the $B_s^0 \to D_s^\mp K^\pm$ oscillation parameters, which determine $\gamma - 2\beta_s$, from a sample of about 6000 signal decays [7]. From the measured parameters, a value of γ of $(128^{+17}_{-22})^\circ$ (modulo 180°) is determined. The result is dominated by statistical uncertainties thanks to the wide use of data-driven methods to determine the decay-time acceptance and resolution, and to calibrate the flavour tagging. The systematic uncertainties are, in decreasing order of importance, related to background from b-hadron decays, to uncertainty on the value of Δm_s, to the calibration of the decay-time resolution and to the flavour tagging. The first contribution can be significantly reduced by a tighter signal selection or by using a different fitting approach; the remaining contributions are expected to scale with the statistics accumulated due to their data-driven nature.

In the case of $B^0 \to D^\mp\pi^\pm$ decays, the smallness of the ratio of amplitudes, $r_{D\pi}$, which limits the sensitivity to S_f and $S_{\bar{f}}$, is compensated for by a large signal yield. About 480 000 flavour-tagged signal decays are available in the Run 1 LHCb data sample [110]. Analysis of this sample gives measurements of S_f and $S_{\bar{f}}$ that are more precise than those from BaBar and Belle [111, 112]. Also in this case the precision is limited by the statistical uncertainty. The dominant sources of systematic uncertainty, such as due to knowledge of Δm_d and of background subtraction, are expected to be reducible with larger samples.

In $B^0 \to D^\mp\pi^\pm$ decays there are only two observables, S_f and $S_{\bar{f}}$, that depend on three unknown quantities, $r_{D\pi}$, $\delta_{D\pi}$ and $2\beta + \gamma$. External input must thus be used to obtain a constraint on $2\beta + \gamma$. A common approach is to determine $r_{D\pi}$ from the branching fraction of $B^0 \to D_s^+\pi^-$ decays, assuming SU(3) symmetry,

$$r_{D\pi} = \tan\theta_c \frac{f_{D^+}}{f_{D_s}} \sqrt{\frac{\mathcal{B}(B^0 \to D_s^+\pi^-)}{\mathcal{B}(B^0 \to D^-\pi^+)}}\,, \tag{16}$$

where $\tan\theta_c$ is the tangent of the Cabibbo angle and f_{D^+}/f_{D_s} is the ratio of decay constants. Using the resulting value of $r_{D\pi} = 0.0182 \pm 0.0012 \pm 0.0036$, where the second uncertainty accounts for

Table 3: Expected statistical uncertainties from LHCb on parameters of $B_s^0 \to D_s^{\mp} K^{\pm}$ and $B^0 \to D^{\mp}\pi^{\pm}$ decays.

possible nonfactorisable SU(3)-breaking effects [113], the intervals $|\sin(2\beta+\gamma)| \in [0.77, 1.00]$ and $\gamma \in [5, 86]^\circ \cup [185, 266]^\circ$ are obtained, at the 68% CL. The uncertainties on $r_{D\pi}$ and β have negligible impact on these intervals, as the dominant uncertainties are from the S_f and $S_{\bar{f}}$ measurements.

The expected statistical sensitivities for the CP violation parameters in $B_s^0 \to D_s^{\mp} K^{\pm}$ and $B^0 \to D^{\mp}\pi^{\pm}$ decays are shown in Table 3. These are based on scaling of yields, and as such assume that the same detector performance as achieved in Run I can be maintained. In particular, the sensitivity depends strongly on the performance of the particle identification, decay time resolution and flavour tagging. The results can be complemented by studies of the related $B_s^0 \to D_s^{*\mp} K^{\pm}$ and $B^0 \to D^{*\mp}\pi^{\pm}$ channels. In particular, the $D^{*\mp}\pi^{\pm}$ mode has an all charged final state, and with a possible gain in the acceptance of slow pions from D^* decays from the addition of magnet side stations, comparable precision to that for $B^0 \to D^{\mp}\pi^{\pm}$ may be possible.

The corresponding expected sensitivities of γ from $B_s^0 \to D_s^{\mp} K^{\pm}$ decays are about 4°, 2.5° and 1° after collecting 23, 50 and 300 fb^{-1}, respectively. It is more challenging to estimate the constraints on $\sin(2\beta+\gamma)$ and γ from $B^0 \to D^{\mp}\pi^{\pm}$ decays, since the precision of the external value of $r_{D\pi}$ will become the dominant source of systematic uncertainty. Theoretical advancements on understanding the nonfactorisable SU(3)-breaking effects are thus required.

LHCb has measured the CP violation parameters in $B^0 \to \pi^+\pi^-$ and $B_s^0 \to K^+K^-$ decays ($C_{\pi^+\pi^-}$, $S_{\pi^+\pi^-}$, $C_{K^+K^-}$, $S_{K^+K^-}$ and $A_{K^+K^-}^{\Delta\Gamma}$) using the full sample of pp collisions collected during Run 1 corresponding to 3.0 fb^{-1} of integrated luminosity [114]. The results are reported in Table 4, together with the projections of the statistical uncertainties to larger samples. The scaling of statistical uncertainties assumes the same detector performances as in Run 1, in particular regarding the flavour tagging, the decay-time resolution and the particle identification performance, which are particularly important for the determination of these observables. The main sources of systematic uncertainties are due to limited knowledge of: the variation of the selection efficiency as a function of the B_q meson decay time, the parameters Γ_s and $\Delta\Gamma_s$, and the calibration of the decay-time resolution. The evaluation of these uncertainties is based on the study of control modes, and hence they are expected to decrease in a statistical manner as the available sample size grows.

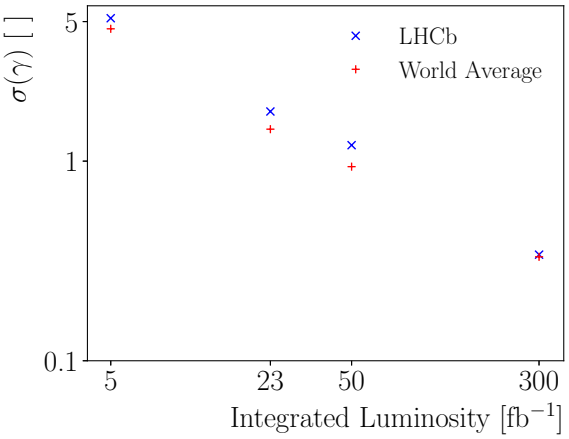

Fig. 10: Projected sensitivity for the LHCb γ combination with the currently used strategies and the world average using projections from Belle II in addition.

2.5.5 Gamma combination and impact of external inputs

Projections for the expected precision of the LHCb γ combination are shown in Fig. 10, estimating the uncertainty on γ to be 1.5° and 0.35° with 23 fb^{-1} and 300 fb^{-1} data samples, respectively. The LHCb projections assume that the statistical uncertainty scales with the data sample size and include the effect of the increased centre-of-mass energy, increased trigger performance and increased integrated luminosity. Most of the systematic uncertainties are driven by the size of the data samples and corresponding simulation samples. The overall sensitivity is predominantly driven by the GLW modes which provide the narrowest solutions for γ. The dominant systematic uncertainty for these modes will depend on knowledge of both the shape and rate of the background from $\Lambda_b^0 \to \Lambda_c^+ K^-$, as well as uncertainties arising from particle identification calibration and instrumental charge asymmetries. In order to obtain the best possible precision on γ it will be necessary to ascertain the correlation of these uncertainties between different GLW modes. The ultimate sensitivity to these modes from Belle II will be considerably less than that at LHCb, however detailed analysis from both experiments will provide an important cross check. For decays with neutrals in the final state, particularly the *CP*-odd GLW mode with $D^0 \to K_S^0 \pi^0$, the LHCb detector has considerable disadvantages over Belle II. These would be mitigated by an improved electromagnetic calorimeter for the LHCb Upgrade II. The GGSZ modes are a powerful way to unambiguously resolve the multiple solutions of the GLW method and furthermore offer considerable standalone sensitivity to γ. Accurate knowledge of the selection efficiency across the Dalitz plane is vital for these modes and contributes a considerable systematic uncertainty. This will naturally reduce with larger datasets as it is obtained via semi-leptonic $B^0 \to D^{*+}\mu^-\overline{\nu}_\mu X$ control modes but requires large simulation samples. More precise measurement of important external parameters, particularly c_i and s_i from BESIII, will be required to reduce the uncertainty associated with the model independent GGSZ method. The uncertainties of inputs from charm threshold data collected by CLEO-c will begin to limit the sensitivity by the end of Run 2, so it is essential to work together with BESIII to provide updated measurements for the suite of charm decays and $D \to K_S^0 h^+ h^-$ in particular. Provided that the charm inputs are improved sub-degree level precision on γ is attainable. Understanding the correlations between different B decay modes that all use these external parameters will be vitally important as they are likely to contribute one of the largest overall systematic uncertainties in the combination. A comparison between the current LHCb GGSZ and GLW/ADS measurements [80, 115] with their future projections at 300 fb^{-1} is shown in Fig. 11. The order of magnitude increase in precision is very apparent and the importance of the combination clear, given the multiple ambiguous solutions for GLW/ADS measurements is not resolved with increased luminosity.

The GGSZ modes are considered the *golden modes* at Belle II and drive the overall uncertainty on

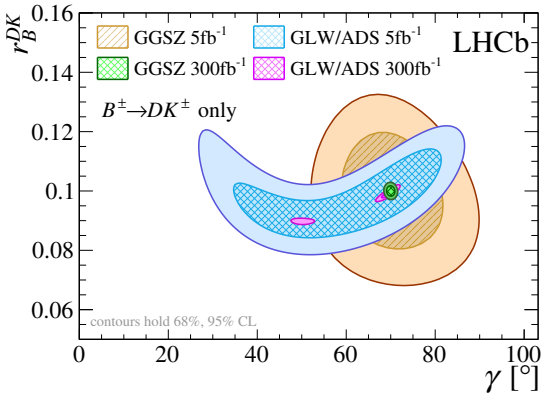

Fig. 11: Comparison between the current LHCb 3-body GGSZ and 2-body GLW/ADS measurements alongside their future projections with 300 fb^{-1} in the plane of γ vs. r_B^{DK} (note the curtailed y-axis for r_B^{DK}). The scan is produced using a pseudo-experiment, centred at $\gamma = 70^\circ$, $r_B^{DK} = 0.1$, with $B^\pm \to DK^\pm$ decays only.

γ which is expected to reach 1.5° with a data sample of $50\ \mathrm{ab}^{-1}$. This is comparable to the sensitivity that the LHCb γ combination will achieve with a data sample corresponding to approximately $23\,\mathrm{fb}^{-1}$. Subsequently input from Belle II will still contribute towards the world average by the end of Run 4 but LHCb will dominate γ measurements with Upgrade II ($300\,\mathrm{fb}^{-1}$) contributing entirely towards a world average precision of $\sim 0.35^\circ$. It should be emphasised that this projection includes only the currently used strategies, and does not include improvements from other approaches. A comparison between the projected uncertainties for LHCb and the world average as a function of integrated luminosity is shown in Fig. 10.

2.5.6 *Determinations of Δm_s, Δm_d, and interplay with b-hadron lifetimes*

The world-leading measurements of both Δm_d and Δm_s are from LHCb [116, 117], and can be improved further assuming that good flavour tagging performance can be maintained. This will not only reduce systematic uncertainties in CP-violation measurements but also provide a strong constraint on the length of one side of the unitarity triangle, although progress here is mainly dependent on improvements in lattice QCD calculations. The decay-time-dependent angular analysis of $B_s^0 \to J/\psi\,\phi$ allows measurement of $\Delta\Gamma_s$ simultaneously with CP-violation parameters. Therefore, improved knowledge of $\Delta\Gamma_s$ will be obtained together with measurements of $\phi_s^{c\bar{c}s}$. Precision at the LHC is expected not to be systematically limited. The LHCb Upgrade II will allow to exploit measurements in various channels. ATLAS and CMS projections in the $B_s \to J/\psi\,\phi$ decay mode can be found in 2.5.8.1. For theory predictions of $\Delta\Gamma_s$ see Ref. [118].

Width differences between different types of b hadrons, such as $\Gamma_s - \Gamma_d$, are also of interest. They test the heavy-quark expansion, used to make theoretical predictions. In addition, their precise knowledge is important to control systematic uncertainties in measurements where a decay mode of one type of b hadron is used as a control channel in studies of a decay of another. Detailed understanding of acceptances is necessary for such measurements, which can be achieved using topologically similar final states (see, e.g., Ref. [119]). These measurements are therefore expected to be significantly improved with LHCb Upgrade II.

2.5.7 *Semileptonic asymmetries and prospects for $\Delta\Gamma_d$*

Semileptonic decays, being flavour specific, provide a unique probe of B_q^0, where $q = s, d$, meson mixing phenomena. In particular, CP violation in B_q^0 meson mixing can be expressed through the semileptonic

asymmetries

$$a^q_{\rm sl} = \frac{\Gamma(\overline{B}^0_q \to f) - \Gamma(B^0_q \to \bar{f})}{\Gamma(\overline{B}^0_q \to f) + \Gamma(B^0_q \to \bar{f})} \approx \frac{\Delta\Gamma_q}{\Delta M_q} \tan\phi^q_{12}, \tag{17}$$

where f is a flavour-specific final state that is only accessible through the decay of the B^0_q state. Mixing is required to mediate the transition $\overline{B}^0_q \to B^0_q \to f$, and its conjugate. Semileptonic decays of the type $B^0_q \to D^-_q \mu^+ \nu_\mu X$ are well suited because (i) they are immune to any unknown CP violation in decay and (ii) they have large branching ratios.

Including the effect of an unknown production asymmetry, a_p, the time-dependent *untagged* asymmetry is defined as:

$$A^q_{\rm sl}(t) \equiv \frac{N - \bar{N}}{N + \bar{N}} = \frac{a^q_{\rm sl}}{2} - \left[a_p + \frac{a^q_{\rm sl}}{2}\right] \cdot \left[\frac{\cos\Delta M_q t}{\cosh\Delta\Gamma_q t/2}\right], \tag{18}$$

where N and $\bar{N}$ denote the number of observed decays to f and $\bar{f}$ final states, respectively. A decay-time-dependent fit can disentangle the $B^0_d - \bar{B}^0_d$ production asymmetry from $a^d_{\rm sl}$ [120]. In the B^0_s case the *time integrated* asymmetry is employed [13]. Owing to the large value of Δm_s the term containing a_p is suppressed to a calculable correction of a few $\times 10^{-4}$, after integrating over decay time. These approaches have been applied in the measurements with the Run 2 dataset that are listed in Table 5, giving the world's best single measurements. These measurements are far from any uncertainty floor in the SM predictions, and are sensitive to anomalous NP contributions to Γ^q_{12} and M^q_{12}. The difference $\Gamma_d - \Gamma_s$ further probes NP in penguin coefficients [121].

The following briefly reviews the dominant sources of uncertainty on the current LHCb measurements, and considers strategies to fully exploit the potential of the LHCb Upgrade II. All uncertainties are as evaluated on a^q_{sl} (i.e., all sources of raw asymmetry, and their uncertainties, are scaled by a factor of two as expected from Eq. 18).

Statistical precision: The statistical uncertainty on $a^s_{\rm sl}$ straightforwardly extrapolates to 2.1×10^{-4}. In the case of $a^d_{\rm sl}$ it should be noted that stringent fiducial cuts and weights were imposed on the signal sample to control certain tracking asymmetries that were not well known at the time. By the time of the subsequent $a^s_{\rm sl}$ measurement, a new method with $J/\psi \to \mu^+\mu^-$ decays had been developed, and others are in the pipeline. A further factor of two increase in yields is therefore assumed, which extrapolates to an uncertainty of 1.1×10^{-4}.

Detection asymmetries: The single largest contributor is the $K^-\pi^+$ asymmetry in $a^d_{\rm sl}$. This asymmetry was determined with a single method using D^+ decays to the $K^-\pi^+\pi^+$ and $K^0_{\rm S}\pi^+$ final states, with a precision of around 2.0×10^{-3} [120]. Thanks to trigger improvements, a factor of two increase in the effective yield of the most limiting $K^0_{\rm S}\pi^+$ final state [122, 123] can be anticipated. This will extrapolate to an uncertainty of 1.1×10^{-4}. Improvements in the reconstruction of downstream tracks in the earliest stage of the software trigger may also allow us to exploit $K^0_{\rm S}\pi^+$ final states with $K^0_{\rm S}$ decays downstream of the LHCb vertex detector (VELO). Further methods have since been proposed using partially reconstructed D^{*+} decays and $D^0 \to K^-K^+$ decays. The partial reconstruction method will be greatly improved by the reduction of material before the first VELO measurement point. The systematic uncertainties in these approaches will be controlled by using ultra high statistics fast simulations to track the kinematic dependencies in the asymmetries. The target uncertainty is 1.0×10^{-4}, including systematic uncertainties. The equivalent K^+K^- asymmetry in the $a^s_{\rm sl}$ measurement will be smaller and more precisely controlled. The $\mu^+\pi^-$ asymmetry will be controlled by a combination of $J/\psi \to \mu^+\mu^-$ decays, partially reconstructed D^{*+} decays, $D^0 \to h^-h^+$ decays, and high statistics fast simulations.

Background asymmetries: These measurements are challenging because the $B^0_q \to D^-_q \mu^+ \nu_\mu X$ final states can be fed by the decays of other b hadron species. This dilutes the relation between the

Table 5: Current theoretical and experimental determinations of the semileptonic asymmetries $a^d_{\rm sl}$ and $a^s_{\rm sl}$.

Sample ($\mathcal{L}$)	$\delta a^s_{\rm sl}/10^{-4}$	$\delta a^d_{\rm sl}/10^{-4}$
Run 1 (3 fb^{-1}) [13, 120]	33	36
Run 1-3 (23 fb^{-1})	10	8
Run 1-5 (300 fb^{-1})	3	2
Current theory [118, 126]	0.03	0.6

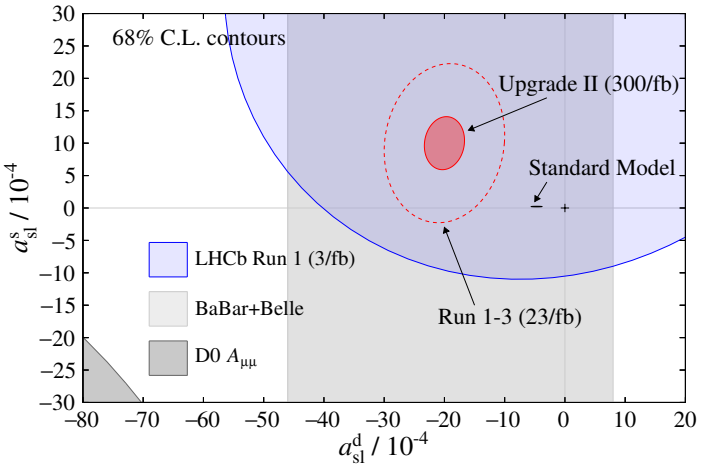

Fig. 12: Current and future landscape for the semileptonic asymmetries. The grey vertical band indicates the current B-Factory average for $a^d_{\rm sl}$. The blue ellipse represents the current LHCb Run 1 measurements [13, 120]. The red ellipse, which is arbitrarily centred, delineates the LHCb Upgrade II projected precision. The black ellipse shows the SM prediction, the uncertainty of which is barely visible.

raw asymmetry and $a^q_{\rm sl}$ and leads to a cocktail of production asymmetry corrections. We assume that these backgrounds can be statistically subtracted by extending the signal fits to include the $D^-_q\mu^+$ corrected mass dimension. It is assumed that the background asymmetry uncertainties can be controlled to the 1.0×10^{-4} level.

Other considerations: We must carefully consider the impact of having unequal sample sizes in the two polarities. This can be partially compensated for by assigning weights to one polarity [124]. We note that the choice of crossing angles should be carefully considered [125]. While we do not account for them in the current estimation, we could consider using other D^+_q decay modes to better align the detection asymmetries between $a^s_{\rm sl}$ and $a^d_{\rm sl}$. For example, $D^+\to K^-K^+\pi^+$ and $D^+\to K^0_{\rm S}\pi^+$ decays can be used, taking advantage of possible improvements in the trigger efficiency for $K^0_{\rm S}$ decays in LHCb Upgrade II. While the former decay is singly Cabibbo suppressed, its CP asymmetry could be measured using promptly produced D^+ mesons.

In summary the LHCb Upgrade II dataset should allow both $a^s_{\rm sl}$ and $a^d_{\rm sl}$ asymmetries to be measured to the level of a few parts in 10^{-4}, see Table 5. This will give unprecedented new physics sensitivity, and is still far from saturating the *current* theory uncertainties in the SM predictions. Fig. 12 shows the prospective LHCb Upgrade II measurement, arbitrarily centred at a value that differs from the SM prediction at the 10^{-3} level.

The ratio $\Delta\Gamma_d/\Gamma_d$, is typically measured from the difference in effective lifetimes between B^0 decays to final states that are flavour-specific, namely $J/\psi\,K^{*0}$, and CP-eigenstates, namely $J/\psi\,K^0_{\rm S}$ [127].

With this approach LHCb determined $\Delta\Gamma_d/\Gamma_d = -0.044 \pm 0.025 \pm 0.011$ using $1\,\text{fb}^{-1}$ of data [128]. ATLAS and CMS published competitive measurements [129, 130] reaching at their best statistical and systematic uncertainties of 0.011 and 0.009 respectively. The expected statistical uncertainty for LHCb Upgrade II, taking into account the larger centre-of-mass energy and the increase in luminosity, is $\sigma(\Delta\Gamma_d/\Gamma_d) \sim 0.001$. This can be compared with the SM prediction $\Delta\Gamma_d^{\rm SM}/\Gamma_d^{\rm SM} = (0.00397 \pm 0.00090)$ [126]. Thus, if systematic uncertainties can be controlled sufficiently, it will be possible to measure a significantly non-zero value of $\Delta\Gamma_d$ even if it is not enhanced above its SM prediction.

The challenge in controlling the systematic uncertainty is to understand precisely the decay-time acceptance difference between the $J/\psi K^{*0}$ and $J/\psi K^0_{\rm S}$ decay topologies. However, if the B^0 vertex position is reconstructed identically, namely using only the J/ψ decay products, and only $K^0_{\rm S}$ mesons decaying inside the VELO are considered, the largest sources of systematic uncertainty should cancel almost exactly and therefore not dominate the measurement. Similarly, the asymmetry in production rate between B^0 and $\overline{B}^0$ is expected to be precisely measured in independent control samples, and thus will not limit the achievable precision. In addition to the intrinsic interest in determining $\Delta\Gamma_d$, precise knowledge of its value will benefit many other studies of B^0 decay modes, since any systematic uncertainties associated with the assumption that $\Delta\Gamma_d = 0$ can be removed.

2.5.8 Measurements of ϕ_s from $b \to c\bar{c}s$ transitions

The single statistically most sensitive measurement of $\phi_s^{c\bar{c}s}$ is given by the flavour-tagged decay-time-dependent angular analysis of $B^0_s \to J/\psi(\mu^+\mu^-)\phi(K^+K^-)$ decay. The current world average is consistent with the SM prediction [63, 126], with new physics effects of a few tens of miliradians still allowed **??**. As the experimental precision improves it will be essential to have good control over possible hadronic effects [131, 132] that could mimic the BSM signal. It will also be crucial to achieve precise control of penguin pollution, both in $B^0_s \to J/\psi(\mu^+\mu^-)\phi(K^+K^-)$ and in other $b \to c\bar{c}s$ transitions. The wide range of $b \to c\bar{c}s$ modes accessible at LHCb Upgrade II will be vital to achieving both of these, and therefore contribute significantly more than their naive statistical sensitivity to the overall reach of this physics programme.

2.5.8.1 Projections for $B^0_s \to J/\psi(\mu^+\mu^-)\phi(K^+K^-)$

Fully exploiting the statistical power of HL-LHC for measurements of $\Delta\Gamma_s$ and the weak phase difference ϕ_s will require excellent flavour tagging performance, invariant mass resolution and proper-time resolution. The planned detector improvements in all three experiments are critical to deliver these requirements despite the much higher HL-LHC pileup.

Improvements in the decay time resolution are expected in ATLAS and CMS thanks to their upgraded inner detectors. Fig. 13 shows the ATLAS proper time resolution for Run-1, Run-2, and HL-LHC as a function of the B meson transverse momentum. Similarly Fig. 14 shows the CMS [133] expected HL-LHC performances in the proper decay length uncertainty, obtained from a simulation of of an ideal Phase-2 detector response. Besides the improvements in the tracker, which include the L1 trigger capability to reconstruct charged tracks above 2 GeV in transverse momentum with almost offline-like resolutions, the extended pseudorapidity coverage (up to $|\eta| = 4$) will increase the CMS acceptance for track reconstruction [1]. The CMS Phase-2 L1 (hardware) and HLT (software) trigger performances are expected to be comparable to those in Run 2 and sustainable in terms of rates; the offline selections for this projection are thus the same as in the 2012 data analysis [134]. The same signal purity is assumed as in the previous analysis; this assumption also relies on the future presence of the timing layer [4] which will mitigate the background pollution due to tracks coming from pileup vertices.

The ATLAS sensitivity study [135] follows the same approach as the previous study found in [136] and is based on the extrapolation of the ATLAS 2012 analysis [137], correcting for the full-simulation based observation of the signal invariant mass and proper-time resolutions. A full simulation of the HL-

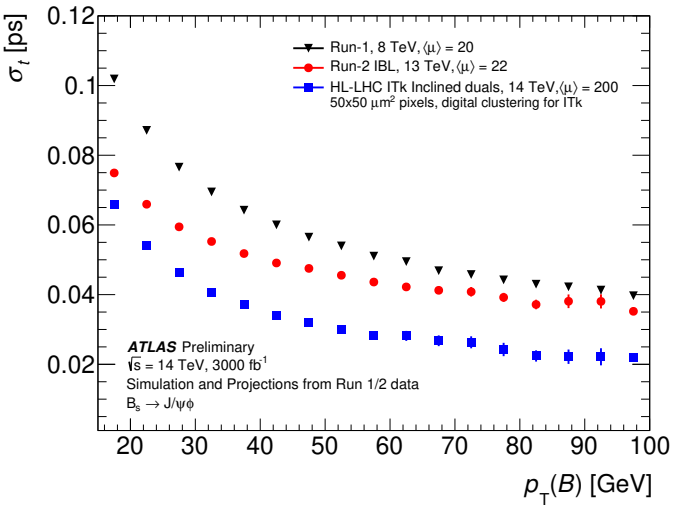

Fig. 13: The proper decay time resolution of the B_s^0 meson in ATLAS for the signal $B_s \to J/\psi\phi$ decay as function of the B meson p_{T}. Per-candidate resolutions corrected for scale-factors are shown, comparing the performance in Run 1, Run 2 and upgrade HL-LHC MC simulations. All samples use 6 GeV muon p_{T} cuts.

Table 6: Summary of the ATLAS $B_s \to J/\psi\phi$ performance at the HL-LHC compared with the Run 1 measurements and projections (numbers in parenthesis are predictions). The ϵ is the flavour-tagging efficiency, $D = 1-2\omega$ is the dilution factor, ω the wrong tag fraction, and $\sigma(t)$ the proper time resolution.

Period	L_{int} [fb^{-1}]	N_{sig}	ϵD^2	$\sigma\,(t)$ [ps]	$\delta_{\phi_s}^{stat}$ [rad]	$\delta_{\Delta\Gamma_s}^{stat}$ [ps^{-1}]
2011	4.9	22700	1.45	0.1	0.25 (0.22)	0.021
2012	14.3	73700	1.5	0.09	0.082	0.013
HL-LHC $\mu6\mu6$	3000	$9.7 \cdot 10^6$	1.5	0.05	(0.004)	(0.0011)
HL-LHC $\mu10\mu6$	3000	$5.9 \cdot 10^6$	1.5	0.04	(0.005)	(0.0014)
HL-LHC $\mu10\mu10$	3000	$1.7 \cdot 10^6$	1.5	0.04	(0.009)	(0.003)

LHC ATLAS tracking system is employed, including the effect of an average of 200 pile-up event per bunch crossing. An offline emulation of HL-LHC trigger responses is employed to evaluate the signal yield expectations corresponding to different dimuon transverse momentum thresholds: (p_T^1, p_T^2)= (6 GeV, 6 GeV), (6 GeV, 10 GeV) and (10 GeV, 10 GeV). Table 6 summarises the expected sensitivities, compared to the ATLAS Run-1 measurements and Fig. 15 left shows the $\delta\phi_s$ distributions. The CMS study is based on fully simulated signal events using the same model as in the previous CMS analysis [134] and toy Monte Carlo experiments for three different tagging scenarios: a where the flavour tagging performance is based on opposite-side muons and jet-charge, b where a muon and electron flavour tagging is used (as in the CMS 2012 data analysis), and c where a well performing flavour tagging based on leptons, jet-charge, and same side jet-charge/kaon tagging is tested. Fig. 15 right shows the CMS ϕ_s statistical uncertainty predictions for the different tagging scenarios. Assuming the new tagging power to be in the range 1.2-2.4% , and a total of 9 million fully reconstructed $B_s^0 \to J/\psi\phi(1020)$ candidates, CMS expects the ϕ_s statistical uncertainty to be 5-6 mrad at the end of the HL-LHC data taking. Both ATLAS and CMS systematic uncertainties are expected to be reduced to 1 mrad in the HL-LHC period, and thus the total ϕ_s uncertainty will still be statistically limited.

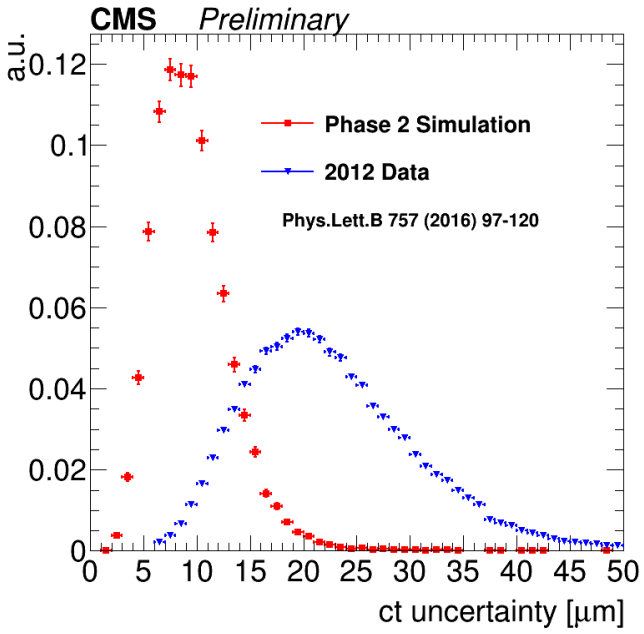

Fig. 14: CMS ct uncertainty distribution in 2012 data (blue) and HL-LHC Monte Carlo (red) samples (taken from [133]).

The ϕ_s measurement is usually illustrated as a constraint in the ϕ_s-$\Delta\Gamma_s$ plane. Fig. 16 summarises the projected contours in the $\Delta\Gamma_s$ vs φ_s plane for the ATLAS, CMS and LHCb experiments, with the CMS systematic uncertainty on $\Delta\Gamma_s$ assumed to be equal to the statistical uncertainty and an ATLAS estimated systematic uncertainty on the same parameter of approximately 0.0005 ps^{-1}. The red contour in the figure illustrates the combined HL-LHC sensitivity, equivalent to ~ 2 mrad in φ_s and ~ 5 ps^{-1} in $\Delta\Gamma_s$.

The expected LHCb precision on $\phi_s^{c\bar{c}s}$ after Upgrade II has been estimated based on the current published results, assuming that the detector performance remains the same in the HL-LHC period. Because of the data-driven nature of the LHCb analysis systematic uncertainties are expected to scale with luminosity and the overall sensitivity is expected to be $\sim 4\,\mathrm{mrad}$. This will be at the same level as the current precision on the indirect determination based on the CKM fit using tree-level measurements, which in turn is expected to improve with better measurements of the other CKM matrix parameters. Fig. 17 left shows the signal-yield asymmetry as a function of the B_s^0 decay time, folded at the frequency of B_s^0 oscillations, for $B_s^0 \to J/\psi\,\phi$ decays from a simulated data set corresponding to $300\,\mathrm{fb}^{-1}$. It clearly shows that a visible CP-violation effect will be observable.

2.5.8.2 *Projections for other $b \to c\bar{c}s$ transitions*

LHCb foresees extending the study of $b \to c\bar{c}s$ transitions to cover multiple independent precision measurements. It permits not only improved precision of the average, but a powerful consistency check of the SM. One important way in which this can be done is by allowing independent CP-violation effects for each polarisation state in the $B_s^0 \to J/\psi\,\phi$. This has been done as a cross-check in the LHCb Run I analysis [10], but this strategy will become the default in LHCb Upgrade II. Additional information can be obtained from $B_s^0 \to J/\psi\,K^+K^-$ decays with K^+K^- invariant mass above the $\phi(1020)$ meson, where higher spin K^+K^- resonances such as $f_2'(1525)$ meson contribute [140]. Among other channels, competitive precision can be obtained with $B_s^0 \to J/\psi\,\pi^+\pi^-$ decays [141], which have been found to be dominated by the CP-odd component. The $B_s^0 \to D_s^+D_s^-$ [11] and $B_s^0 \to \psi(2S)\phi$ [142] modes

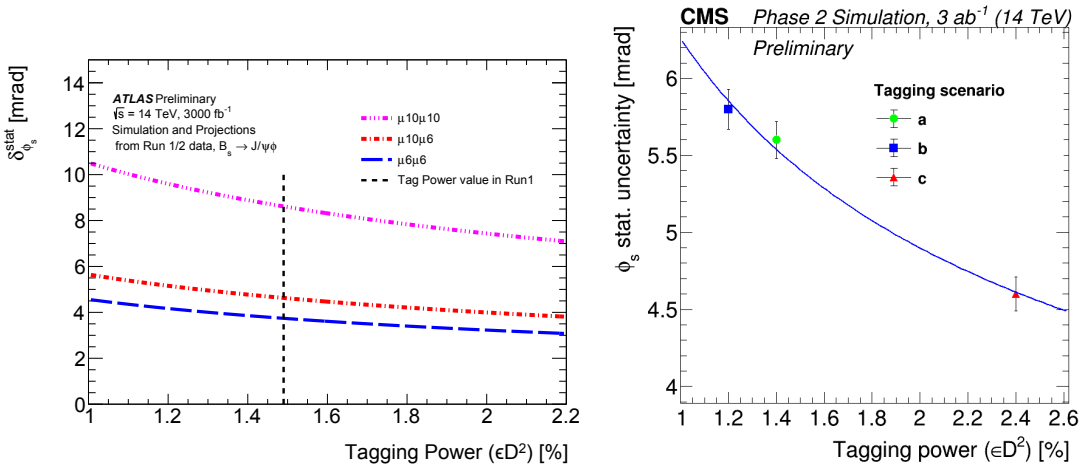

Fig. 15: Variation of the ϕ_s statistical uncertainty in ATLAS (left) and CMS (right) as function of the tagging power (ϵD^2). The behaviour is shown for different ATLAS triggers and CMS flavour tagging scenarios as explained in the text. The vertical dashed line in the ATLAS plot corresponds to the value assumed in the analysis extrapolation. A function proportional to $1/\sqrt{\epsilon D^2}$ is shown in the CMS plot to describe the ϕ_s uncertainty behaviour in a continuous range of the tagging power from 1.0 to 2.6 % (The CMS plot is taken from [133]).

have also been studied with LHCb, and give less precise but still important complementary results. Other channels, which have not been exploited yet, but could be important in LHCb Upgrade II, if good calorimeter performance can be achieved, include $B^0_s \to J/\psi\,\phi$ with $J/\psi \to e^+e^-$ and $B^0_s \to J/\psi\,\eta^{(\prime)}$ with $\eta' \to \rho^0\gamma$ or $\eta\pi^+\pi^-$, and $\eta \to \pi^+\pi^-\pi^0$ or $\gamma\gamma$ [143, 144].

The scaling of the $\phi_s^{c\bar{c}s}$ precision with integrated luminosity for individual decay modes and for their combination is shown in Fig. 18. These uncertainties are statistical only and are scaled from existing results, taking into account the gain in efficiency expected for $B^0_s \to D^+_s D^-_s$ from the removal of the hardware trigger. Maintaining the current performance will put stringent constraints on the design of the detector with regards to the momentum and vertex position resolution, as well as particle identification performance. A key ingredient is the flavour tagging that is very sensitive to event and track multiplicity. Systematic uncertainties are mainly based on the sizes of control samples, and are therefore expected to remain subdominant even with very large samples. Therefore, it is expected that the small value of $-2\beta_s$ predicted in the SM can be measured to be significantly non-zero in several channels. The expected precision on $\phi_s^{c\bar{c}s}$ after LHCb Upgrade II will be $\sim 3\,\mathrm{mrad}$ from all modes combined.

2.5.9 *Measurements of ϕ_d from $b \to c\bar{c}s$ transitions*

The world average of $\sin 2\beta$ is dominated by results from BaBar, Belle and LHCb using $B^0 \to J/\psi\,K^0_S$ decays. The single most precise measurement is from Belle ($\sin\phi_d^{c\bar{c}s} = 0.670 \pm 0.029 \pm 0.013$ [145]), while the LHCb result has competitive uncertainty ($0.731 \pm 0.035 \pm 0.020$ [139]). With $50\,\mathrm{fb}^{-1}$ of data, LHCb will reach a precision on $\sin\phi_d^{c\bar{c}s}$ of about 0.006 with $B^0 \to J/\psi\,K^0_S$ decays. The Belle II experiment is expected to achieve a precision of about 0.005 after accumulating $50\,\mathrm{ab}^{-1}$ [146]. After Upgrade II, LHCb will be able to reach a statistical precision below 0.003. Fig. 17(right) shows the signal-yield asymmetry as a function of the B^0 decay time for $B^0 \to J/\psi\,K^0_S$ decays from a simulated data set corresponding to $300\,\mathrm{fb}^{-1}$.

The majority of systematic uncertainties on $\sin\phi_d^{c\bar{c}s}$ depend on the size of control samples, and are therefore not expected to be limiting. However, at this level of precision it will be necessary to understand possible biases on the result due to CP violation in K^0–$\overline{K}^0$ mixing, and from the difference in

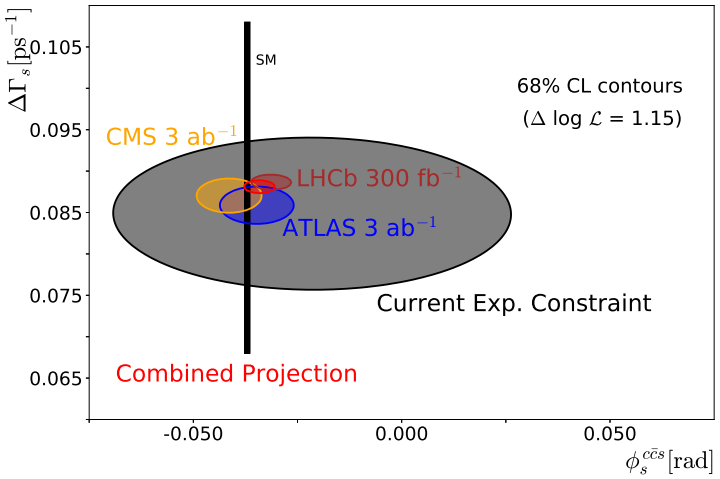

Fig. 16: Projected 68% confidence-level contour in the $\Delta\Gamma_s$ vs φ_s plane for the ATLAS, CMS (still preliminary) and LHCb sensitivity at the HL-LHC compared with the current experimental limit. For clarity of the representation each projection is centered on a random value generated with its uncertainty assuming the SM value as truth. The combined contour is obtained following the HFLAV approach for averages for the PDG 2018 review [138].

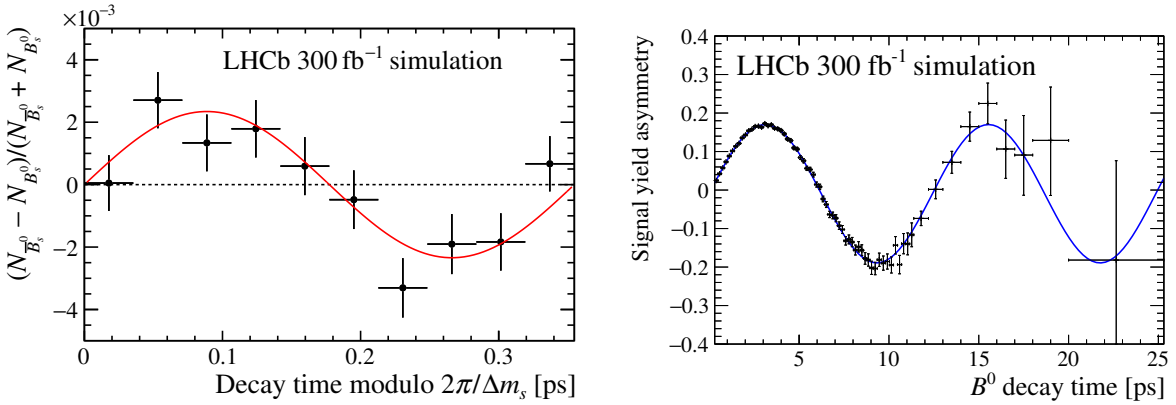

Fig. 17: Signal-yield asymmetry as a function of the $B^0_{(s)}$ decay time, $(N_{\overline{B}^0_{(s)}} - N_{B^0_{(s)}})/(N_{\overline{B}^0_{(s)}} + N_{B^0_{(s)}})$. Here, $N_{\overline{B}^0_{(s)}}$ ($N_{B^0_{(s)}}$) is the number of (left) $B^0_s \to J/\psi\,\phi$ or (right) $B^0 \to J/\psi\,K^0_S$ decays with a $\overline{B}^0_{(s)}$ ($B^0_{(s)}$) flavour tag. The data points are obtained from simulation with the expected sample size at 300 fb^{-1}, and assuming the current performance of the LHCb experiment. The solid curves represent the expected asymmetries for $\phi_s^{c\bar{c}s} = -36.4\,\text{mrad}$ [63] and $\sin\phi_d^{c\bar{c}s} = 0.731$ [139]), the values used in the simulation. The height of the oscillation is diluted from $\sin\phi_{d(s)}^{c\bar{c}s}$ due to mistagging, decay time resolution, and, for $B^0_s \to J/\psi\,\phi$, the mixture of CP-even and CP-odd components in the final state.

the nuclear cross-sections in material between K^0 and $\overline{K}^0$ states. Therefore, some irreducible systematic uncertainties are unavoidable. It is notable that the leading sources of systematic uncertainty are different for Belle II and LHCb, so that having measurements from both experiments will be important. As for the $\phi_s^{c\bar{c}s}$ case, continued good flavour tagging performance and improved understanding of subleading contributions to the decay amplitudes will be required.

The decay $\overline{B}^0 \to D^0\pi^+\pi^-$, and related decays involving excited charm mesons, offer a purely tree-level measurement of $\phi_d = 2\beta$. BaBar and Belle have performed measurements using $B^0 \to D^{(*)}h^0$ with both D decays to CP eigenstates [147] and to the three-body $K^0_S\pi^+\pi^-$ final state [148, 149], where

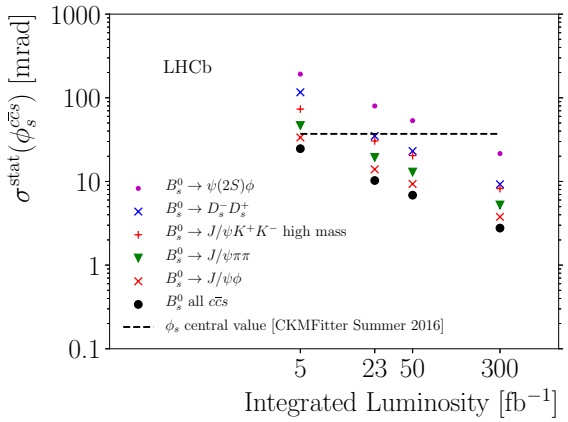

Fig. 18: Scaling of the LHCb statistical precision on ϕ_s from several tree-dominated B_s^0 meson decay modes.

h^0 is a light neutral meson such as π^0. The combined results are $\sin\phi_d = 0.71 \pm 0.09$ and $\cos\phi_d = 0.91 \pm 0.25$ including all uncertainties. While $B^0 \to Dh^0$ can also be studied at LHCb, it is more attractive to measure the same quantities using the $B^0 \to D\pi^+\pi^-$ mode (here D indicates an admixture of D^0 and $\overline{D}^0$ states). The Dalitz-plot structure of the decay $B^0 \to \overline{D}^0\pi^+\pi^-$ has been previously studied [150–152], and the models obtained from these studies could be used in a decay-time-dependent amplitude analysis using the $D \to K^+K^-$ and $D \to \pi^+\pi^-$ channels to determine ϕ_d [153, 154]. In practice it will be more convenient to perform a simultaneous fit including also the $\overline{D}^0 \to K^+\pi^-$ mode, which acts as a control mode to determine the amplitude model, flavour-tagging response and decay-time acceptance.

An estimate of the achievable sensitivity has been made using pseudoexperiments. The expected statistical precisions on $\sin\phi_d$ and $\cos\phi_d$ are ±0.06 and ±0.10, respectively, for the LHCb Run 1 and 2 data samples combined. Extrapolating this to $300\,\text{fb}^{-1}$ gives ±0.007 for $\sin\phi_d$ and ±0.017 for $\cos\phi_d$. Further experimental studies are needed to understand the impact of systematic uncertainties, although the use of the $\overline{D}^0 \to K^+\pi^-$ control sample is expected to minimise effects from many potential sources of systematic bias. In case model uncertainties become a limiting factor, a model-independent version of the method can be used instead [155]. Thus, it is expected that a penguin-free measurement of ϕ_d can be achieved with sensitivity better than Belle II, and comparable to that with $B^0 \to J/\psi K^0_{\rm S}$.

2.5.10 Measurements of penguin pollution in $b \to c\bar{c}s$

Strategies to measure penguin pollution have already been tested using $B^0 \to J/\psi\rho^0$ [156] and $B_s^0 \to J/\psi\overline{K}^{*0}$ [157] decays. These modes constrain the penguin contribution in $B^0 \to J/\psi K^{*0}$. The best constraint on penguin pollution in $\phi_s^{c\bar{c}s}$ is currently obtained from the $B^0 \to J/\psi\rho^0$ channel, benefiting from the fact that $S_{J/\psi\rho^0}$ and $C_{J/\psi\rho^0}$ have been measured, giving a constraint on ${\phi_d}^{J/\psi\rho^0}$. Following Ref. [156], the bias on ϕ_s is

$$\Delta\phi_s^{c\bar{c}s} \approx -\epsilon\left({\phi_d}^{J/\psi\rho^0} - 2\beta\right), \tag{19}$$

where $\epsilon = |V_{us}|^2/(1-|V_{us}|^2) = 0.0534$, and 2β is mainly determined by $B^0 \to J/\psi K^0_{\rm S}$. Since 2β is, and will continue to be, determined precisely, the sensitivity on $\Delta\phi_s^{c\bar{c}s}$ will be driven by the precision on ${\phi_d}^{J/\psi\rho^0}$. Scaling the uncertainties obtained from Ref. [156], the expected statistical precision on ${\phi_d}^{J/\psi\rho^0}$ will be $\lesssim 1^\circ$ with $300\,\text{fb}^{-1}$. It is expected that systematic uncertainties, such as those from modelling the S-wave component in $B^0 \to J/\psi\pi^+\pi^-$ decays, can be kept under control, so that the uncertainty due to penguin pollution is expected to be $\lesssim 1.5\,\text{mrad}$. Thus, this is not expected to limit the sensitivity of the ϕ_s measurement with $B_s^0 \to J/\psi\phi$. However, if significant effects of penguin pollution become

apparent it may complicate the combination of results from different modes, since a separate correction will be required for each. For some modes such as $B_s^0 \to J/\psi\, f_0(980)$ this may be challenging, since the identification of the states in the SU(3) multiplet is not trivial. However, this is not a problem for $B_s^0 \to D_s^+ D_s^-$, related by U-spin subgroup to $B^0 \to D^+ D^-$, which can be used to control penguin pollution [158–161].

Similar strategies can be applied using $B_s^0 \to J/\psi\, K_S^0$ and $B^0 \to J/\psi\, \pi^0$ decays to control the penguin contributions in $\phi_d^{c\bar{c}s}$ [41, 42, 45]. A first analysis of $B_s^0 \to J/\psi\, K_S^0$ decays has been performed [162] as a proof of concept for constraining $\Delta\phi_d^{c\bar{c}s}$ with larger datasets. The CP violation parameters in $B^0 \to J/\psi\, \pi^0$ have been previously measured by BaBar and Belle [163, 164], and the Belle II experiment is expected to reach a sensitivity to $S_{J/\psi\,\pi^0}$ of ~ 0.03, which should be sufficient to keep penguin pollution under control. LHCb can also study $B^0 \to J/\psi\, \pi^0$ decays, although the presence of a neutral pion in the final state makes the analysis more challenging and there is currently no public result from which to extrapolate the sensitivity. Improving the capabilities of LHCb's electromagnetic calorimeter (ECAL) will enhance prospects for studying this mode.

It should be stressed that the methods to constrain penguin pollution rely on SU(3) symmetry, and the approximations associated with the method and inherent in Eq. (19) must also be investigated. This can be done by studying the full set of modes related by SU(3), namely $B_{(s)}^0 \to J/\psi \{\pi^0, \eta, \eta', K^0, \overline{K}^0\}$ and $B^\pm \to J/\psi \{\pi^\pm, K^\pm\}$ for the vector-pseudoscalar final states and $B_{(s)}^0 \to J/\psi \{\rho^0, \omega, \phi, K^{*0}, \overline{K}^{*0}\}$ and $B^\pm \to J/\psi \{\rho^\pm, K^{*\pm}\}$ for the vector-vector final states. Several of these modes have not yet been measured, but with the data sample of LHCb Upgrade II it should be possible to measure all branching fractions and CP asymmetry parameters, allowing a full theoretical treatment and more detailed understanding of subleading contributions. An alternative approach to controlling penguin contributions, which does not involve $SU(3)$ symmetry, can be found in Ref. [46].

2.5.11 Measurements of ϕ_d and ϕ_s in charmless decays

The $B_s^0 \to \phi\phi$ decay is forbidden at tree level in the SM and proceeds predominantly via a gluonic penguin $\bar{b} \to \bar{s}s\bar{s}$ loop process. Hence, this channel provides an excellent probe of physics beyond the SM that may contribute to the penguin diagram [165–167]. This mode is well suited for study at the LHC, as both ϕ mesons can be reconstructed through their decay to K^+K^-, leading to clean signatures even in the absence of hadronic particle identification.

2.5.11.1 CMS $B_s \to \phi\phi$ studies

The lack of particle-ID detectors will limit the CMS investigation of fully hadronic final states. However, some capability is retained through the early use of tracking in the trigger selection. The $B_s \to \phi\phi \to 4K$ is an example of a hadronic final state that would benefit from the tracking performance at trigger level and the ϕ resonance signature. While the full study of the sensitivity to the ϕ measurement in this channel is still ongoing, an analysis was performed by CMS to see if $B_s^0 \to \phi\phi \to 4K$ events can be triggered with high efficiency at L1 using only the tracks reconstructed at that level (L1 tracks) [168].

The L1 track finder will allow identification of $B_s^0 \to \phi\phi \to 4K$ candidates at L1 by forming ϕ candidates from pairs of oppositely charged L1 tracks constrained to come from the same vertex and then combining pairs of such candidates into a B_s^0 candidate. The p_T of the lowest-p_T kaon lies very close to the lowest possible trigger threshold of the L1 tracking of 2 GeV, possibly causing loss of signal efficiency.

Fig. 19 shows the invariant mass of the $B_s^0 \to \phi\phi$ candidates for all ϕ-pairs having separation along the beam axis (z) of $\Delta z(\phi\text{-pair}) < 1$ cm, distance in the plane perpendicular to the beam axis $\Delta xy(\phi\text{-pair}) < 1$ cm, $0.2 < \Delta R(\phi\text{-pair}) < 1$, and $\Delta R(K^+, K^-) < 0.12$, in events with 200 pile-up (PU) interactions. Simulations show that an efficiency of 30-35 % can be achieved at L1 trigger

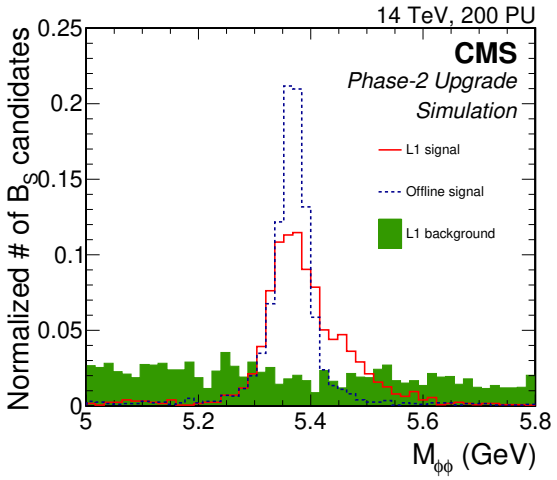

Fig. 19: Normalized invariant mass distribution in CMS of all the ϕ-pairs with $\Delta z(\phi\text{-pair}) < 1$ cm, $\Delta xy(\phi\text{-pair}) < 1$ cm, $0.2 < \Delta R(\phi\text{-pair}) < 1$, $\Delta R(K^+, K^-) < 0.12$. The blue dashed line corresponds to the signal events reconstructed with offline tracks. The signal and background distributions obtained using L1 tracks are shown as red solid line and green histograms, respectively. A pile up scenario of 200 interactions is assumed (taken from [168]).

level, depending on the track candidate selection, and that the events selected at L1 would be accepted by the subsequent offline analysis with high efficiency. For the scenario with 200 PU and a moderate signal efficiency of around 30%, the expected L1 trigger rate is about 15 kHz, within the acceptable limit according to the present understanding of the expected detector performance.

2.5.11.2 LHCb $B_s \to \phi\phi$ projections

The measured and extrapolated LHCb statistical sensitivities for $\phi_s^{s\bar{s}s}$ and similar CP-violating phases measured in other decay modes are shown in Fig. 20. A statistical uncertainty on $\phi_s^{s\bar{s}s}$ of $0.011\,\text{rad}$ can be achieved with $300\,\text{fb}^{-1}$ of data collected at LHCb Upgrade II. Similarly to other measurements of CP violation parameters from decay-time-dependent analyses, many systematic uncertainties are evaluated from control samples, and are therefore expected to scale accordingly with integrated luminosity. Among others, there is an important uncertainty associated with knowledge of the angular acceptance, which is determined from simulation. This therefore relies on good agreement between data and simulation, which can be validated using control channels such as $B^0 \to \phi K^{*0}$. Thus the determination of $\phi_s^{s\bar{s}s}$ is expected to remain statistically limited even with the full LHCb Upgrade II data sample.

2.5.11.3 LHCb projections for ϕ_s from other charmless decays

Another way of measuring ϕ_s is the $B_s^0 \to K^*(892)^0 \overline{K}^*(892)^0$ family of decays, which in the SM is dominated by a gluonic penguin $b \to d\bar{d}s$ diagram. LHCb has recently published the first measurement of $\phi_s^{d\bar{d}s}$ [169] using Run 1 data. In this groundbreaking analysis, it was realised that a significant gain in sensitivity can be obtained by including the full $B_s^0 \to (K^+\pi^-)(K^-\pi^+)$ phase space in the $K\pi$-mass window from 750 to $1600\,\text{MeV}/c^2$, since the fraction of $B_s^0 \to K^*(892)^0 \overline{K}^*(892)^0$ in this region is only $f_{VV} = 0.067 \pm 0.004 \pm 0.024$ (the other contributions are from $K\pi$ S-wave and the $K_2^*(1430)^0$ resonance). The result, $\phi_s^{d\bar{d}s} = -0.10 \pm 0.13 \pm 0.14\,\text{rad}$, is compatible with the SM expectation.

The current result has statistical and systematic uncertainties of comparable size, but both are expected to be reducible with larger data samples. The largest systematic uncertainty, corresponding to

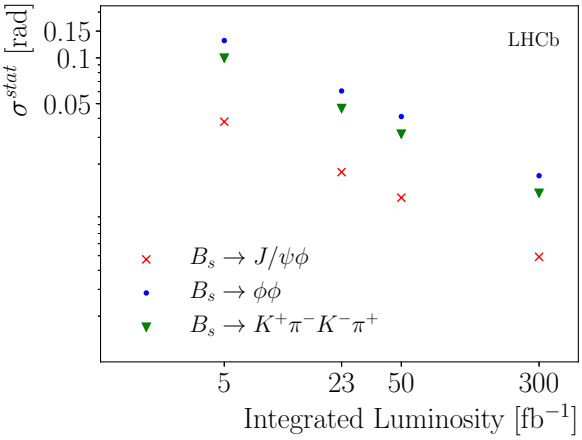

Fig. 20: Comparison of ϕ_s statistical sensitivity at LHCb from different decay modes.

Table 7: Statistical sensitivity on $\phi_s^{s\bar{s}s}$ and $\phi_s^{d\bar{d}s}$ at LHCb.

Decay mode	σ(stat.) [rad]			
	3 fb^{-1}	23 fb^{-1}	50 fb^{-1}	300 fb^{-1}
$B_s^0 \to \phi\phi$	0.154	0.039	0.026	0.011
$B_s^0 \to (K^+\pi^-)(K^-\pi^+)$ (inclusive)	0.129	0.033	0.022	0.009
$B_s^0 \to K^*(892)^0\overline{K}^*(892)^0$	–	0.127	0.086	0.035

the treatment of the acceptance, is mostly driven by the limited size of the simulation samples — due to the large phase space investigated in this analysis, very large simulation samples are required. In order to produce significantly larger samples it will be necessary to exploit rapid simulation production mechanisms, since increases in available CPU power are not expected to keep pace with the size of the data samples. Another important systematic uncertainty due to the modelling of the $K\pi$ resonant and non-resonant components can be reduced by incorporating results of state-of-the-art studies of the $K\pi$ system, but some component of this may be irreducible. Other systematic uncertainties are mainly based on control samples. Therefore it is expected that the limiting systematic uncertainty will be not larger than $\sigma(\text{syst.}) \sim 0.03\,\text{rad}$.

The measured and extrapolated statistical sensitivities for $\phi_s^{d\bar{d}s}$ are given in Table 7, both for the average over the $B_s^0 \to (K^+\pi^-)(K^-\pi^+)$ system and for the exclusive $B_s^0 \to K^*(892)^0\overline{K}^*(892)^0$ decay. The sensitivities for $B_s^0 \to (K^+\pi^-)(K^-\pi^+)$ are also included in Fig. 20. In the current analysis, the same weak phase is assumed for all contributions, but as the precision increases it will be possible to determine $\phi_s^{d\bar{d}s}$ separately for each, including possible polarisation dependence in the $B_s^0 \to K^*(892)^0\overline{K}^*(892)^0$ decay. The systematic uncertainty related to modelling of components is expected to be smaller when focusing on the $K^*(892)$ resonance, since its lineshape is well known. Moreover, by making similar studies with the $B^0 \to (K^+\pi^-)(K^-\pi^+)$ mode, it will be possible to obtain all necessary inputs for the U-spin analysis of each component separately, leading to good control of the theoretical uncertainty on the prediction for $\phi_s^{d\bar{d}s}$.

Finally, LHCb can also make measurements of $\phi_s^{d\bar{u}u}$ using a decay-time-dependent flavour-tagged Dalitz-plot analysis of $B_s^0 \to K_S^0\pi^+\pi^-$ decays [170]. Preliminary sensitivity studies indicate that the precision achievable on $\phi_s^{d\bar{u}u}$ with the full Run 1 + Run 2 dataset is approximately $0.4\,\text{rad}$. Extrapolation to

$300\,\text{fb}^{-1}$ indicates potential for a precision of around $0.07\,\text{rad}$. Similar studies for the $B_s^0 \to K_S^0 K^\pm \pi^\mp$ decay mode can be performed, which requires a more complicated analysis since both $K_S^0 K^- \pi^+$ and $K_S^0 K^+ \pi^-$ final states are accessible to both B_s^0 and $\overline{B}_s^0$ decays with comparable magnitude. Although currently the precision of such measurements are dominated by the statistical uncertainty [171], the expected yields of more than 10^6 signal decays for $300\,\text{fb}^{-1}$ will allow a complete understanding of the $B_s^0 \to K_S^0 K^\pm \pi^\mp$ phase space.

2.5.11.4 LHCb projections for ϕ_d from other charmless decays

The large yields of $B^0 \to K_S^0 h^+ h^-$ decays available [172] at LHCb enable a relevant reach for ϕ_d from these modes. For the $B^0 \to K_S^0 \pi^+ \pi^-$ mode, a decay-time-integrated analysis has been performed resulting in the first observation of CP violation in the $B^0 \to K^{*+}\pi^-$ channel [173]; with more data this analysis can be updated to include decay-time-dependence and determine also CP-violating parameters for the $B^0 \to \rho^0 K_S^0$ and $f_0(980) K_S^0$ channels.

Studies of $B_{(s)}^0 \to h^+ h^- \pi^0$ decays will provide further sensitivity. For example, resonant contributions of the type $K^{*\pm} h^\mp$ will decay to the final state $K^\pm h^\mp \pi^0$ in addition to $K_S^0 \pi^\pm h^\mp$, and therefore a combined analysis of both can provide additional information that helps to test the SM prediction [96–99]. Large yields will be available and the improved capabilities of the Upgrade II ECAL will allow backgrounds to be controlled. Two particularly important features of these decays are that background from $B \to V\gamma$ decays, where $V \to h^+ h^-$, must be suppressed and that it must be possible to resolve B^0 and B_s^0 decays to the same final state. Thus, it will be important to have both good γ–π^0 separation and good mass resolution.

2.5.12 Measurements of α

The main input from LHCb to the isospin analysis determination of α from $B \to \pi\pi$ decays will be world-leading measurements of the CP-violating parameters in $B^0 \to \pi^+\pi^-$ decay. Important input can also be expected on the $B^+ \to \pi^+\pi^0$ decay, using the method pioneered in Ref. [174] for $B^+ \to K^+\pi^0$ decays. Clearly, good performance of the electromagnetic calorimeter will be critical for such a measurement. Progress on the $B^0 \to \pi^0\pi^0$ mode, which is currently limiting the precision of α determination from $B \to \pi\pi$ decays, will mainly come from the Belle II experiment.

The situation is quite different for the $B \to \rho\rho$ system, which currently provides the strongest constraints on α. Although the presence of two vector particles in the final state makes the analysis more complicated in principle [34, 175–177], the observed dominance of longitudinal polarisation and the smaller penguin contribution compared to $B \to \pi\pi$ lead to good sensitivity on α. The rarest of the three isospin-partner modes is the $B^0 \to \rho^0\rho^0$ decay, which has a final state of four charged tracks following $\rho^0 \to \pi^+\pi^-$ decays, making it well suited for study at LHCb. Indeed, this decay was first observed by LHCb, and a time-integrated angular analysis on Run 1 data was performed [178]. With larger data samples it will be possible not only to improve the measurements of the branching fraction and longitudinal polarisation fraction, but to make precise determinations of the CP-violating parameters. Consequently, the determination of α from $B \to \rho\rho$ decays will benefit from the additional information inherent in $S_{\rho^0\rho^0}$, compared to the $B \to \pi\pi$ system for which $S_{\pi^0\pi^0}$ is barely measurable (Belle II plans to measure $S_{\pi^0\pi^0}$ using Dalitz decay of π^0, but only rather limited sensitivity is possible).

First measurements of $B^0 \to \rho\pi$ have been published by BaBar and Belle [179–181], but do not yet provide strong constraints on α. LHCb has not yet published any result on this channel, but it is expected that large yields will be available in LHCb Upgrade II, and that it should be possible to control backgrounds with good understanding of π^0 reconstruction. It is worth noting that a significant proportion of the photons from neutral pions produced at the B decay vertex convert into e^+e^- pairs in the LHCb detector material, with approximately half of these conversions occurring before the magnet. Tracks from these converted photons provide additional information with which to constrain the B decay

vertex and the neutral pion momentum, resulting in improved resolution and background rejection.

2.5.13 *Measurements of CP violation in baryon decays*[2]

In contrast with the study of CP violation in beauty-meson decays, the sector of beauty baryons remains almost unexplored. Previous to the LHC era, only a measurement of direct CP asymmetries in $\Lambda_b^0 \to pK^-$ and $\Lambda_b^0 \to p\pi^-$ decays was available with $\mathcal{O}(0.1)$ precision [182]. Thanks to the large production cross-section of beauty baryons in pp collisions at the LHC, the LHCb experiment is the only experiment capable of expanding our knowledge in this sector, as these decays are not accessible at the e^+e^- KEK collider. Hence, even though a handful of CP asymmetries of Λ_b^0 decays have been measured so far by LHCb [183–186], the landscape of CP violation in the decays of beauty baryons is expected to change rapidly in the next few years.

The unprecedented number of beauty baryons available with the data sample expected to be collected in the LHCb Upgrade II phase, will allow a precision measurement programme of CP violation observables in b-baryon decays to be pursued, analogously to b-meson decays. A very interesting example is the study of decays governed by $b \to u$ and $b \to c$ tree-level transitions, like the decays $\Lambda_b^0 \to D^0\Lambda$ and $\Lambda_b^0 \to D^0 pK^-$. These decays can be used to measure the angle γ of the unitarity triangle [187–189] in a similar way to what can be done with $B^0 \to DK^+\pi^-$ decays. The LHCb experiment reported the first observation of the $\Lambda_b^0 \to D^0(K^-\pi^+)pK^-$, based on a signal yield of 163 ± 18 using a sample of pp collisions corresponding to $1\,\text{fb}^{-1}$ of integrated luminosity at a centre-of-mass energy of 7 TeV [190]. Extrapolating to Upgrade II approximately 95000 signal decays are expected. However, extrapolating the sensitivity to γ is not easy, since it strongly depends on the values of the hadronic parameters involved in the process. In addition, even though the determination of γ from the analysis of these decays is expected to be theoretically very clean, the possible polarisation of Λ_b^0 baryons produced in pp collisions has to be taken into account and might represent a limiting factor for high-precision measurements.

Another very interesting sector is that of beauty baryons decaying to final states without a charm quark. These decays receive relevant contributions from $b \to d$, s loop-level transitions, where new physics beyond the SM may appear. Also in this case, similar quantities to those measured with B-meson decays are available. For example, statistical precisions of $\mathcal{O}(10^{-3})$ and $\mathcal{O}(10^{-2})$ are expected for the CP asymmetries of $\Lambda_b^0 \to ph^-$ and $\Lambda_b^0 \to \Lambda h^+h^-$ decays (with $h = K, \pi$), respectively. Very large signal yields are also expected in several multibody final states of Λ_b^0 and Ξ_b decays: about 10^6 $\Lambda_b^0 \to p\pi^-\pi^+\pi^-$ and $\Lambda_b^0 \to pK^-K^+K^-$ decays, and about 10^5 $\Xi_b^0 \to pK^-\pi^+K^-$ decays [191, 192]. Such a signal yield will allow very precise measurements of CP-violating quantities to be made over the phase space of these decays, characterised by a rich set of resonances. Unfortunately, as for the charmless decays of B mesons, the interpretation of these quantities in terms of CKM parameters is still unclear from the theoretical point of view. Hence, more theoretical work is crucial to exploit the full potential of beauty baryons.

Experimentally, the main issues are the determination of particle-antiparticle production asymmetries and detection asymmetries that could mimic CP-violation effects. This task is generally more difficult for heavy baryons, with respect to B mesons, since methods used for measuring meson production asymmetries [193] cannot be applied. In addition, different interactions of baryons and antibaryons with the detector material are difficult to calibrate. Nonetheless, several quantities can be measured in b-baryon decays that are sensitive to different manifestations of CP violation and are largely unaffected by experimental effects. A few examples are the difference of CP-violating asymmetries of particles decaying to a similar final state, ΔA_{CP} [194], triple-product asymmetries (TPA) [191] and energy-test (ET) [195]. It is important to note that TPA and ET are important tools for discovery of CP violation in multibody decays, while an amplitude analysis is required to study the source of CP violation.

[2]We thank I. Bigi for stressing the importance of baryon decays.

2.6 Future of global CKM fits

2.6.1 Summary of the projections

As discussed above, HL-LHC will improve the determination of several flavour observables crucial for the extraction of CKM parameters. We consider two phases for the HL-LHC projections: in Phase 1, we assume an integrated luminosity of 23 fb^{-1} for LHCb and 300 fb^{-1} for CMS/ATLAS; in Phase 2 we have 300 fb^{-1} for LHCb and 3000 fb^{-1} for CMS/ATLAS. Several observables will be measured more precisely at Belle-II. For uncertainties on these observables we use the 50 ab^{-1} projections in Ref. [196]. Since we are interested in the future sensitivity for Phase 1 and Phase 2, we choose the central values of future measurements to coincide with their SM predictions using the current best-fit values of $\overline{\rho}$ and $\overline{\eta}$.

2.6.2 CKMfitter results

The inputs used by CKMfitter collaboration for the fits are shown in Table 8. For easier comparison the "Current" column shows present uncertainties, taking central values corresponding to a perfect agreement of the various constraints in the SM. Note that this choice does change slightly the present determination of CKM parameters – the global fit described in Sec. 2.3 exhibits slight discrepancies, in particular for $|V_{us}|$, which currently increases the accuracy of the determination of the CKM parameters. In order to determine the increase in accuracy on the CKM parameters in a fair way, we therefore compare the three scenarios presented in Table 8 with the same central values taken to have perfect agreement (rather

Table 9: The 68% CL uncertainties on the determination from the CKMfitter global fit.

than comparing the future projections with the CKMfitter results for the Summer 2018 update).

From the global fit we determine the 68% CL intervals for the 4 CKM parameters and other parameters of interest. In Fig. 21 we show the Phase 1 (left panels) and Phase 2 (right panels) determinations in the standard UT plane for a global fit (upper), as well as when using only subsets of constraints, tree only (middle) or loop only (lower panels). The uncertainties obtained are listed in Table 9. We show the corresponding constraints for the B_s meson system also in Fig. 22, defining the apex of the B_s unitarity triangle as [63]

$$\bar{\rho}_{sb} + i\bar{\eta}_{sb} = -\frac{V_{us}V_{ub}^*}{V_{cs}V_{cb}^*}. \tag{20}$$

2.6.3 UTfit results

The projection of the UT analysis in the HL-LHC era is obtained by performing a global fit using the same future expected values of experimental and theoretical input parameters as CKMfitter, Table 8. In particular, the lattice uncertainties for Phase 1 and Phase 2 are the same as Table 41 in Sec. 11. For both theoretical and experimental parameters the SM expectations were taken as central values, in order to ensure the compatibility of the extrapolated constraints.

The improvement of the UT global analysis can be appreciated in Fig. 23, where the present and future Phase 1 and Phase 2 constraints on the standard UT plane are shown next to each other, after zooming into the SM preferred region. For a more quantitative comparison we collect in Table 10 the uncertainties on the indirect determination of CKM parameters and angles, obtained from the predictive posterior p.d.f.'s (i.e., obtained without including the corresponding direct measurements in the fit). These uncertainties are reduced by a factor 3–5 for Phase 1, and are further reduced by up to a factor of 2 for Phase 2, allowing for an increasingly improved tests of the SM, as discussed next. A similar progression of improvements is seen in the projections from CKMfitter collaboration, cf. Fig. 21.

2.7 Future extrapolation of constraints on NP in $\Delta F = 2$ amplitudes

The Unitarity Triangle Analysis can be generalized beyond the SM to obtain a simultaneous determination of CKM parameters and NP contributions to $\Delta F = 2$ amplitudes [60, 198]. Assuming that NP is absent (or negligible) in charged current amplitudes, but allowing for NP to be present in FCNC

Table 10: Relative uncertainties on the predictions of UT parameters and angles, using current and extrapolated input values for measurements and theoretical parameters (UTfit collaboration).

	λ	$\bar{\rho}$	$\bar{\eta}$	A	$\sin 2\beta$	γ	α	β_s
Current	0.12%	9%	3%	1.5%	4.5%	3%	2.5%	3%
Phase 1	0.12%	2%	0.8%	0.6%	0.9%	0.9%	0.7%	0.8%
Phase 2	0.12%	1%	0.6%	0.5%	0.6%	0.8%	0.4%	0.5%

amplitudes, where its virtual effects compete with loop-level SM amplitudes, we can still use the measurements of $|V_{ud}|$, $|V_{us}|$, $|V_{cb}|$, $|V_{ub}|$, γ and α (allowing for NP contributions in penguins, but barring order-of-magnitude enhancements of electroweak penguins) to obtain the "tree-level" determination of the UT. This allows us to obtain the SM prediction for K, B_d and B_s mixing amplitudes. Comparing them with the experimental results we can extract $C_{\varepsilon_K} = \varepsilon_K/\varepsilon_K^{\rm SM}$ and

$$C_{B_q} e^{i\phi_{B_q}} = \frac{\langle B_q | H^{\rm SM+NP} | \bar{B}_q \rangle}{\langle B_q | H^{\rm SM} | \bar{B}_q \rangle} \,. \tag{21}$$

The SM point is $C_i = 1, \phi_i = 0$. Using semileptonic asymmetries it is possible to break the degeneracy for $\gamma \leftrightarrow \gamma + 180^\circ$ present in the tree-level determination of the CKM matrix [199], getting rid of the solution in the third quadrant. We then obtain the results in Table 11 for the projected errors on CKM parameters and on the NP parameters. Note that at present the NP contribution that are about an order of magnitude smaller than the SM are still perfectly allowed. At the end of Phase 2 we will be able to probe amplitudes that are another factor of 4 smaller than possible at present (corresponding to about a factor of 2 higher reach in the NP scale for dimension 6 NP operators). The corresponding two-dimensional distributions for B_d and B_s mixing are shown in Fig. 24.

Combining the results of the generalized UT analysis with the constraints on CP violation in D mixing from Sec. 3.7.5, we can consider the most general $\Delta F = 2$ effective Hamiltonian and place bounds on its coefficients (barring accidental cancellations). The most general effective Hamiltonians for $\Delta F = 2$ processes beyond the SM have the following form [200] (with $q_1 q_2 = sd, uc, bq$ for $M = K, D, B_q$)

$$\mathcal{H}_{\rm eff}^{M-\bar{M}} = \sum_{i=1}^{5} C_i \, Q_i^{q_1 q_2} + \sum_{i=1}^{3} \tilde{C}_i \, \tilde{Q}_i^{q_1 q_2} , \tag{22}$$

Phase 2	0.0047	0.0040	0.036	0.030	0.28	0.026	0.29

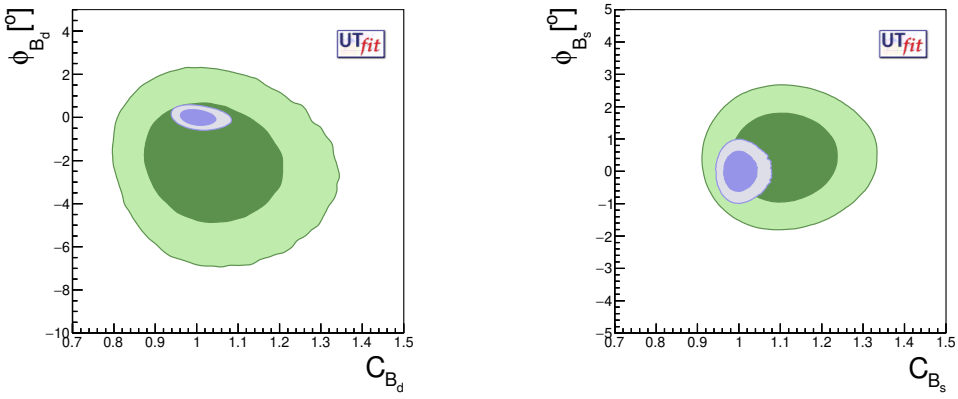

Fig. 24: The present (green) and future Phase 2 (blue) constraints on NP contributions to B_d-$\bar{B}_d$ (left) and B_s-$\bar{B}_s$ (right) mixing, with 1σ (2σ) regions shown with darker (lighter) shading.

where the operator basis consists of dimension 6 operators $Q_1^{q_iq_j} = (\bar{q}_{jL}^{\alpha}\gamma_\mu q_{iL}^{\alpha})(\bar{q}_{jL}^{\beta}\gamma^\mu q_{iL}^{\beta})$, $Q_2^{q_iq_j} = (\bar{q}_{jR}^{\alpha}q_{iL}^{\alpha})(\bar{q}_{jR}^{\beta}q_{iL}^{\beta})$, $Q_3^{q_iq_j} = (\bar{q}_{jR}^{\alpha}q_{iL}^{\beta})(\bar{q}_{jR}^{\beta}q_{iL}^{\alpha})$, $Q_4^{q_iq_j} = (\bar{q}_{jR}^{\alpha}q_{iL}^{\alpha})(\bar{q}_{jL}^{\beta}q_{iR}^{\beta})$, $Q_5^{q_iq_j} = (\bar{q}_{jR}^{\alpha}q_{iL}^{\beta})(\bar{q}_{jL}^{\beta}q_{iR}^{\alpha})$, and the operators $\tilde{Q}_{1,2,3}^{q_iq_j}$ that are obtained from the $Q_{1,2,3}^{q_iq_j}$ by exchanging $L \leftrightarrow R$. Here $q_{R,L} = P_{R,L}\, q$, with $P_{R,L} = (1 \pm \gamma_5)/2$, and α and β are colour indices. Following the procedure detailed in Ref. [198], the UTFit collaboration obtained p.d.f.'s for the Wilson coefficients based on the extrapolated UT and D mixing analyses. For self-consistency, the coefficients are computed at a scale μ_H roughly corresponding to the bound on the NP scale Λ that one obtains from the analysis (see below). The present and expected Phase 2 allowed regions at 95% probability on the Wilson coefficients

$$C_i(\Lambda) = \frac{F_i L_i}{\Lambda^2}\,, \tag{23}$$

are reported in Fig. 25. In the left panel in Fig. 25 the flavour and loop factors were set to $F_i = L_i = 1$, i.e., this shows the limits on the mass of NP states that contribute to meson mixing at tree level and couple with $\mathcal{O}(1)$ strength to the corresponding SM fermions. In Fig. 25 right, the flavour factor was set to $F_i = V_{tq_1}V_{tq_2}^*$, and the loop factor to $L_i = \alpha_2^2$, with α_2 the weak structure constant. That is, the right panel of Fig. 25 shows the reach for masses of NP states that have MFV-like couplings to SM fermions and contribute only at one loop level.

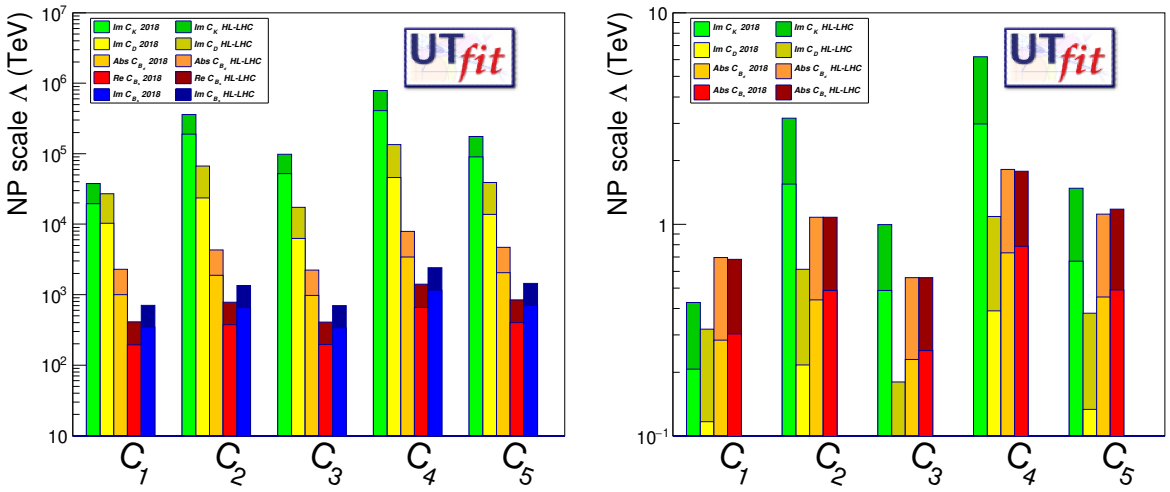

Fig. 25: Present (lighter) and future Phase 2 (darker) constraints on the NP scale from the UTfit NP analysis. The right panel shows constraints assuming NP is weakly coupled, has MFV structure of couplings, and enters observables only at one loop, see text for details.

3 Charm-quark probes of new physics

Authors (TH): J. Brod, S. Fajfer, A. Kagan, A. Lenz, L. Silvestrini.

In the SM, the FCNC processes involving charmed hadrons are suppressed compared to those involving strange or beauty hadrons since they are proportional to the small breaking of the GIM mechanism by the bottom quark mass. This also means that the contributions from long-distance physics, due to intermediate d, s quarks, are relatively more important, complicating the predictions. Moreover, due to small off-diagonal CKM matrix elements the third generation approximately factorizes from the first two generations, leading to additional suppression of the CP violating effects in charmed hadrons. The charmed hadrons can then be used as sensitive probes of new physics in the up-quark sector, to the extent that theoretical uncertainties can be brought under control, e.g., by constructing null tests, or circumvented by using experimental data.

3.1 Charm mixing

Weak interactions mix D^0 and $\bar{D}^0$ mesons, so that the mass eigenstates are $|D_{1,2}\rangle = p|D^0\rangle \pm q|\bar{D}^0\rangle$. By convention $|D_2\rangle$ is CP-even in the absence of CP violation. The mass and width differences, $\Delta M = m_2 - m_1$, and $\Delta\Gamma = \Gamma_2 - \Gamma_1$, are parametrized as

$$x \equiv \Delta M^D/\Gamma^D = 0.46\% \pm 0.13\%\,, \qquad y \equiv \Delta\Gamma^D/(2\Gamma^D) = 0.62\% \pm 0.07\%. \tag{24}$$

Here Γ is the total decay rate of the neutral D mesons, while the numerical values are from the fits to the experimental measurements [197]. As follows from Eq. (24), it appears that in D system $x \sim y$ or $\Gamma_{12} \sim M_{12}$. This is to be contrasted with the B system, where $|\Gamma_{12}/M_{12}| \ll 1$ holds. We also define the "theoretical" mixing parameters,

$$x_{12} \equiv \frac{2|M_{12}^D|}{\Gamma^D}\,, \quad y_{12} \equiv \frac{|\Gamma_{12}^D|}{\Gamma^D}\,, \quad \phi_{12} \equiv \arg\left(\frac{M_{12}^D}{\Gamma_{12}^D}\right)\,, \tag{25}$$

where M_{12}^D and Γ_{12}^D are the dispersive and absorptive contributions to the $D^0 - \overline{D}^0$ mixing amplitude, $\langle D^0|H|\bar{D}^0\rangle = M_{12}^D - \frac{i}{2}\Gamma_{12}^D$. The phase ϕ_{12} gives rise to CP violation in mixing, cf. Sec. 3.2. Its magnitude is currently bounded to lie below ~ 100 mrad at 95% CL [197, 201]. These parameters are related to x and y as,

$$(x - iy)^2 = x_{12}^2 - y_{12}^2 - 2\,i\,x_{12}y_{12}\cos\phi_{12}\,, \tag{26}$$

so that, up to negligible corrections quadratic in $\sin\phi_{12}$ (in general, $|y| \leq y_{12}$ [202, 203]),

$$|x| = x_{12}, \quad |y| = y_{12}\,. \tag{27}$$

It is convenient to begin the discussion of the SM mixing amplitudes with their U-spin flavor symmetry decomposition [204, 205]. Employing CKM unitarity, $\lambda_d + \lambda_s + \lambda_b = 0$, with $\lambda_x = V_{cx}V_{ux}^*$, Γ_{12}^D can be written as

$$\Gamma_{12}^D = \frac{(\lambda_s - \lambda_d)^2}{4}\,\Gamma_2 + \frac{(\lambda_s - \lambda_d)\lambda_b}{2}\,\Gamma_1 + \frac{\lambda_b^2}{4}\,\Gamma_0\,, \tag{28}$$

where

$$\begin{aligned}
\Gamma_2 &= \Gamma_{ss} + \Gamma_{dd} - 2\Gamma_{sd} \;\sim\; (\bar{s}s - \bar{d}d)^2 = \mathcal{O}(\epsilon^2)\,,\\
\Gamma_1 &= \Gamma_{ss} - \Gamma_{dd} \;\sim\; (\bar{s}s - \bar{d}d)(\bar{s}s + \bar{d}d) = \mathcal{O}(\epsilon)\,,\\
\Gamma_0 &= \Gamma_{ss} + \Gamma_{dd} + 2\Gamma_{sd} \;\sim\; (\bar{s}s + \bar{d}d)^2 = \mathcal{O}(1)\,,
\end{aligned} \tag{29}$$

with $\epsilon \sim 0.2$ denoting the U-spin breaking parameter. The $\Gamma_{2,1,0}$ are the $\Delta U_3 = 0$ elements of the U-spin 5-plet, triplet, and singlet, respectively. The individual Γ_{ij} are identified, at the quark level, with box

diagrams containing on-shell internal i and j quarks. They possess flavor structure $\Gamma_{ij} \sim (\bar{i}i)(\bar{j}j)(\bar{u}c)^2$, where the external u and c quarks are irrelevant for the U-spin decomposition. The U-spin decomposition of M_{12}^D is analogous to Eq. (28), with $\Gamma \to M$ replacement everywhere. At the level of quark box diagrams, $M_{1,0}$ also receive contributions containing internal b quarks. The small value of $\lambda_b \sim \mathcal{O}(10^{-4})$ implies that we can neglect the $\Delta U = 1, 0$ contributions to the mass and width differences, even though the $\Delta U = 2$ piece is higher order in ϵ.

Evaluation of the SM mixing amplitudes is very challenging, because the charm quark mass lies at an intermediate scale between the masses of the light quarks and the bottom quark. Broadly speaking, there are two approaches: (i) an inclusive one employing the operator product expansion (OPE), which expands in powers of $\Lambda_{\rm QCD}/m_c$, as in the heavy quark expansion (HQE), and assumes that local quark-hadron duality holds [206–209]; and (ii) an exclusive one in which y is estimated by summing over contributions of exclusive states, and x is estimated via a dispersion relation which relates it to y. In the first approach, the HQE applied to Γ_{12}^D, combined with the relevant non-perturbative dimension six operator matrix elements evaluated in [210–213], yields contributions of the individual Γ_{ij} to y that are five times larger than the experimental value [214]. This corresponds to $\Gamma_{ij} \sim \Gamma^D$, which is not surprising, given that the HQE can accommodate the charm meson lifetimes [213, 215]. However, the result for Γ_2, cf. Eqs. (28), (29), yields a value of y lying about four orders of magnitude below experiment, due to large GIM-cancellations between the Γ_{ij} contributions. Evidently, the inclusive approach is not well suited for analyzing the U-spin breaking responsible for $D^0 - \overline{D}^0$ mixing, i.e., the charm quark is not sufficiently massive, and $(m_s - m_d)/\Lambda_{\rm QCD}$ is not sufficiently small. First estimates of the dimension nine contribution in the HQE [216] indicate an enhancement compared to the leading dimension six terms, but do not alter this conclusion. The HQE result $\theta_c^2\, \Gamma_{ij} \sim 5\, y$ would require large U-spin violation, e.g. $\mathcal{O}(\epsilon^2) = 20\%$ in Γ_2, cf. (29), which could be attributed to long-distance duality violation [203]. One possibility for directly addressing the origin of U-spin violation in $D^0 - \overline{D}^0$ mixing is the second (exclusive) approach mentioned above.

The starting point for the exclusive approach [204, 205, 217–219] is a sum over the decay modes contributing to the absorptive and dispersive mixing amplitudes, see e.g. [220],

$$\Gamma_{12}^D = \sum_f \rho_f A_f^* \, \bar{A}_f \,; \qquad M_{12}^D = \langle D^0 | H^{\Delta D=2} | \bar{D}^0 \rangle + P \sum_f \frac{A_f^* \, \bar{A}_f}{m_{D^0}^2 - E_f^2} \,, \tag{30}$$

where $A_f = \langle f | H_{\Delta c=1} | D^0 \rangle$ and $\bar{A}_f = \langle f | H_{\Delta c=1} | \bar{D}^0 \rangle$ are the $D^0 \to f$ and $\bar{D}^0 \to f$ decay amplitudes, respectively, ρ_f is the density of the state f, and P is the principal value. Unfortunately, the charm quark mass is not sufficiently light for D meson decays to be dominated by a few final states. Moreover, the strong phase differences entering Γ_{12}^D, and the off-shell decay amplitudes entering M_{12}^D are not calculable from first principles. Thus, simplified treatments of $SU(3)_F$ flavor symmetry breaking have been utilized. A rough U-spin based estimate for y is simply obtained from the first term in (28),

$$y \;=\; \sin^2\theta_c \times \Gamma_2/\Gamma^D \;\sim\; \sin^2\theta_C \;\times\; \epsilon^2 \sim (0.2 - 5)\%, \tag{31}$$

where we have taken $\Gamma_2 \sim \Gamma^D \epsilon^2$ (which can be motivated by the HQE result $\Gamma_{ij} \sim \Gamma^D$); and $\epsilon \sim 0.2 - 1$, corresponding to variation from nominal to maximal U-spin breaking. The authors of [204, 217] only took $SU(3)_F$-breaking phase space effects into account in the exclusive sum. They found that $y \lesssim 1\%$ could naturally be realized, where a value at the high end would require contributions from higher multiplicity final states, due to the larger $SU(3)_F$ breaking effects near threshold (consistent with the large U-spin breaking required from duality violations in the OPE/HQE approach). This conclusion was subsequently supported in [218, 219], which added experimental branching ratio inputs together with factorization based models for dynamical $SU(3)_F$ breaking effects, e.g., in the form factors and strong phases. Rough dispersion relation estimates in [217, 218] suggested that $|x/y| \sim 0.1 - 1$.

We conclude that the estimates of x and y in the SM are consistent with their measured values, cf. (24). Unfortunately, the large theoretical uncertainties eliminate the window for NP in these quantities.

The situation is markedly different for the CPV mixing observables, due to their large suppression in the SM, as discussed below. On a very long time-scale, direct lattice calculations might be able to predict the SM values of x and y by building on the methods described in [221].

3.2 CP violation in $D^0 - \overline{D}^0$ mixing

In the SM, *CP* violation (CPV) in $D^0 - \overline{D}^0$ mixing is highly suppressed, entering at $\mathcal{O}(|V_{cb}V_{ub}/V_{cs}V_{us}|) \sim 10^{-3}$. This raises several questions, which we briefly address, based on work to appear in [222]: What is the resulting theoretical uncertainty on the indirect CPV observables? How large is the current window for New Physics (NP)? What is an appropriate parametrization for indirect CPV effects, given the expected sensitivity in the LHCb/Belle-II era?

There are two types of CPV due to mixing; both are referred to as "indirect" CPV. The first is CPV due to interference between the dispersive and absorptive mixing amplitudes ("CPVMIX"), which arises when $\phi_{12} \neq 0$. CPVMIX can be directly measured via the semileptonic *CP* asymmetry

$$A_{\rm SL} \equiv \frac{\Gamma(D^0 \to K^+\ell^-\nu) - \Gamma(\bar{D}^0 \to K^-\ell^+\nu)}{\Gamma(D^0 \to K^+\ell^-\nu) + \Gamma(\bar{D}^0 \to K^-\ell^+\nu)} = \frac{|q/p|^4 - 1}{|q/p|^4 + 1} = \frac{2x_{12}y_{12}}{x_{12}^2 + y_{12}^2}\sin\phi_{12}\,. \tag{32}$$

The second type of indirect CPV is due to interference between a direct decay amplitude and a "mixed" amplitude followed by decay ("CPVINT"), i.e., interference between $D^0 \to f$ and $D^0 \to \bar{D}^0 \to f$. For decays to a *CP* eigenstate final state, there are two CPVINT observables [223, 224],

$$\lambda_f^M \equiv \frac{M_{12}}{|M_{12}|}\frac{A_f}{\overline{A}_f} = \eta_f^{CP}\left|\frac{A_f}{\overline{A}_f}\right| e^{i\phi_f^M}\,, \quad \lambda_f^\Gamma \equiv \frac{\Gamma_{12}}{|\Gamma_{12}|}\frac{A_f}{\overline{A}_f} = \eta_f^{CP}\left|\frac{A_f}{\overline{A}_f}\right| e^{i\phi_f^\Gamma}\,, \tag{33}$$

parametrizing the interference for a dispersive and absorptive mixing amplitudes, respectively. The ϕ_f^M and ϕ_f^Γ are CPV weak phases, with $\phi_{12} = \phi_f^M - \phi_f^\Gamma$, while $\eta_f^{CP} = +(-)$ for *CP* even (odd) final states. In general, ϕ_f^M and ϕ_f^Γ are final-state specific due to non-universal weak and strong phases entering the CKM suppressed SM (and potential NP) contributions to the subleading decay amplitudes.

Non-vanishing ϕ_f^M and ϕ_f^Γ yield *time-dependent CP* asymmetries. For example, in singly Cabibbo suppressed (SCS) decays to CP-eigenstates, $f = K^+K^-$, $\pi^+\pi^-$, ..., the effective decay widths, $\hat{\Gamma}$, for D^0 and $\bar{D}^0$ decays (the time-dependence of these decays can, to good approximation, be parametrized in exponential form $\propto e^{-\hat{\Gamma}\tau}$, where $\tau \equiv \Gamma_D t$) will differ,

$$\Delta Y_f \equiv \frac{\hat{\Gamma}_{\bar{D}^0\to f} - \hat{\Gamma}_{D^0\to f}}{2\Gamma_D} = -x_{12}\sin\phi_f^M + a_f^d\, y_{12}\,. \tag{34}$$

The first and second terms on the RHS are the dispersive CPVINT and direct CPV contributions, respectively, where the direct *CP* asymmetry is defined as $a_f^d = 1 - \left|\bar{A}_f/A_f\right|$. They can, in principle, be disentangled via measurements of the corresponding time-integrated *CP* asymmetries (43), which satisfy $A_{CP}(D^0 \to h^+h^-) = \Delta Y_{h^+h^-}\,\langle t\rangle/\tau_D + a^d_{h^+h^-}$. Examples of time-dependent *CP* asymmetries in decays to non-CP eigenstates include the SCS final states $f = K^*K$ or $f = \rho\pi$, and the Cabibbo favored/doubly Cabibbo suppressed (CF/DCS) final states $f = K^\pm\pi^\mp$. These asymmetries generally depend on both ϕ_f^M and ϕ_f^Γ, unlike decays to *CP* eigenstates, due to the additional strong phases [222].

The dispersive and absorptive observables are simply related [222] to the more familiar parametrization of indirect CPV, see, e.g., [220]. The latter consists of $|q/p| - 1$, and

$$\lambda_f \equiv \frac{q}{p}\frac{\bar{A}_f}{A_f} = -\eta_f^{CP}\left|\lambda_f\right| e^{i\,\phi_{\lambda_f}}\,, \tag{35}$$

for *CP* eigenstate final states, and pairs of observables λ_f, $\lambda_{\bar{f}}$ for non-CP eigenstate final states. The same number of independent parameters is employed in each case (recall that $\phi_{12} = \phi_f^M - \phi_f^\Gamma$).

Single mrad precision for ϕ_{12} could become a realistic target at LHCb, see below and Sec. 3.7, to be compared with the current $\sim 50 - 100$ mrad bounds [95% CL] quoted by HFLAV and UTfit Collaboration [197, 201]. Thus, we must estimate the final state dependence in ϕ_f^M, ϕ_f^Γ due to the subleading decay amplitudes, and consider how to best parameterize this. This is accomplished via the U-spin flavor symmetry decomposition of the $D^0 - \overline{D}^0$ mixing amplitudes given in Eq. (28). We define three theoretical CPV phases

$$\phi_2^\Gamma \equiv \arg\left(\frac{\Gamma_{12}}{\Gamma_{12}^{\Delta U=2}}\right), \quad \phi_2^M \equiv \arg\left(\frac{M_{12}}{\Gamma_{12}^{\Delta U=2}}\right), \quad \phi_2 \equiv \arg\left(\frac{q}{p}\Gamma_{12}^{\Delta U=2}\right), \tag{36}$$

which are the theoretical analogs of the final state dependent phases ϕ_f^M, ϕ_f^Γ, and ϕ_{λ_f}, respectively. The U-spin breaking hierarchy $\Gamma_1/\Gamma_2 = \mathcal{O}(1/\epsilon)$ yields the estimate

$$\phi_2^\Gamma \approx \mathrm{Im}\left(\frac{2\lambda_b}{\lambda_s - \lambda_d}\frac{\Gamma_1}{\Gamma_2}\right) \sim \left|\frac{\lambda_b}{\theta_c}\right| \sin\gamma \times \frac{1}{\epsilon}, \tag{37}$$

and similarly for ϕ_2^M (the $O(\lambda_b^2)$ contributions are negligible). Taking the nominal value $\epsilon \sim 0.2$ for U-spin breaking, we obtain the rough SM estimates

$$\phi_{12} \sim \phi_2^\Gamma \sim \phi_2^M \sim 3 \times 10^{-3}\,. \tag{38}$$

Comparison with the current 95% CL bounds on ϕ_{12} implies that there is an $\mathcal{O}(10)$ window for NP in indirect CPV. An alternative expression for ϕ_2^Γ follows from (37) via the relation $\Gamma_2 \cong y\,\Gamma^D$,

$$|\phi_2^\Gamma| = \left|\frac{\sin\gamma\ \lambda_b\,\lambda_s}{y}\right| \frac{|\Gamma_1|}{\Gamma^D} \approx 0.005\,\frac{|\Gamma_1|}{\Gamma^D} \sim 0.005\,\epsilon\,, \tag{39}$$

where in the last relation we have taken $\Gamma_1 \sim \Gamma^D\epsilon$ (recall that the HQE yields $\Gamma_{ij} \sim \Gamma^D$). In principle, Γ_1 can be estimated via the exclusive approach as more data on SCS D^0 decay branching ratios and direct CP asymmetries becomes available.

The misalignments between ϕ_f^M, ϕ_f^Γ, ϕ_{λ_f} in (33), (35), and their theoretical counterparts satisfy

$$\delta\phi_f \equiv \phi_f^\Gamma - \phi_2^\Gamma = \phi_f^M - \phi_2^M = \phi_2 - \phi_{\lambda_f}\,. \tag{40}$$

We can characterize the magnitude of the misalignment $\delta\phi_f$ in the SM as follows: (i) For CF/DCS decays it is precisely known and negligible, i.e., $\delta\phi_f = \mathcal{O}(\lambda_b^2/\theta_c^2)$; (ii) In SCS decays, $\delta\phi_f$ is related to direct CPV as $\delta\phi_f = a_f^d \cot\delta$ via the U-spin decomposition of the decay amplitudes [225], where a strong phase $\delta = \mathcal{O}(1)$ is expected due to large rescattering at the charm mass scale. Thus, for $f = \pi^+\pi^-, K^+K^-$, the experimental bounds $a_f^d \lesssim \mathcal{O}(10^{-3})$ imply that $\delta\phi_f \lesssim \mathcal{O}(10^{-3})$; (iii) In SCS decays, $\delta\phi_f = \mathcal{O}(\lambda_b \sin\gamma/\theta_c) \times \cot\delta$, i.e., it is $\mathcal{O}(1)$ in $SU(3)_F$ breaking. Thus, (37) yields $\delta\phi_f/\phi_2^\Gamma = \mathcal{O}(\epsilon)$, implying an order of magnitude suppression of the misalignment. An exception to property (iii) arises in $D^0 \to K_sK_s$, where the leading "tree-level" decay amplitude enters at $O(\epsilon)$ [226], thus yielding $\delta\phi_{K_sK_s}/\phi_2^\Gamma = \mathcal{O}(1)$. Note that $\delta\phi_{K^{*0}K_S}$ could also be enhanced due to a suppression of the leading amplitudes [227].

In the HL-LHC era, a single pair of dispersive and absorptive phases, identified with ϕ_2^M and ϕ_2^Γ, respectively, should suffice to parametrize all indirect CPV effects. We refer to this fortunate circumstance as *approximate universality*. Moreover, approximate universality generalizes beyond the SM under the following conservative assumptions about NP contributions: (i) they can be neglected in CF/DCS decays (a highly exotic NP flavor structure would otherwise be required in order to evade the ϵ_K constraint [228]); (ii) in SCS decays they are of similar size or smaller than the SM QCD penguin amplitudes,

as already hinted at by the experimental bounds on the direct CP asymmetries $a^d_{K^+K^-}$, $a^d_{\pi^+\pi^-}$. These assumptions can be tested by future direct CPV measurements.

Under approximate universality, $\phi_f^M \to \phi_2^M$ and $\phi_f^\Gamma \to \phi_2^\Gamma$ in expressions for time-dependent CP asymmetries. A global fit to the CPV data for any two of the three phases, ϕ_2^M, ϕ_2^Γ, ϕ_{12}, is equivalent to the traditional two-parameter fit for $|q/p|$ and ϕ , where ϕ is identified with ϕ_2 [222]. The relations

$$\left|\frac{q}{p}\right| - 1 \approx \frac{|x||y|}{x^2+y^2}\sin\phi_{12}, \qquad \tan 2(\phi_2+\phi^\Gamma) \approx -\frac{x_{12}^2}{x_{12}^2+y_{12}^2}\sin 2\phi_{12}\,, \tag{41}$$

together with $\phi_{12} = \phi_2^M - \phi_2^\Gamma$, allow one to translate between $(\phi_2, |q/p|)$ and $(\phi_2^M, \phi_2^\Gamma)$. To illustrate the potential reach of LHCb in ϕ_2^M and ϕ_2^Γ from prompt charm production at 300 fb^{-1}, the projected statistical errors on ϕ, $|q/p|$, x, y from $D^0 \to K_s\pi^+\pi^-$ (combined with the Belle error correlation matrix [229]), and on $\Delta Y_f = -A_\Gamma$, given in the last rows of Tables 14 and 16, and assuming the central values $|q/p| = 1$, $\phi = 0$, $x = 0.57\%$, and $y = 0.7\%$, yield

$$\sigma(\phi_2^M) = 2 \text{ mrad}, \quad \sigma(\phi_2^\Gamma) = 5 \text{ mrad}\,. \tag{42}$$

The projected statistical errors are smaller for $D^0 \to K^+\pi^-\pi^-\pi^+$ than for $D^0 \to K_s\pi^+\pi^-$, cf. Tab. 15. Thus, if the systematic errors are not prohibitively large, cf. Sec. 3.7, LHCb could probe indirect CPV in the SM.

Finally, we remark, that if NP predominantly couples to left-handed quark currents, there are strong correlations between NP contributions to $D-\bar{D}$ and $K-\bar{K}$ mixing [230, 231]. In such a case, the combination of measurements in these two systems is particularly powerful.

3.3 Direct *CP* violating probes

Direct CP asymmetries,

$$A_{CP}(D^0 \to h^-h^+) \equiv \frac{\Gamma(D^0 \to h^-h^+) - \Gamma(\overline{D}^0 \to h^-h^+)}{\Gamma(D^0 \to h^-h^+) + \Gamma(\overline{D}^0 \to h^-h^+)}, \tag{43}$$

with h a light meson, are suppressed in the SM but could be enhanced by NP. A prominent test of direct CPV in charm is the observable

$$\Delta A_{CP} = A_{CP}(K^-K^+) - A_{CP}(\pi^-\pi^+), \tag{44}$$

which measures the difference between direct CPV in SCS modes $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$. This is despite that the SM prediction is hard to obtain. However, assuming nominal breaking of the $SU(3)$ flavor symmetry, $\epsilon \approx f_K/f_\pi - 1 \approx \mathcal{O}(20\,\%)$, one can infer from the observed branching ratios of the CF decay$D^0 \to \pi^+K^-$ and DCS decay $D^0 \to \pi^-K^+$ a consistent picture involving large matrix elements for U-spin breaking penguin [225, 232–236] (see also [237]). These can account, in the presence of large strong phases, for values of $\Delta A_{CP} \lesssim 0.2\%$ [238], in accordance with the current measurements. Light cone QCD sum rule calculations, on the other hand, predict a much smaller quantity, $\Delta A_{CP} = (0.020 \pm 0.003)\%$ [239]. LHCb is expected to probe far into this region after Upgrade II (see Sec. 3.7.6).

SCS D decay modes are sensitives probes of CP violation in and beyond the SM [240]. Other decay modes can also be sensitive to CP asymmetries of the same order, both in the SM and in NP extensions that modify the QCD penguin operators. Besides the modes $D^+ \to K^+\bar{K}^0$ and $D_s^+ \to \pi^+K^0$, obtained from the above via exchange of the spectator quark, the mode $D^0 \to K_SK_S$ is particularly interesting, because a large CP asymmetry $\lesssim 1\,\%$ can be expected [226, 238]. The related $D \to KK^*$ modes have smaller asymmetries, but this can be compensated by the higher experimental efficiency [227]. Such quasi two-body decays can interfere, if they contribute to the same three- or four-body final state, which

needs to be taken into account in the analysis (for theory discussion, see, e.g., [241], for experimental prospects at LHCb Upgrade II see Sec. 3.7.6).

Another interesting class of observables are the semileptonic D decays, $D \to P\ell^+\ell^-$ and $D \to P_1P_2\ell^+\ell^-$, where P, P_1, P_2 are light pseudoscalars. In analogy to the well-studied corresponding semileptonic B decay modes, interesting null tests of CP violation can be constructed [242–244]. In certain regions of phase space, the CP asymmetries can be largely enhanced via interferences with resonances, which makes these decays an interesting class of observables for LHCb [245].

A set of observables related to direct CP asymmetry are $\widehat{T}$-violating triple products [246] (see also Sec. 3.7.6). To be nonzero they require a source of CPV, and at least three independent momenta or polarization vectors in the final state, such as in $D \to VV$ decays or decays to four pseudoscalars. Unlike direct CP asymmetry, the $\widehat{T}$-violating triple products can be nonzero even in the case of vanishing strong phase differences.

3.4 Null tests from isospin sum rules

SM predictions for hadronic D decays are notoriously difficult. In some cases it is possible to obtain strong indications for the presence of NP by relating various modes using the approximate flavor symmetry $SU(3)$ (invariance under interchange of up, down, and strange quarks) or the more precise isospin (invariance under interchange of up and down quarks).

Probably the simplest example is the $D^+ \to \pi^+\pi^0$ decay [238]. The final state has isospin $I = 2$ which cannot be reached from the $I = 1/2$ initial state via the $\Delta I = 1/2$ QCD penguin operators, predicting very suppressed direct CPV in the SM. An important question in this context is the size of isospin-breaking effects. Isospin-breaking due to QED and the difference of up- and down-quark mass is CP conserving and can be safely neglected. The electroweak penguin contribution is relatively suppressed by α/α_s in the SM. Thus, enhanced direct CPV in $D^+ \to \pi^+\pi^0$ would signal the presence of isospin-violating NP.

Another example is the sum of rate differences [247]

$$\begin{aligned} &|A_{\pi^+\pi^-}|^2 - |\bar{A}_{\pi^+\pi^-}|^2 + |A_{\pi^0\pi^0}|^2 - |\bar{A}_{\pi^0\pi^0}|^2 \\ &\qquad - \frac{3}{2}\left(|A_{\pi^+\pi^0}|^2 - |\bar{A}_{\pi^-\pi^0}|^2\right) = 3\left(|A_{1/2}|^2 - |\bar{A}_{1/2}|^2\right), \end{aligned} \tag{45}$$

which depends only on $\Delta I = 1/2$ amplitudes. There are two possibilities. If the sum is non-zero, there are $\Delta I = 1/2$ contributions to CP violation; they can be due to SM or NP. If the sum is zero, but the individual asymmetries are non-zero, the CP asymmetries are likely dominated by $\Delta I = 3/2$ NP contributions. More sum rules, involving also vector meson final states, can be devised for the decay modes $D \to \rho\pi$, $D \to K^{(*)}\bar{K}^{(*)}\pi(\rho)$, $D_s^+ \to K^*\pi(\rho)$ [247]. For an exhaustive list of sum rules based on the flavor $SU(3)$ or its subgroups, see Refs. [248–250]. For decays with only charged particles in the final state a significant improvement in precision is projected at LHCb Upgrade II. The final states with neutral pions are more challenging (for experimental prospects at LHCb Upgrade II see Sec. 3.7.6). However, precise information on these CP asymmetries is expected from Belle-II.

3.5 Radiative and leptonic charm decays

In the down-type quark sector the GIM suppression is less effective because of the large top quark mass, so that the diagrams with the top-quark running in the loop dominate. In the *charm* sector the GIM suppression is more efficient at least at the perturbative level, since none of the down-type quarks are heavy. The exact suppression for a particular FCNC decay depends on how well the GIM suppression is carried over to the non-perturbative contributions ("long distance" physics). The result is that the SM branching ratios for radiative and leptonic charm decays, while suppressed, are in general not too small to be out of reach. The branching ratios for semi-leptonic FCNC decays, such as $D \to P\ell\ell$, $D \to V\ell\ell$,

and $D \to PP\ell\ell$ are at the level of $10^{-7} - 10^{-6}$, while for the radiative decays, $D \to V\gamma$, they are at the level of $10^{-4} - 10^{-5}$. The branching ratios for these decays are resonance dominated, and this holds true even in the presence of new physics. However, one can still search for new physics effects by using appropriate observables such as CP asymmetries, polarization asymmetries, and angular observables, as well as enhancements of differential rates away from resonance regions.

3.5.1 *Radiative Decays*

The effective weak Lagrangian for the exclusive $c \to u\gamma$ FCNC transitions $D \to V\gamma$ is, see, e.g., [243],

$$\mathcal{L}_{\text{eff}}^{\text{weak}} = \frac{4G_F}{\sqrt{2}} \left(\sum_{q\in\{d,s\}} V_{cq}^* V_{uq} \sum_{i=1}^{2} C_i O_i^{(q)} + \sum_{i=3}^{6} C_i O_i + \sum_{i=7}^{8} \left(C_i O_i + C_i' O_i' \right) \right), \tag{46}$$

with the operators $\mathcal{O}_{2(1)} = (\bar{u}_L \gamma_\mu (T^a) q_L)(\bar{q}_L \gamma^\mu (T^a) c_L)$, $\mathcal{O}_7^{(\prime)} = e\, m_c/16\pi^2 (\bar{u}_{L(R)} \sigma^{\mu\nu} c_{R(L)}) F_{\mu\nu}$ and $\mathcal{O}_8^{(\prime)} = g_s\, m_c/16\pi^2 (\bar{u}_{L(R)} \sigma^{\mu\nu} T^a c_{R(L)}) G^a_{\mu\nu}$. The SM effective Wilson coefficients $C_i^{(\text{eff})}$, which absorb the universal long-distance effects from quark loops in perturbation theory, are known at two-loop level in QCD [243, 251–253]. The authors of Ref. [243] improved the SM prediction for the branching ratios of $D \to V\gamma$, by including power corrections and updating the hybrid model predictions. The hybrid model combines the heavy quark effective theory and chiral perturbation theory using experimentally measured parameters [254, 255]. They also included corrections to the perturbative Wilson coefficients by employing a QCD based approach, worked out for B physics as reviewed in [243]. Updated values for the SM Wilson coefficients at leading order in α_s are given in [242, 243, 251]. The GIM mechanism suppresses strongly C_8^{eff} in the SM. The experimental branching ratio for the Cabibbo allowed decay is $\mathcal{B}(D^0 \to K^*(892)\gamma) = (4.1 \pm 0.7) \times 10^{-4}$ and for the Cabibbo suppressed decays $\mathcal{B}(D^0 \to \phi\gamma) = (2.74 \pm 0.19) \times 10^{-5}$, $\mathcal{B}(D^0 \to \rho^0\gamma) = (1.76 \pm 0.31) \times 10^{-5}$ [256]. The hybrid model predicts in the SM $\mathcal{B}(D^0 \to \rho^0\gamma)_{\text{SM}} = (0.041 - 1.17) \times 10^{-5}$, $\mathcal{B}(D^0 \to \phi\gamma)_{\text{SM}} = (0.24 - 2.8)) \times 10^{-5}$, $\mathcal{B}(D^0 \to \bar{K}^{*0}\gamma)_{\text{SM}} = (0.26 - 4.6) \times 10^{-4}$ [243, 257]. The NP scenarios discussed in Ref. [257] can contribute at the loop level to $C_{7,8}^{\text{eff}}$, and cannot significantly modify the branching ratios. However, the NP induced CPV asymmetry was found to still be modest, e.g., $\sim \mathcal{O}(10\%)$ for $D^0 \to \rho^0\gamma$. In the case of baryonic mode $\Lambda_c \to p\gamma$ the rate is estimated to be $\sim \mathcal{O}(10^{-5})$. The forward-backward asymmetry of photon momentum relative to Λ_c boost probes the handedness of $c \to u\gamma$ transitions. It can be 0.2 in the SM, and somewhat smaller within scenarios of NP discussed in [243, 257]. The probes of photon polarization include time-dependent analysis in $D^0, \bar{D}^0 \to V\gamma$, where $V = \rho^-, K^0, \phi$, or an up-down asymmetry in $D_{(s)} \to K_1(\to K\pi\pi)\gamma$ [258].

3.5.2 *Rare leptonic decays of charm*

To describe NP effects the effective Lagrangian for the $c \to u\bar{\ell}\ell$ has to be extended by the following operators

$$\begin{aligned} \mathcal{O}_{9(10)} &= \frac{e^2}{(4\pi)^2} (\bar{u}\gamma^\mu P_L c)(\bar{\ell}\gamma_\mu(\gamma_5)\ell)\,, & \mathcal{O}_{S(P)} &= \frac{e^2}{(4\pi)^2} (\bar{u} P_R c)(\bar{\ell}(\gamma_5)\ell)\,, \\ \mathcal{O}_T &= \frac{e^2}{(4\pi)^2} (\bar{u}\sigma_{\mu\nu} c)(\bar{\ell}\sigma^{\mu\nu}\ell)\,, & \mathcal{O}_{T5} &= \frac{e^2}{(4\pi)^2} (\bar{u}\sigma_{\mu\nu} c)(\bar{\ell}\sigma^{\mu\nu}\gamma_5\ell). \end{aligned} \tag{47}$$

Among these only C_9 is nonzero in the SM. For each $\mathcal{O}_i$ one can introduce $\mathcal{O}_i'$ with the corresponding Wilson coefficient C_i' by replacing the chirality operator $P_L = 1/2(1-\gamma^5)$ by $P_R = 1/2(1+\gamma^5)$ [259]. In Ref. [242] the authors obtained (N)NLO QCD SM Wilson coefficients at $\mu_c = m_c$, $C_7 \simeq (-0.0011 - 0.0041i)$ and $C_9 \simeq -0.021 X_{ds}$, where $X_{ds} = V_{cd}^* V_{ud} L(m_d^2, q^2) + V_{cs}^* V_{us} L(m_s^2, q^2)$, with $L(m^2, q^2)$ defined in eq. (B1) of [242]. In the range of $m_c/\sqrt{2} \le \mu_c \le \sqrt{2} m_c$ the effective Wilson

Table 12: Maximal experimentally allowed magnitudes of the Wilson coefficients, $|\tilde{C}_i| = |V_{ub}V_{cb}^* C_i|$, obtained from non-resonant part of $D^+ \to \pi^+\mu^+\mu^-$ decay, low q^2 region I: $q^2 \in [0.0625, 0.276]\,\text{GeV}^2$; high q^2 region: $q^2 \in [1.56, 4.00]\text{GeV}^2$); and from $\mathcal{B}(D^0 \to \mu^+\mu^-) < 7.6 \times 10^{-9}$ at 95% C.L. [260]. The last row applies to the case $\tilde{C}_9 = \pm\tilde{C}_{10}$. All the bounds assume real C_i, and also apply to coefficients with flipped chirality, $\tilde{C}'_j$.

	$\dfrac{|\tilde{C}_i|_{\max}}{\mathcal{B}(\pi\mu\mu)_I}$	$\mathcal{B}(\pi\mu\mu)_{II}$	$\mathcal{B}(D^0 \to \mu\mu)$
$\tilde{C}_7$	2.4	1.6	-
$\tilde{C}_9$	2.1	1.3	-
$\tilde{C}_{10}$	1.4	0.92	0.63
$\tilde{C}_S$	4.5	0.38	0.049
$\tilde{C}_P$	3.6	0.37	0.049
$\tilde{C}_T$	4.1	0.76	-
$\tilde{C}_{T5}$	4.4	0.74	-
$\tilde{C}_9 = \pm\tilde{C}_{10}$	1.3	0.81	0.63

coefficients were found to be $(-0.0014 - 0.0054i) \leq C_7 \leq (-0.00087 - 0.0033i)$ and $-0.060 X_{ds}(\mu_c = \sqrt{2}m_c) \leq C_9 \leq 0.030 X_{ds}(\mu_c = m_c/\sqrt{2})$. In the small $q^2 \gtrsim 1\,\text{GeV}^2$ region $|C_9| \lesssim 5 \cdot 10^{-4}$.

One can consider contributions of this effective Lagrangian in the exclusive decay channels. For the D meson di-leptonic decays the best upper bound to date is obtained by the LHCb collaboration at the 90% CL [260] $\mathcal{B}(D^0 \to \mu^+\mu^-) < 6.2 \times 10^{-9}$. In the decay $D^+ \to \pi^+\mu^+\mu^-$ the LHCb experiment determined bounds on the branching ratio in the two kinematic regions of the di-lepton mass, chosen to be either below or above the dominant resonant contributions. The measured total branching ratio, obtained by extrapolating spectra over the non-resonant region, is [261] $\mathcal{B}(D^+ \to \pi^+\mu^+\mu^-) < 8.3 \times 10^{-8}$, while the separate branching fractions in the low- and high-q^2 bins are bounded to be below $\mathcal{B}(\pi^+\mu^+\mu^-)_I < 2.5 \times 10^{-8}$ for region I, $q^2 \in [0.0625, 0.276]\,\text{GeV}^2$, and $\mathcal{B}(\pi^+\mu^+\mu^-)_{II} < 2.9 \times 10^{-8}$ for region II, $q^2 \in [1.56, 4.00]\text{GeV}^2$ [261]. These can be used to put bounds on Wilson coefficients. Allowing for NP contributions to only one Wilson coefficient at a time gives the upper bounds listed in Table 12, where $\tilde{C}_i = V_{ub}V_{cb}^* C_i$ [259]. The bound on $\mathcal{B}(D^0 \to \mu^+\mu^-)$ gives the most stringent bounds on $C_{S,P,10}$ Wilson coefficients.

For baryonic $c \to u\ell^+\ell^-$ transitions the relevant form factors are known from lattice QCD calculations for the $\Lambda_c \to p\ell^+\ell^-$ decay [262]. The dominant contributions to the branching ratio come from resonant regions of $\Lambda_c \to p\rho, (\omega, \phi)$ with ρ, ω and ϕ decaying to $\mu^+\mu^-$. This permits to investigate the impact of NP on the differential branching ratio, the fraction of longitudinally polarized di-muons and the forward-backward asymmetry. The upper 90% CL bound $\mathcal{B}(\Lambda_c \to p\mu^+\mu^-)_{exp} < 7.7 \times 10^{-8}$ [263], obtained by excluding the ± 40 MeV intervals around resonances still allows NP contribution in C_9 and C_{10}. The $\Lambda_c \to p\mu^+\mu^-$ forward-backward asymmetry appears as a result of a nonzero C_{10} Wilson coefficient, generated by the NP. Therefore this observable provides a clean null test of the SM as suggested in Ref. [262].

The above bounds allow for appreciable NP contributions. An example are leptoquark mediators [264], which are well motivated as the NP explanations of the B-meson anomalies, see, e.g., [265]. Refs. [242] and [259] showed that leptoquark exchanges do not affect much the branching ratios, but can lead to CP asymmetries in $D \to \pi l^+ l^-$ and $D_s \to K l^+ l^-$ of a few percent [242, 266]. Namely, such CP asymmetries are defined close to the ϕ resonance that couples to the lepton pair and they can be generated by imaginary parts of the C_7 Wilson coefficients in the effective Lagrangian for $c \to u l^+ l^-$

processes. In the case of any NP scenario one cannot consider any charm rare decays without considering bounds from the $D^0 - \bar{D}^0$ oscillation as pointed out in [267]. In some particular NP scenarios, bounds on NP are stronger if from the $D^0 - \bar{D}^0$ oscillation.

In addition, if the NP is realized by the left-handed doublets of the weak isospin, then NP present in B physics also inevitably appears in charm physics, accompanied with the appropriate CKM matrix elements. Tests of lepton flavour universality are of particular interest, such as the observable $R_{hh} = \mathcal{B}(D \to hh\mu^+\mu^-)/\mathcal{B}(D \to hhe^+e^-)$. The ratio R_{hh} is theoretically clean, but only when both numerator and denominator have the same kinematic cuts, and when these are well above the muon threshold [244, 259]. LHCb has already measured $D \to \pi^+\pi^-\mu^+\mu^-$ and $D \to K^+K^-\mu^+\mu^-$ [268], and BESIII set upper limits on the electron modes [269], but with different cuts on q^2.

3.6 Inputs for B physics

If discovered, the presence of direct CP violation in D decays can affect the extraction of the CKM angle γ from the "tree-level" decays $B \to DK$ [48,49,51,53]. If one includes the $B \to D\pi$ modes, the effect can be of order one [270]. One of the advantages of obtaining γ from tree decays is that all hadronic parameters can be fit from data. This remains essentially true even if direct CPV is present in the decays of the final-state D mesons [270–272], as long as one includes all direct CP asymmetries in the fit – there are still more observables than parameters in the fit. However, one can show that there remains an ambiguity: A shift in the angle γ can be compensated by a corresponding, unobservable shift in the contributing strong phases. This shift symmetry can be broken by assuming the absence of CPV in one of the D decay modes (for instance, in the SM this is the case for CF and DCS decay modes). Alternatively, one could consider ratios of $B \to f_D K$ and $B \to f_D \pi$ modes where the strong phase cancels, or use information on the relative strong phases, e.g., by measuring entangled decays at D factories [270].

3.7 Experimental prospects

We now summarize the status of experimental measurements and their prospects for the future. We generally follow the notation of Sec. 3.2. In the case of time-dependent CPV, we also define the parameters x' and y' which depend linearly on the mixing parameters, $x' \equiv x\cos\delta + y\sin\delta$ and $y' \equiv y\cos\delta - x\sin\delta$. Here δ is the strong phase difference between the favoured and doubly Cabibbo suppressed final states.

3.7.1 Mixing and time-dependent CPV in two-body decays

The mixing and CPV parameters in D^0–$\overline{D}^0$ oscillations can be accessed by comparing the decay-time-dependent ratio of $D^0 \to K^+\pi^-$ to $D^0 \to K^-\pi^+$ rates with the corresponding ratio for the charge-conjugate processes.

The latest measurement from LHCb [21] uses Run 1 and early Run 2 (2015–2016) data, corresponding to a total sample of about $\mathcal{L} = 5\,\text{fb}^{-1}$ of integrated luminosity. Assuming CP conservation, the mixing parameters are measured to be $x'^2_{K\pi} = (3.9 \pm 2.7) \times 10^{-5}$, $y'_{K\pi} = (5.28 \pm 0.52) \times 10^{-3}$, and $R_D^{K\pi} = (3.454 \pm 0.031) \times 10^{-3}$. Studying D^0 and $\overline{D}^0$ decays separately shows no evidence for CP violation and provides the current most stringent bounds on the parameters $A_D^{K\pi}$ and $|q/p|$ from a single measurement, $A_D^{K\pi} = (-0.1 \pm 9.1) \times 10^{-3}$ and $1.00 < |q/p| < 1.35$ at the 68.3% confidence level.

In Table 13 the signal yields and the statistical precision from Ref. [21] are extrapolated to the end of Run 2 and to the end of Upgrade II, assuming that the central values of the measurements stay the same. This assumption is particularly important for the CP-violation parameters, as their precision may depend on the measured values.

Systematic uncertainties are estimated using control samples of data and none of them are foreseen to have irreducible contributions that exceed the ultimate statistical precision, if the detector performance (particularly in terms of vertexing/tracking and particle identification capabilities) is kept at least in line with what is currently achieved at LHCb.

Table 13: Extrapolated signal yields, and statistical precision on the mixing and CP-violation parameters, from the analysis of promptly produced DCS $D^{*+} \to D^0(\to K^+\pi^-)\pi^+$ decays. Signal yields of promptly produced CF $D^{*+} \to D^0(\to K^-\pi^+)\pi^+$ decays are typically 250 times larger.

Sample ($\mathcal{L}$)	Yield ($\times 10^6$)	$\sigma(x'^2_{K\pi})$	$\sigma(y'_{K\pi})$	$\sigma(A_D)$	$\sigma(\lvert q/p\rvert)$	$\sigma(\phi)$
Run 1–2 (9 fb^{-1})	1.8	1.5×10^{-5}	2.9×10^{-4}	0.51%	0.12	10°
Run 1–3 (23 fb^{-1})	10	6.4×10^{-6}	1.2×10^{-4}	0.22%	0.05	4°
Run 1–4 (50 fb^{-1})	25	3.9×10^{-6}	7.6×10^{-5}	0.14%	0.03	3°
Run 1–5 (300 fb^{-1})	170	1.5×10^{-6}	2.9×10^{-5}	0.05%	0.01	1°

3.7.2 Mixing and time-dependent CPV in $D^0 \to K^0_S\pi^+\pi^-$

The self-conjugate decay $D^0 \to K^0_S\pi^+\pi^-$ includes both CF and DCS, as well as CP-eigenstate processes reconstructed in the same final state. This allows for the relative strong phase between different contributions to be determined from data, and, in turn, enables both the mixing parameters x and y, as well as the CP-violation parameters $|q/p|$ and ϕ to be directly measured without need for external input. As a result, this channel provides the dominant constraint on the parameter x in the global fits.

The mixing and CPV parameters modulate the time-dependence of the complex amplitudes, and these amplitudes themselves vary over the two-dimensional final state phase-space. As such, the measurement relies both on the precise understanding of the detector acceptance as a function of phase-space and decay time, and on the accurate description of the evolution of the underlying decay amplitudes over the Dalitz plane. Both model-dependent and model-independent approaches using quantum-correlated $D\bar{D}$ pairs from $\psi(3770)$ decays can be applied.

Previous measurements from the CLEO [273], BaBar [274], and Belle [229] collaborations have used the model-dependent approach, with the Belle measurement having the best precision to date, $x = (0.56^{+0.20}_{-0.23})\%$, $y = (0.30^{+0.16}_{-0.17})\%$ (assuming CP symmetry), and $|q/p| = 0.90^{+0.18}_{-0.16}$, $\phi = (-6 \pm 12)^\circ$. The one published LHCb result was based on 1 fb^{-1} of Run 1 data [275], and used a model-independent approach with strong phases taken from the CLEO measurement [276] to determine $x = (-0.86 \pm 0.56)\%$, $y = (0.03 \pm 0.48)\%$. This analysis used around 2×10^5 $D^{*+} \to D^0\pi^+$, $D^0 \to K^0_S\pi^+\pi^-$ decays from 2011, which suffered from low K^0_S trigger efficiencies that were significantly increased for 2012 and beyond, and will benefit further from software trigger innovations at the LHCb in the upgrade era.

At LHCb these decays can be reconstructed either through semileptonic decays, for instance $B^- \to D^0\mu^-\bar{\nu}_\mu$, where the muon charge is used to tag the initial D^0 flavour, or through prompt charm production, where the charge of the slow pion in the decay $D^{*+} \to D^0\pi^+$ tags the initial flavour. The two channels have complementary properties and both will be important components of future mixing and CP violation analyses at LHCb.

The prompt charm yields are significantly larger than for the semileptonic channel, due to the increased production cross-section. However, for the semileptonic channel the triggering on signal candidates is much more efficient, and introduces fewer non-uniformities in the acceptance. The estimated future yields are presented in Table 14. Also shown are projected statistical precisions on the four mixing and CPV parameters, which have been extrapolated from complete analyses of the Run 1 data for both the semileptonic and prompt cases.

For this channel the dominant systematic uncertainties on mixing parameters come from two main sources. First is the precision with which the non-uniformities in detector acceptance can be determined versus as a function of phase space and decay time. Second is the knowledge of the strong-phase variation across the Dalitz plane. For the LHCb Run 2 analysis, both contributions are significantly smaller than the statistical precision. In the longer term new approaches will be necessary to further reduce these systematic uncertainties. Trigger and event selection techniques should be adapted to emphasise

Table 14: Extrapolated signal yields at LHCb, together with statistical precision on the mixing and CP violation parameters, for the analysis of the decay $D^0 \to K^0_S \pi^+ \pi^-$. Candidates tagged by semileptonic B decay (SL) and those from prompt charm meson production are shown separately.

Sample (lumi $\mathcal{L}$)	Tag	Yield	$\sigma(x)$	$\sigma(y)$	$\sigma(\lvert q/p \rvert)$	$\sigma(\phi)$
Run 1–2 (9 fb^{-1})	SL	10M	0.07%	0.05%	0.07	4.6°
	Prompt	36M	0.05%	0.05%	0.04	1.8°

Run 1–5 (300 fb^{-1})	SL	490M	0.009%	0.008%	0.009	0.69°
	Prompt	3500M	0.005%	0.005%	0.004	0.18°

uniform acceptance, a task made easier by the removal of the calorimeter-based hardware trigger. New techniques, such as the bin-flip method [277], can further reduce dependence on the non-uniform acceptance, although at the cost of degraded statistical precision on the mixing and CP-violation parameters. In the model-dependent approach many of the model systematic uncertainties may reduce or vanish with increased integrated luminosity, as currently fixed parameters are incorporated into the data fit, and the data become increasingly capable of rejecting unsuitable models provided that there is suitable evolution in the model descriptions. For the model-independent approach, the uncertainty from external inputs (currently from CLEO-c, later with 50% reduction from BESIII) will also reduce with luminosity as the LHCb data starts to provide constraining power. There are no systematic uncertainties which are known to have irreducible contributions that exceed the ultimate statistical precision.

For the CP violation parameters additional sources of systematic uncertainty come from the knowledge of detector-induced asymmetries. In particular, there is a known asymmetry between K^0 and $\bar{K}^0$ in their interactions with material. The limitation here will be the precision with which the material traversed by each K^0_S meson can be determined. The LHCb Upgrade II detector will be constructed to minimise material, and to allow precise evaluation of the remaining contributions. In summary, this channel has comparable power on CP violating parameters, but with a simpler two-dimensional phase space and complementary detector systematic uncertainties, as the four-body decays that we discuss next.

3.7.3 Mixing and time-dependent CPV in four-body decays

Like $D^0 \to K^-\pi^+$ and $D^0 \to K^+\pi^-$, the decays $D^0 \to K^-\pi^+\pi^-\pi^+$ and $D^0 \to K^+\pi^-\pi^-\pi^+$ are a pair of CF and DCS decays with high sensitivity to charm mixing. However, the rich amplitude structure across the five dimensional phase space of the latter decays offers unique opportunities (and challenges) in these four-body modes.

In the phase-space integrated analysis using 3fb^{-1} of data, LHCb made the first observation of mixing in this decay mode, and measured quantities $R_D^{K3\pi} = (3.21 \pm 0.014) \cdot 10^{-3}$, as well as $R_{\rm coher}^{K3\pi} y'_{K3\pi} = (0.3 \pm 1.8) \cdot 10^{-3}$, and $\frac{1}{4}(x^2 + y^2) = (4.8 \pm 1.8) \cdot 10^{-5}$ [278]. The coherence factor, $R_{\rm coher}^{K3\pi}$, measures the effect of integrating over the entire four-body phase space [279, 280].

The unique power of multibody decays lies to a large extent in the fact that the strong phase difference between the interfering D^0 and $\bar{D}^0$ amplitudes varies across the phase space. This can be fully exploited only by moving away from the phase-space-integrated approach to the analyses of phase

Table 15: Extrapolated signal yields for LHCb, and sensitivity to the mixing and CP-violation parameters, from the analysis of $D^0 \to K^+\pi^-\pi^-\pi^+$ decays (statistical uncertainties only).

Sample ($\mathcal{L}$)	Yield ($\times 10^6$)	$\sigma(x'_{K\pi\pi\pi})$	$\sigma(y'_{K\pi\pi\pi})$	$\sigma(\lvert q/p\rvert)$	$\sigma(\phi)$

Run 1-4 (50 fb^{-1})	3.36	0.6×10^{-4}	0.6×10^{-4}	0.005	0.3°
Run 1-5 (300 fb^{-1})	22.5	0.2×10^{-4}	0.2×10^{-4}	0.002	0.1°

space distributions, either in bins or unbinned. Such a "phase space resolved" approach allows a direct measurement of $x'_{K\pi\pi\pi}$ and $y'_{K\pi\pi\pi}$ (rather than only the x'^2 and y' as in the 2-body case), and, crucially, provides high sensitivity to the CP violating variables ϕ and $|q/p|$.

On the other hand, the same phase variations that make multibody decays so powerful, are also a major challenge, as they need to be known precisely in order to cleanly extract the mixing and CP violation parameters of interest. In principle, the relevant phases can be inferred from an amplitude model such as that obtained from 3fb^{-1} of LHCb data [93]. Such models may introduce theoretical uncertainties that are unacceptably large for the precision era of LHCb Upgrade II, unless there are significant innovations in the theoretical description of four-body amplitudes. The alternative is to use model-independent approaches. These use quantum-correlated events at the charm threshold to infer the required phase information in a model-unbiased way. BESIII is working closely with LHCb [281] to provide the necessary model-independent inputs for $D^0 \to K^+\pi^-\pi^-\pi^+$ across different regions of phase space for measurements of the γ angle as well as charm mixing and CP violation measurements.

Sensitivity studies with model-dependent approaches give a useful indication of the precision that can be achieved. A recent such study, Ref. [282], uses LHCb's latest $D^0 \to K^+\pi^-\pi^-\pi^+$ amplitude model [93]. Table 15 gives the yields and sensitivities scaled from the study in [282], illustrating the impressive sensitivity of this decay mode. The study is based on promptly produced D^{*+} mesons, decaying in the flavour-conserving $D^{*+} \to D^0\pi^+$ channel. Several systematic uncertainties require improvements in the analysis method in order to scale with increasing sample sizes. However, given the huge potential of this channel, sufficient effort is expected to be dedicated to this challenge, such that adequate methods can be developed, and that the necessary input from threshold measurements is both generated at BESIII and exploited optimally at LHCb. Indeed, once these are in place, this channel has the potential for probing CP violation at the $\mathcal{O}(10^{-5})$ level, given the current world average value of x.

3.7.4 *Measurement of A_Γ*

The parameter A_Γ is related to indirect CP violation ($\simeq -A_{CP}^{\text{indir}}$) and is defined as

$$A_\Gamma \equiv \frac{\hat{\Gamma}(D^0 \to h^+h^-) - \hat{\Gamma}(\overline{D}^0 \to h^+h^-)}{\hat{\Gamma}(D^0 \to h^+h^-) + \hat{\Gamma}(\overline{D}^0 \to h^+h^-)} \tag{48}$$

Neglecting contributions from subleading amplitudes, A_Γ is independent of the final state f.

The large yields available in the SCS modes, $f = \pi^+\pi^-$ or $f = K^+K^-$, together with tagging from the $D^{*\pm}$ decay, allow for a precise measurement of A_Γ, provided the systematic uncertainties can be controlled with high degree of precision. Tagging based on semileptonic decays of a parent bottom hadron is also possible and has been used in a published LHCb measurement [283], but contributes significantly lower yields.

Most potential systematic effects are essentially constant in t and therefore cause little uncertainties in the observed decay time evolution of the asymmetry. However, second-order effects and detector–induced correlation between momentum and proper decay time are sufficient to produce spu-

Table 16: Extrapolated signal yields at LHCb, and statistical precision on indirect CP violation from A_Γ.

Sample ($\mathcal{L}$)	Tag	Yield K^+K^-	$\sigma(A_\Gamma)_{K^+K^-}$	Yield $\pi^+\pi^-$	$\sigma(A_\Gamma)_{\pi^+\pi^-}$
Run 1–2 (9 fb^{-1})	Prompt	60M	0.013%	18M	0.024%
Run 1–3 (23 fb^{-1})	Prompt	310M	0.0056%	92M	0.0104 %
Run 1–4 (50 fb^{-1})	Prompt	793M	0.0035%	236M	0.0065 %
Run 1–5 (300 fb^{-1})	Prompt	5.3G	0.0014%	1.6G	0.0025 %

rious asymmetries, that must be appropriately corrected. In addition, contamination from secondary decays is a first-order effect in time that must be suppressed, and its residual bias accounted for. Both corrections are dependent on the availability of a large number of CF $D^0 \to K^-\pi^+$ decays as calibration, and can be expected to scale with statistics; collection of this sample with the same trigger as for the signal modes is therefore a crucial tool for performing this measurement with high precision in the future.

The Run 1 LHCb measurement of this quantity gave consistent results in the two h^+h^- modes, averaging $A_\Gamma = (-0.13 \pm 0.28 \pm 0.10) \times 10^{-3}$ [20], which is still statistically dominated. For the reasons mentioned above, this precision is at the threshold of becoming physically interesting, making it a worthy target to pursue with more data. It seems highly unlikely that any experiment built in the foreseeable future will be able to do this, except for an upgrade of LHCb to higher luminosity.

Table 16 shows expected yields and precisions attainable in LHCb Upgrade II, under the same assumptions on efficiencies adopted in the previous sections; this must include provisions for acquiring and storing 5×10^{10} CF decays. The ultimate combined precision is 1×10^{-5}.

3.7.5 Combined mixing and time dependent CPV sensitivity

The projected precisions of the analyses presented in the previous sections are shown in Fig. 26, and are compared with the expected precisions at Belle II. The expected LHCb constraints on ϕ are translated into asymmetry constraints ($A_{CP}^{ind.} \approx x\sin(\phi)$) by multiplying by the current HFLAV average of x and neglecting the uncertainty on this under the assumption that x will be comparatively well determined in the future. This comparison neglects additional constraining power from $|q/p|$. The relative values of these asymmetry constraints with those from A_Γ is indicative only.

The analyses presented in the previous sections are also combined to establish the sensitivity to the CP-violating parameters $|q/p|$ and ϕ. The combination is performed using the method described in Ref. [284]. At an integrated luminosity of 300 fb^{-1} the sensitivity to $|q/p|$ is expected to be 0.001 and that to ϕ to be 0.1°. This remarkable sensitivity is contrasted in Fig. 27 with the HFLAV world average as of 2017. We can conclude that the LHCb Upgrade II will have impressive power to characterise NP contributions to CP violation and is the only foreseen facility with strong potential of probing the SM contribution.

3.7.6 Direct CP violation

The SCS decays $D^0 \to K^-K^+$ and $D^0 \to \pi^-\pi^+$ play a critical role in the measurement of time-integrated direct CP violation through time-integrated CP asymmetry in the h^-h^+ decay rates, Eq. (43). The sensitivity to direct CP violation is enhanced through a measurement of the difference in CP asymmetries between $D^0 \to K^-K^+$ and $D^0 \to \pi^-\pi^+$ decays, ΔA_{CP}, Eq. (44). The individual asymmetries $A_{CP}(K^-K^+)$ and $A_{CP}(\pi^-\pi^+)$ can also be measured.

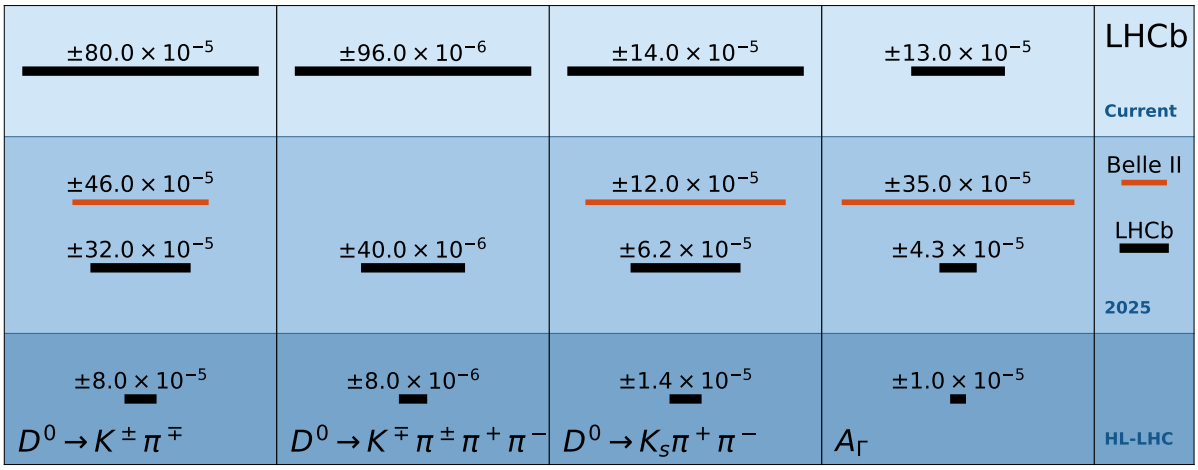

Fig. 26: The predicted constraints on the indirect *CP* violation asymmetry in charm from the decay channels indicated in the labels at the bottom of the columns. Predictions are shown in LS2 (2020) from LHCb, LS3 (2025) from LHCb, at the end of Belle II (2025), and at the end of the HL-LHC LHCb Upgrade II programme.

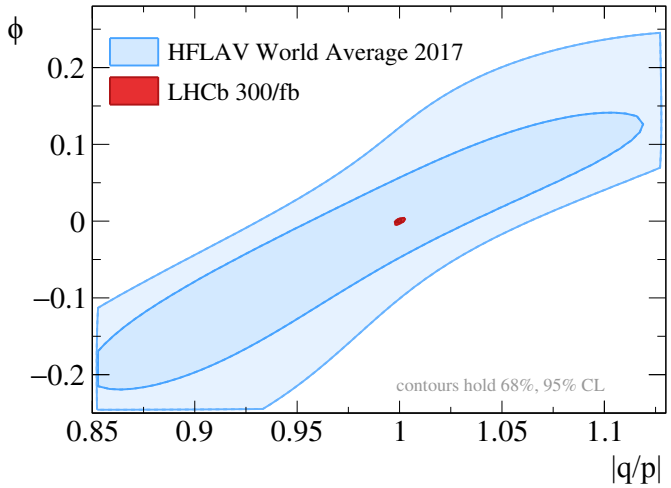

Fig. 27: The estimated constraints for LHCb Upgrade II on ϕ, $|q/p|$ from the combination of the analyses (red), see main text for details, compared to the current world-average precision (light blue). The notation on the axes or lowercase a corresponds to the uppercase A used in the section text.

A measurement of the time-integrated *CP* asymmetry in $D^0 \to K^-K^+$ has been performed in LHCb with 3 fb^{-1} collected at centre-of-mass energies of 7 and 8 TeV. The flavour of the charm meson at production is determined from the charge of the pion in $D^{*+} \to D^0\pi^+$ decays, or via the charge of the muon in semileptonic b-hadron decays, $\overline{B} \to D^0\mu^-\overline{\nu}_\mu X$. The analysis strategy so far relies on the $D^+ \to K^+\pi^+\pi^-$, $D^+ \to K^0_s\pi^+$ and $D^{*+} \to D^0(\to K^-\pi^+)\pi^+$ decays as control samples [285]. In this case, due to the weighting procedures aiming to fully cancel the production and reconstruction asymmetries, the effective prompt signal yield for $A_{CP}(K^-K^+)$ is reduced. The expected signal yields and the corresponding statistical precision in LHCb Upgrade II are summarised in Table 17.

The observable ΔA_{CP} is robust against systematic uncertainties. The main sources of systematic uncertainties are inaccuracies in the fit model, the weighting procedure, the contamination of the prompt sample with secondary D^0 mesons and the presence of peaking backgrounds. There are no systematic

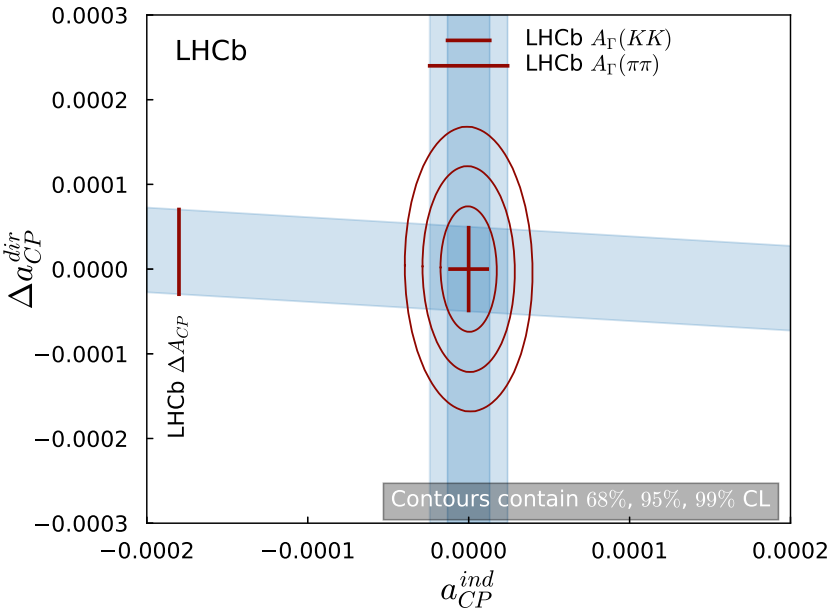

Fig. 28: The estimated constraints for LHCb Upgrade II on indirect and direct charm *CP* violation from the analysis of two-body *CP* eigenstates. The current world-average precision [286] is $\pm 2.6 \times 10^{-4}$ for indirect and $\pm 18 \times 10^{-4}$ for direct *CP* violation and thus larger than the full scale of this plot.

uncertainties with expected irreducible contributions above the ultimate statistical precision. This channel is already entering the upper range of the physically interesting sensitivities, and will likely continue to provide the world's best sensitivity to direct *CP* violation in charm at LHCb Upgrade II. The power of these two-body *CP* eigenstates at LHCb Upgrade II is illustrated in Fig. 28, which shows the indirect (see Sect. 3.7.4) and direct *CP* constraints that will come from these modes.

There are a number of other two-body modes of strong physics interest for which Upgrade II will also make important contributions. These include the decay modes $D^0 \to K^0_S K^0_S$ (0.28%), $D^0 \to K^0_S \bar{K}^{*0}$ (0.21%), $D^0 \to K^0_S K^{*0}$ (0.15%), $D_s^+ \to K^0_S \pi^+$ (3.2×10^{-4}), $D^+ \to K^0_S K^+$ (1.2×10^{-4}), $D^+ \to \phi\pi^+$ (6×10^{-5}), $D^+ \to \eta'\pi^+$ (3.2×10^{-5}), $D_s^+ \to \eta'\pi^+$ (3.2×10^{-4}), where the projected statistical only *CP* asymmetry sensitivities are given in brackets after the decay mode. The first three modes mentioned are notable as they receive sizeable contributions from exchange amplitudes at tree-level and could have a relatively enhanced contribution from penguin annihilation diagrams which are sensitive to NP. Consequently, they could be potential *CP* violation discovery channels [226], [227].

Searches for direct *CP* violation in the phase space of SCS $D^+ \to h_1h_2h_3$ decays, hereafter referred to as $D \to 3h$, are complementary to that of $D^{(0,+)} \to h_1h_2$ ($h_i = \pi, K$). In charged D systems, only *CP* violation in the decay is possible. The main observable is the *CP* asymmetry, which, in

Table 18: Extrapolated signal yields at LHCb, in units of 10^6, for the SCS decays $D^+ \to K^-K^+\pi^+$, $D^+ \to \pi^-\pi^+\pi^+$, and for the DCS decays $D^+ \to K^-K^+K^+$, $D^+ \to \pi^-K^+\pi^+$.

the case of two-body decays, is a single number. In contrast, $D \to 3h$ decays allow to study the variation of the CP asymmetry across the two-dimensional phase space (usually represented by the Dalitz plot).

The estimated signal yields in future LHCb upgrades are summarised in Table 18, based on an extrapolation of the Run 2 yields per unit luminosity. The estimated sensitivities to observation of CP violation, using $D^+ \to \pi^-\pi^+\pi^+$ as an example, are presented in Table 19.

The SM generated CP violation could be observed in the SCS decays, such as $D^0 \to \pi^+\pi^-\pi^+\pi^-$ and $D^0 \to K^+K^-\pi^+\pi^-$, while NP is needed to justify any observation of CP violation in the DCS decays, such as $D^0 \to K^+\pi^-\pi^+\pi^-$. Many techniques can be adopted to search for CP violation, all of them exploiting the rich resonant structure of the decays. The methods used so far at LHCb are based on $\widehat{T}$-odd asymmetries and the energy test, while studies are ongoing to measure model-dependent CP asymmetries in the decay amplitudes.

The study of $\widehat{T}$-odd asymmetries exploits potential P-odd CP violation from the interference between different amplitude structures in the decay, as described in Ref. [287]. This uses a triple product $C_T = \vec{p}_A \cdot (\vec{p}_B \times \vec{p}_C)$ constructed from the momenta of three of the final state particles $\vec{p}_A, \vec{p}_B, \vec{p}_C$. LHCb has studied T-odd asymmetries using $3\,\text{fb}^{-1}$ data from the Run 1 dataset, and obtained a sensitivity of 2.9×10^{-3} with very small systematic uncertainties [288]. The peculiarity of this measurement is the absence of instrumental asymmetries, since it is given by the difference of two asymmetries measured separately on D^0 and $\overline{D}^0$ decays, $a_{CP} = (A_T - \bar{A}_T)/2$, where

$$A_T = \frac{(\Gamma(D^0, C_T > 0) - \Gamma(D^0, C_T < 0))}{(\Gamma(D^0, C_T > 0) + \Gamma(D^0, C_T < 0))}, \quad \bar{A}_T = \frac{(\Gamma(\overline{D}^0, \bar{C}_T > 0) - \Gamma(\overline{D}^0, \bar{C}_T < 0))}{(\Gamma(\overline{D}^0, \bar{C}_T > 0) + \Gamma(\overline{D}^0, \bar{C}_T < 0))}. \tag{49}$$

One can therefore expect the errors to scale with luminosity to reach a sensitivity down to 2.9×10^{-5} (9.4×10^{-5}) for $D^0 \to \pi^+\pi^-\pi^+\pi^-$ ($D^0 \to K^+K^-\pi^+\pi^-$) decays, as detailed in Table 20.

The energy test method is insensitive to global asymmetries. However, it is expected that it will become sensitive to variations in phase space of production and detection asymmetries. These can be controlled in data by application of the method to CF decays, such as $D^0 \to K^-\pi^+\pi^+\pi^-$. Assuming scaling with the square-root of the ratio of sample sizes, the same p-values can be expected for the CP

Table 20: Extrapolated signal yields, and statistical precision on $\widehat{T}$-odd CP-violation observables at LHCb.

$\rho^0\rho^0$ (P)	0.8°	0.35°	0.10°

asymmetries given in Table 21.

Charm decays with neutrals in the final state can help to shed light on the SM or beyond-SM origin of possible CP-violation signals by testing correlations between CP asymmetries measured in various flavour-SU(3) or isospin related decays, see Sec. 3.4 and Refs. [233, 234, 290]. These modes are, however, particularly challenging in hadronic collisions, where the calorimeter background for low energy clusters is high, while the trigger retention rate needs to be kept low to allow for affordable rates.

Nevertheless, good performances are achieved when considering decays with at least two charged particles in the final states, such as $D^0 \to \pi^+\pi^-\pi^0$, since the charged particles help to identify the displaced decay vertex of the charm meson. In only 2 fb^{-1} of data, collected during 2012, LHCb has reconstructed about 660,000 $D^0 \to \pi^+\pi^-\pi^0$ decays [195], i.e., about five times more than Babar from its full data set [291], with comparable purity. Preliminary estimates for Run 2 data, give about 500 000 signal decays per fb^{-1}, making future CP-violation searches in this channel very promising. Similarly, large samples of $D^+_{(s)} \to \eta^{(\prime)}\pi^+$ decays, with $\eta^{(\prime)} \to \pi^+\pi^-\gamma$, or $D^+ \to \pi^+\pi^0$ decays, with $\pi^0 \to e^+e^-\gamma$, are already possible with the current detector. The $D^+_{(s)} \to \eta'\pi^+$ mode, as an example, has been used by LHCb during Run 1 to perform the most precise measurement of CP asymmetries in these channels to date, with uncertainties below the 1% level [292].

More challenging final states consisting only of neutral particles, such as $\pi^0\pi^0$ or $\eta\eta$, can still be reconstructed with $\pi^0 \to \gamma\gamma$ or $\eta \to \gamma\gamma$ candidates made of photons which, after interacting with the detector material, have converted into an e^+e^- pair. Such conversions must occur before the tracking system to have electron tracks reconstructed. Although the reconstruction efficiency of these "early" converted photons in the current detector reaches only a few percent of the calorimetric photon efficiency, their purity is much higher. This approach may become interesting only with the large data sets that are expected to be collected by the end of Upgrade II. The η decays can also be reconstructed through the $\pi^+\pi^-\gamma$ final state.

Unlike the D^0 decays which are usually tagged with a soft pion from D^{*+} decays, there is no easy tagging of the D^+ modes, which thus often suffer from a high combinatorial background. Employing a

π^0 tag using $D^{*+} \to D^+\pi^0$ decays could facilitate future studies of D^+ decays, in particular those with challenging and/or high multiplicity final states.

The study of these modes may be challenging in Run 3 due to the cluster pile-up at higher luminosities and radiation damage of the current calorimeter. The new calorimeter proposed for LHCb Upgrade II would have an improved granularity. It would therefore improve the efficiency for $\pi^0 \to \gamma\gamma$ decays and, in particular, could make the π^0 tag feasible.

3.7.7 Rare leptonic and radiative charm decays

The most experimentally accessible very rare charm decay is $D^0 \to \mu^+\mu^-$. The world's best limit on $\mathcal{B}(D^0 \to \mu^+\mu^-)$ was obtained by LHCb with $0.9\,\text{fb}^{-1}$ of 2011 data [260], resulting in

$$\mathcal{B}(D^0 \to \mu^+\mu^-) < 6.2 \times 10^{-9} \text{ at } 90\% \text{ CL}. \tag{50}$$

Extrapolating the current detector performance, the expected limit is about 5.9×10^{-10} with 23 fb^{-1} and 1.8×10^{-10} with 300 fb^{-1} of integrated luminosity, covering a large part of the unambiguous space to search for NP without being affected by long distance uncertainties in the SM predictions.

The next class of rare charm decays which are particularly suited for experiments at hadron colliders are three-body decays with a pair of leptons in the final state, such as $D^+_{(s)}/\Lambda_c^+ \to h^+\ell^+\ell^-$ and $D^0 \to h^+h^-\ell^+\ell^-$. In some NP scenarios the short distance contributions can be enhanced by several orders of magnitude allowing NP to manifest as an enhancement of the branching fraction. An example of such a model is shown in Fig. 29, where the Wilson coefficients were assumed to obtain NP contributions, $C_9^{\text{NP}} = -0.6$ and $C_{10}^{\text{NP}} = 0.6$ (cf. Eqs. (46), (47)). Outside of the resonance regions the short distance contributions are comparable to the long distance effects. The chosen NP benchmark point leads to branching ratios just below the current LHCb limit [263]

$$\mathcal{B}(\Lambda_c^+ \to p\mu^+\mu^-) < 5.9 \times 10^{-8} \text{ at } 90\% \text{ CL}. \tag{51}$$

In the Upgrade II LHCb is expected to improve the limit to

$$\mathcal{B}(\Lambda_c^+ \to p\mu^+\mu^-) < 4.4 \times 10^{-9} \text{ at } 90\% \text{ CL}. \tag{52}$$

An order of magnitude improvement is expected for the limit on $\mathcal{B}(D^+_{(s)} \to \pi^+\mu^+\mu^-)$ decays, which is currently at 7.3×10^{-8} at 90% CL [261]. The expected upper limits are about 1.3×10^{-8} with $23\,\text{fb}^{-1}$ and 0.37×10^{-8} with $300\,\text{fb}^{-1}$. In addition, LHCb will have the ability to measure angular observables such as the forward-background asymmetry, A_{FB}, or time integrated A_{CP}, which will provide additional handles to separate the long distance from the short distance contributions, and for which some theoretical predictions in NP scenarios already exist [242], as shown in Fig. 30.

Last but not least with a sample corresponding to an integrated luminosity of 300 fb^{-1} LHCb will be able to perform searches for the LFV decays $D^+_{(s)}/\Lambda_c^+ \to h^+\ell^+\ell'^-$ and perform tests of lepton universality via the ratios $\mathcal{B}(D^+_{(s)}/\Lambda_c^+ \to h^+\mu^+\mu^-)/\mathcal{B}(D^+_{(s)}/\Lambda_c^+ \to h^+e^+e^-)$.

The decays $D^0 \to h^+h^-\ell^+\ell^-$ have richer dynamics than the two- and three-body decays, allowing for a variety of differential distributions to be investigated. Due to the huge charm production cross-section at the LHC, and LHCb's ability to trigger on low p_{T} dimuons, LHCb has unique physics reach in studying these decays. In fact, significant progress has already been made with the observation of the CF decay $D^0 \to K^-\pi^+\mu^-\mu^+$ (with the dimuon mass in the ρ/ω region) with a branching fraction $(4.17 \pm 0.42) \times 10^{-6}$ [293] and the SCS decays $D^0 \to \pi^+\pi^-\mu^+\mu^-$ and $D^0 \to K^+K^-\mu^+\mu^-$ with branching fractions of $(9.64 \pm 1.20) \times 10^{-7}$ and $(1.54 \pm 0.33) \times 10^{-7}$, respectively [268]. For the latter, also the differential branching fraction as a function of the dimuon mass squared, q^2, was measured. Furthermore, LHCb has performed the first measurement of CP- and angular asymmetries

the D mesons, which decreases the power of selections based on the displacement of the charm vertex, increasing the prompt combinatorial background, which mainly comprises low-momentum pions and kaons. Selections of charm baryons then heavily rely on good discrimination between proton, kaon, and pion hypotheses in the reconstruction of charged tracks, and on a precise secondary vertex reconstruction. The latter is also necessary when reconstructing charm baryons originating from semileptonic b-hadron decays, which has the advantage of both a simple trigger path (a high-p_{T}, displaced muon) and a cleaner experimental signature due to the large b-hadron lifetime. The presence of the proton in the final state, whilst a useful handle for selections, poses experimental challenges for CP-violation measurements in addition to those present for measurements with D mesons, as the proton-antiproton detection asymmetry must be accounted for. This has not yet been measured at LHCb due to the lack of a suitable control mode.

The most precise measurement of CP violation in charm baryons was made recently by the LHCb collaboration using Run 1 data, corresponding to $3\,\mathrm{fb}^{-1}$ of integrated luminosity [194]. The difference between the phase-space-averaged CP asymmetries in $\Lambda_c^+ \to pK^-K^+$ and $\Lambda_c^+ \to p\pi^-\pi^+$ decays was found to be consistent with CP symmetry to a statistical precision of $0.9\,\%$. This difference is largely insensitive to the proton detection asymmetry, but masks like-sign CP asymmetries between the two modes. Further studies must then gain a precise understanding of the proton detection asymmetry, in addition to measuring the variation of CP violation across the decay phase space.

Although there is little literature on the subject, the magnitude of direct CP violation in charm baryon decays is expected to be similar to that for charmed mesons [294], and so the first step in furthering our understanding is to reach a precision of 0.5×10^{-4}. This can be met by LHCb given the $300\,\mathrm{fb}^{-1}$ of integrated luminosity collected by the end of Run 5. The acquisition of more data is vital in enabling studies of states heavier than the Λ_c^+ baryon, as their alternate compositions may permit considerably different dynamics. In this respect it is interesting to note that the Ξ_{cc}^{++} baryon was discovered [295] by LHCb using the $\Lambda_c^+ K^-\pi^+\pi^+$ final state with data taken in 2016, corresponding to an integrated luminosity of $1.7\,\mathrm{fb}^{-1}$. A signal yield of 313 ± 33 was determined, which can be extrapolated to around $100,000$ such decays obtainable with data corresponding to $300\,\mathrm{fb}^{-1}$, allowing asymmetry measurements with a precision of $0.4\,\%$. The flexible trigger and real-time analysis concept of LHCb's Upgrade II will however enable not only this measurement but a detailed mapping of the entire landscape of multiply-heavy charmed hadrons.

4 Strange-quark probes of new physics

Authors (TH): Giancarlo D'Ambrosio, Diego Guadagnoli, Teppei Kitahara, Diego Martinez Santos.

Although not specifically built for the study of strange hadrons, LHCb's forward geometry allows for a rich physics programme with strange hadrons. LHCb Upgrade II phase will substantially enlarge in scope this programme. Its relevance is evident from the fact that kaon physics provides among the most stringent constraints on new-physics interactions. As with the charm and beauty counterparts, the HL-LHC will be a uniquely powerful factory for strange baryons which the LHCb Upgrade II is well placed to exploit.

4.1 The (HL) LHC as a strangeness factory

The capabilities of LHCb for strangeness decays are due to the large strange-hadron production rates at the LHC, combined with the specific features of LHCb in comparison with the other LHC detectors. These are the higher efficiency for low transverse-momentum particles and the better invariant-mass and vertex resolutions. A simple estimate with `Pythia 8.226` yields a K^0 cross section in 14 TeV pp collisions of about 0.6 barn, as well as another 0.6 barn for $K^\pm$. These are roughly 1000 times larger than the production cross sections for B mesons. Hyperon cross sections are also large, attaining in `Pythia` 0.14, 0.04, 0.01 barn for Λ^0, Σ^+, and Ξ^-, respectively (including their antiparticles), while the cross section for Ω^- is similar to that of B's.

The LHCb capabilities for strange decays were first demonstrated in Ref. [296], which achieved the world's best result in $\mathcal{B}(K^0_S \to \mu^+\mu^-)$ even though the trigger efficiency on well reconstructed decays was only $\sim 1\%$ (to be compared to $\sim 90\%$ for $B^0_s \to \mu^+\mu^-$). In Run 2, dedicated trigger lines have been implemented, selecting muons down to 80 MeV in transverse momentum and increasing the trigger efficiency by one order of magnitude for strangeness decays to dimuons [297]. The main limitation is the hardware trigger (L0). In Run 3 the LHCb trigger will be fully software-based, which can in principle allow for efficiencies as high as those achieved for B's. The main challenge for LHCb Upgrade II will be to fully exploit the software trigger, and enable high trigger efficiency at low transverse momentum using the displacement of the decay products. In addition, using downstream reconstruction in the trigger may boost the LHCb capabilities for charged kaon decays by up to a factor 5 [298].

Among the different strange hadron species, the LHCb detector layout is particularly suitable for K^0_S and hyperons, which have relatively shorter lifetimes compared to $K^\pm$ or K^0_L, which mostly decay outside the detector. An approximate acceptance ratio for $K^0_S : K^\pm : K^0_L$ is estimated as $1 : 0.01 : 3 \times 10^{-3}$ [298] for full tracking and $1 : 0.02 : 0.01$ for downstream tracking (i.e, no usage of VELO information). Hence, measurements with $K^\pm$ decays will also be possible, with potential overlap with NA62. LHCb Upgrade II will reach sensitivities for $\mathcal{B}(K^0_S \to \mu^+\mu^-)$ below the 10^{-11} level if it keeps the performance of the current detector [299], taking into account that the full software trigger will allow for very high trigger efficiencies. Similarly, sensitivities at the 10^{-10} level are expected for $\mathcal{B}(K^0_S \to \pi^0\mu^+\mu^-)$ [300].

The same analysis strategy as $\mathcal{B}(K^0_S \to \pi^0\mu^+\mu^-)$ can be applied to other decays, such as $K^0_S \to \gamma\mu^+\mu^-$, although the sensitivity will be worse due to poorer mass resolution [298]. Other kaon decays that can be studied at LHCb include $K^+ \to \pi\mu\mu$ (both with opposite-sign and same-sign muon pairs), $K^0_S \to 4\mu$, or decays involving electrons, especially interesting in order to search for lepton flavor violation (LFV) and lepton-flavor universality violation (LFUV). The LHCb Upgrade II will also have an abundant enough sample of $\Sigma^+ \to p\mu^+\mu^-$ to do precise study of the differential decay rate. The $\Sigma^+ \to pe^+e^-$ can be studied using dedicated triggers. Semileptonic hyperon decays are reconstructed in LHCb [298] and kinematic constraints can be used to reconstruct the mass peak of the hyperon. Since the expected yields for these decays can be very large, the main challenge is the fight against peaking backgrounds, such as $\Lambda \to p\pi^-$ or $\Xi^- \to \Lambda\pi^-$. LHCb Upgrade II will also be able to update existing limits on LFV kaon decays [301]. A longer list of decays that LHCb will be able to probe can be found

in Ref. [298].

4.2 $K_S^0 \to \mu^+\mu^-$ and $K_L^0 \to \mu^+\mu^-$ decays

LHCb Upgrade I and Upgrade II are expected to be able to probe short-distance physics using the $K^0 \to \mu^+\mu^-$ decay. In the SM, $K_S \to \mu^+\mu^-$ is significantly dominated by P-wave CP-conserving long-distance (LD) contribution, while S-wave CP-violating short-distance (SD) contributions from Z-penguin and W-box are small [302–304]:

$$\mathcal{B}(K_S \to \mu^+\mu^-)_{\rm SM} = [(4.99 \pm 1.50)_{\rm LD} + (0.19 \pm 0.02)_{\rm SD}] \times 10^{-12}. \tag{53}$$

The large uncertainty comes from the LD contribution which has been computed in ChPT [302]. This uncertainty is expected to be reduced by a dispersive treatment of $K_S \to \gamma^*\gamma^*$ [305], where $K_S \to \gamma\gamma$, $K_S \to \mu^+\mu^-\gamma$, $K_S \to \mu^+\mu^-e^+e^-$ and $K_S \to \mu^+\mu^-\mu^+\mu^-$ are measurable in LHCb experiment and KLOE-2 experiment at DAΦNE [306]. It is important to note that, in contrast to the $K_L \to \mu^+\mu^-$ decay:

- The decay $K_S \to \mu^+\mu^-$ provides another sensitive probe of *imaginary* parts of SD couplings and consequently is very sensitive to new sources of CP violation. This is not the case of $K_L \to \mu^+\mu^-$ which is governed by *real* couplings.
- As seen in Eq. (53) the LD and SD contributions to the total rate are added incoherently [302,303], which represents a big theoretical advantage over $K_L \to \mu^+\mu^-$, where LD and SD amplitudes interfere.

This means that in BSMs in which the SD contribution is significantly enhanced, the LD-uncertainty in $K_S \to \mu^+\mu^-$ ceases to be important, and theoretically clean tests of new-physics scenarios are possible. In particular, being the SD contribution dominant, correlations of $K_S \to \mu^+\mu^-$ with ε'/ε and also $K_L \to \pi^0\nu\bar{\nu}$ are present within many new-physics models.

Indeed, within concrete BSMs, $\mathcal{B}(K_S \to \mu^+\mu^-)$ can be modified substantially, for example $\mathcal{B} \sim \mathcal{O}(10^{-10})$ in the leptoquark models [307] and $\mathcal{B} \sim \mathcal{O}(10^{-11})$, or even saturate the current experimental bound in certain MSSM parameter space [308], albeit somewhat fine-tuned. Already the present upper bound from LHCb can have some impact on the allowed parameter range of certain models. This shows that future improvement of this bound can have important impact on various BSM scenarios.

The LHCb full Run1 analysis has set the upper limit for $K_S \to \mu^+\mu^-$ [309],

$$\mathcal{B}(K_S \to \mu^+\mu^-)_{\text{LHCb Run1}} < 0.8\,(1.0) \times 10^{-9} \text{ at } 90\%\,(95\%)\text{ CL}, \tag{54}$$

which is 2 orders of magnitude larger than the SM sensitivity. With LHCb upgrades the sensitivity is significantly improved. Using the upgraded software trigger, the LHCb experiment is aiming to reach the SM sensitivity, as shown in Fig. 31.

A crucial aspect of the $K^0 \to \mu^+\mu^-$ decay is a flavor-tagged measurement which can probe CP-violating SD contributions directly. Its numerical effect is $\mathcal{O}(1)$ compared to the prediction in Eq. (53) even in the SM [304]. While K_L decays typically outside the LHCb fiducial volume, for K_S the interference between K_L and K_S affects the number of signal events as $\Gamma_{\text{int.}} \propto \mathcal{A}(K_L \to \mu^+\mu^-)\mathcal{A}(K_S \to \mu^+\mu^-)^*$ when the flavor tagging, K^0 or $\overline{K}^0$ at $t = 0$, is performed. An effective branching ratio into $\mu^+\mu^-$, which includes the interference correction and would correspond to experimental event numbers after the removal of $K_L \to \mu^+\mu^-$ background, is given by [304],

$$\begin{aligned}\mathcal{B}(K_S \to \mu^+\mu^-)_{\text{eff}} =& \tau_S \left[\int_{t_{\min}}^{t_{\max}} dt e^{-\frac{t}{\tau_S}}\varepsilon(t)\right]^{-1} \int_{t_{\min}}^{t_{\max}} dt \Bigg\{ \Gamma(K_S \to \mu^+\mu^-)e^{-\frac{t}{\tau_S}} \\ &+ \frac{D f_K^2 m_K^3 \beta_\mu}{8\pi} \text{Re}\left[i\left(A_S A_L - \beta_\mu^2 B_S^* B_L\right) e^{-i\Delta m_K t}\right] e^{-\frac{t}{2\tau_S}\left(1+\frac{\tau_S}{\tau_L}\right)} \Bigg\} \varepsilon(t),\end{aligned} \tag{55}$$

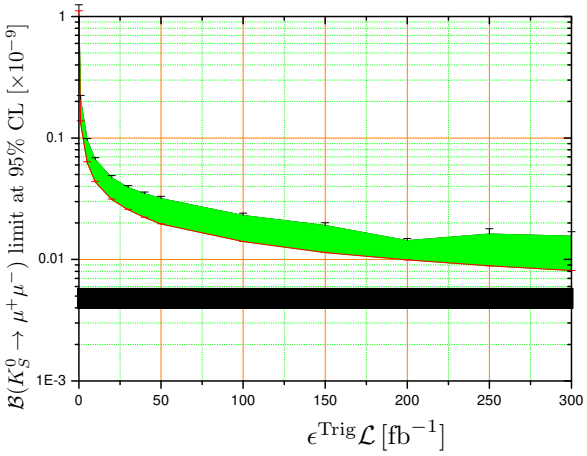

Fig. 31: Projected LHCb reach for $\mathcal{B}(K_S^0 \to \mu^+\mu^-)$ as a function of the integrated luminosity times trigger efficiency (which is expected to be $\mathcal{O}(1)$ in LHCb Upgrade II. The black band is the SM prediction. Figure adapted from Ref. [299], which is based on the data used in [309].

with $\Gamma(K_S \to \mu^+\mu^-) = f_K^2 m_K^3 \beta_\mu \left(A_S^2 + \beta_\mu^2 |B_S|^2\right)/(16\pi)$, where final-state muon polarizations are summed over, $t_{\rm min}$ to $t_{\rm max}$ corresponds to a range of detector for K_S tagging, $\varepsilon(t)$ is the decay-time acceptance of the detector, $\beta_\mu = \left(1 - 4m_\mu^2/m_K^2\right)^{1/2}$, and $f_K = (155.9 \pm 0.4)$ MeV [310]. The $K_L \to \mu^+\mu^-$ background can be subtracted by a combination of the simultaneous measurement of $K_S \to \pi^+\pi^-$ and the knowledge of the observed value of $\mathcal{B}(K_L \to \mu^+\mu^-)$ [304]. The dilution factor D is a measure of the initial K^0–$\overline{K}^0$ asymmetry,

$$D = \left(K^0 - \overline{K}^0\right)/\left(K^0 + \overline{K}^0\right). \tag{56}$$

The $A_{S,L}$ and $B_{S,L}$ are the S-wave and P-wave contributions in $K_{S,L} \to \mu^+\mu^-$ transitions, respectively. The expressions for them are given in Ref. [308] using the general $\Delta S = 1$ effective Hamiltonian. Note that A_S and B_L are real, while B_S and A_L are complex.

The interference contribution is proportional to the dilution factor, D, which requires flavor tagging. This can be done by detecting the accompanying K^- in the process $pp \to K^0 K^- X$, Λ^0 in the process $pp \to K^0 \Lambda^0 X$, or π^+ in the process $pp \to K^{*+} X \to K^0 \pi^+ X$ [304].

In the SM, the effective branching ratio in Eq. (55) can be reduced to [304, 308]

$$A_S A_L - \beta_\mu^2 B_S^* B_L = \frac{4G_F^2 M_W^2 m_\mu^2}{m_K^2 \pi^2} \underbrace{{\rm Im}C_{A,{\rm SM}}}_{\rm SD\ (CPV)} \left(\underbrace{A^\mu_{L\gamma\gamma}}_{\rm LD\ (CPC)} - \frac{\pi^2}{G_F^2 M_W^2} \underbrace{{\rm Re}C_{A,{\rm SM}}}_{\rm SD\ (CPC)} \right). \tag{57}$$

The Wilson coefficient C_A is defined by, $\mathcal{H}_{\rm eff} = -C_A(\bar{s}\gamma^\mu P_L d)(\bar{\ell}\gamma_\mu\gamma_5\ell) + {\rm h.c.}$, and

$$C_{A,{\rm SM}} = -\frac{[\alpha_2(M_Z)]^2}{2M_W^2}\left(V_{ts}^* V_{td} Y_t + V_{cs}^* V_{cd} Y_c\right), \tag{58}$$

where $\alpha_2 = g^2/(4\pi)$, $Y_t = 0.950 \pm 0.049$ and $Y_c = (2.95 \pm 0.46) \times 10^{-4}$ [311]. The large CP-conserving LD two-photon contribution to K_L is [303, 312]

$$A^\mu_{L\gamma\gamma} = \pm 2.01(1) \times 10^{-4} \times (0.71(101) - i\,5.21), \tag{59}$$

where the sign is theoretically and experimentally unknown. The large imaginary (absorptive) component in $A^\mu_{L\gamma\gamma}$ can amplify the small CP-violating SD contribution in $K_S \to \mu^+\mu^-$. Fig. 32 shows the

effective branching ratio and time distributions in the SM, where the interference of the CP-violating contribution can affect $K_S \to \mu^+\mu^-$ decay up to $\mathcal{O}(60)\%$. This quantity is also sensitive to NP contributions to the electroweak penguin, that contributes to ε'/ε (direct CP violation in $K_L^0 \to \pi\pi$). To illustrate this correlation we plot with a green band in Fig. 32 (left) the effect in the effective lifetime (as a function of D) of a Z penguin BSM contribution that would explain the experimental value of ε'/ε assuming the SM predictions obtained in Refs. [313, 314]. These are based on the current lattice result [315] or in Ref. [316], although it is important to note that there are SM calculations of ε'/ε consistent with the experimental data [317, 318]. Some studies in new physics models are also given in Refs. [308, 319].

Using the effective branching ratio in Eq. (55), one can define the flavor-tagging asymmetry in $K_S \to \mu^+\mu^-$ by [308]

$$A_{CP}(K_S \to \mu^+\mu^-)_{D,D'} = \frac{\mathcal{B}(K_S \to \mu^+\mu^-)_{\rm eff}(D) - \mathcal{B}(K_S \to \mu^+\mu^-)_{\rm eff}(D')}{\mathcal{B}(K_S \to \mu^+\mu^-)_{\rm eff}(D) + \mathcal{B}(K_S \to \mu^+\mu^-)_{\rm eff}(D')}, \tag{60}$$

where D' is obtained by requiring an opposite flavor tagging. For instance, when a positive dilution factor is achieved by collecting the di-muon signals accompanying K^-, the negative dilution factor, that is expressed as D', can be obtained by collecting the signals accompanying K^+. This asymmetry is a theoretically clean quantity that emerges from a genuine direct CP violation in general new-physics models. In the SM, $A_{CP}(K_S \to \mu^+\mu^-)^{\rm SM}_{D,-D} = \mathcal{O}(0.7) \times D$ is predicted in the case of $D' = -D$ and it is sensitive to a new CP-violating phase beyond the SM [308].

In a similar way, the CP asymmetry of $B_{d,s} \to \mu^+\mu^-$ has been studied [320, 321]. However, for the B_s system the situation differs substantially from K_S, since the LD contributions are negligible and the life-time difference between the two mass eigenstates is small compared to $K_{S,L}$. The CP asymmetry in $B_{d,s} \to \mu^+\mu^-$ vanishes in the SM, but is also sensitive to a new CP-violating phase.

Before closing this section, we briefly comment on $K_L \to e^+e^-$. Both $K_L \to e^+e^-$ and $K_L \to \mu^+\mu^-$ are dominated by LD two-photon contributions [322,323]. The branching ratio for $K_L \to e^+e^-$ is dominated by the double logarithm contribution, $\propto \log^2(m_e/m_K)$. The subdominant local term is fixed, up to a two-fold ambiguity, from the measured $\mathcal{B}(K_L \to \mu^+\mu^-)$; so that $\mathcal{B}(K_L \to e^+e^-)/\mathcal{B}(K_L \to \gamma\gamma) = (1.552 \pm 0.014) \times 10^{-8}$ or $\mathcal{B}(K_L \to e^+e^-)/\mathcal{B}(K_L \to \gamma\gamma) = (1.406 \pm 0.013) \times 10^{-8}$ is predicted [323]. The measured value $(1.65 \pm 0.91) \times 10^{-8}$ [310] is not yet precise enough to resolve the ambiguity.

4.3 $K_S \to \mu^+\mu^-\gamma$, $K_S \to \mu^+\mu^-e^+e^-$ and $K_S \to \mu^+\mu^-\mu^+\mu^-$

To improve the LD determination of $\mathcal{B}(K_S \to \mu^+\mu^-)$, it is important to measure $K_S \to \mu^+\mu^-\gamma$, $K_S \to \mu^+\mu^-e^+e^-$ and $K_S \to \mu^+\mu^-\mu^+\mu^-$. These channels are at reach for LHCb Upgrade II and thus may give necessary LD information needed for a better control of $K_L \to \mu^+\mu^-$. These four body decays have a peculiar feature: similarly to $K_{S,L} \to \pi^+\pi^-e^+e^-$ [323], the two different helicity amplitudes interfere. One can then measure the sign of $K_L \to \gamma^*\gamma^* \to \ell^+\ell^-\ell^+\ell^-$ by studying the time interference between K_S and K_L, which has a decay length $2\Gamma_S$ [324].

The ChPT prediction for $\mathcal{B}(K_S \to \gamma\gamma)$ [325], which has been experimentally confirmed, allows one to make a prediction for $\mathcal{B}(K_S \to \mu^+\mu^-\gamma) = 7.25 \times 10^{-10}$; this value is increased by vector meson dominance (VMD) and unitarity corrections to $\mathcal{B}(K_S \to \mu^+\mu^-\gamma) = (1.45 \pm 0.27) \times 10^{-9}$ [305].

4.4 $K_S \to \pi^0\ell^+\ell^-$ and $K^\pm \to \pi^\pm\ell^+\ell^-$

At low dilepton mass squared, q^2, the dominant contribution to $K^\pm(K_S) \to \pi^\pm(\pi^0)\ell^+\ell^-$ is due to a single virtual-photon exchange. The resulting amplitude involves a vector form factor $V_i(z)$ $(i = \pm, S)$,

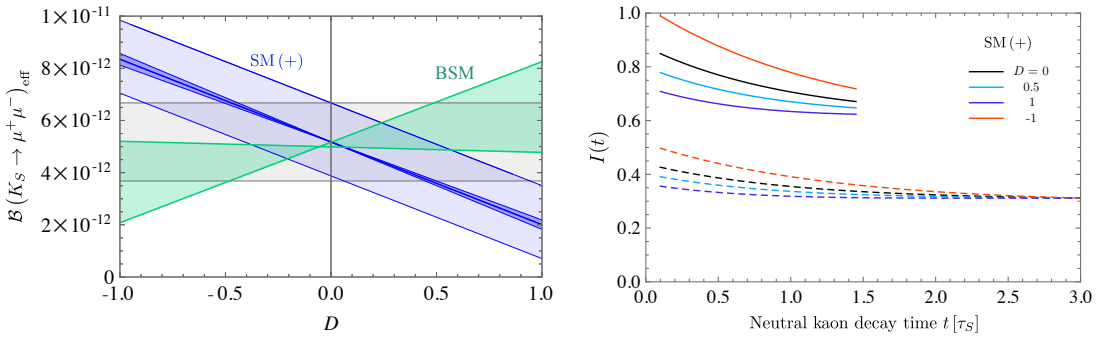

Fig. 32: Left panel: The effective branching ratios with the blue (gray) band denoting the SM prediction with (without) taking into account the dilution D. The green band corresponds to a BSM scenario entering through electroweak penguins studied in Ref. [304]. Right panel: The $K \to \mu^+\mu^-$ time distributions in the SM for several choices of D. The $D = 0$ decay intensity is normalized, either over the interval $0.1\tau_S$ to $1.45\tau_S$ (solid lines) or $0.1\tau_S$ to $3\tau_S$ (dashed lines). Positive sign of $A^{\mu}_{L\gamma\gamma}$ is assumed in Eq. (59). A detailed explanation and results for the negative sign of $A^{\mu}_{L\gamma\gamma}$ are given in Ref. [304].

Table 22: Fitted values of coefficients entering the vector form factor in Eq. (61).

Channel	a_+	b_+	Reference
ee	-0.587 ± 0.010	-0.655 ± 0.044	E865 [328]
ee	-0.578 ± 0.016	-0.779 ± 0.066	NA48/2 [329]
$\mu\mu$	-0.575 ± 0.039	-0.813 ± 0.145	NA48/2 [330]

which can be decomposed in the general form up to $\mathcal{O}(p^6)$ in the chiral expansion as [326, 327],

$$V_i(z) = a_i + b_i z + V_i^{\pi\pi}(z)\,, \quad z = q^2/m_K^2\,, \quad \text{for} \quad i = \pm, S. \tag{61}$$

Here the low energy constants (LECs), a_i and b_i, parametrize the polynomial part of the amplitude, while the rescattering contribution $V_i^{\pi\pi}$ can be determined from fits to $K \to \pi\pi$ and $K \to \pi\pi\pi$ data (no $\Delta I = 1/2$ contribution to $V_S^{\pi\pi}$). The chiral loops, encoded in $V_i^{\pi\pi}$, have been computed, model-independently and at leading order, in the framework of chiral perturbation theory [326, 327]. Chiral symmetry alone does not constrain the values of the LECs, so instead, we consider the differential decay rate $d\Gamma/dz \propto |V_+(z)|^2$ as a means to extract a_+ and b_+ from experiment. The resulting fit to the decay spectra from all available high-statistics experiments is given in Table 22. The experimental size of the b_+/a_+ ratio exceeds the naive dimensional analysis estimate, calling for a large VMD contribution.

The branching ratios of $K_S \to \pi^0\ell^+\ell^-$, on the other hand, are approximately

$$\mathcal{B}(K_S \to \pi^0 e^+ e^-) \approx 5 \times 10^{-9} \cdot a_S^2, \qquad \mathcal{B}(K_S \to \pi^0 \mu^+ \mu^-) \approx 1.2 \times 10^{-9} \cdot a_S^2, \tag{62}$$

and NA48, assuming just a VMD form factor, finds respectively [331, 332]

$$|a_S|_{ee} = 1.06^{+0.26}_{-0.21} \pm 0.07, \qquad |a_S|_{\mu\mu} = 1.54^{+0.40}_{-0.32} \pm 0.06. \tag{63}$$

The uncertainty of $|a_S|_{\mu\mu}$ gives the dominant theoretical uncertainty in $K_L \to \pi^0\mu^+\mu^-$. Therefore, this measurement is a crucial piece of information required to establish the relative roles of indirect CP violation vs. direct CP violation in $K_L \to \pi^0\mu^+\mu^-$, in order to probe SD effects [312]. The LHCb Upgrade II can reach a precision in $\mathcal{B}(K_S^0 \to \pi^0\mu^+\mu^-)$ at the 10^{-10} level (see Fig. 33), and, through an analysis of the differential decay rate, a 10% statistical precision on the form factor term $|a_S|$ with free b_S [298].

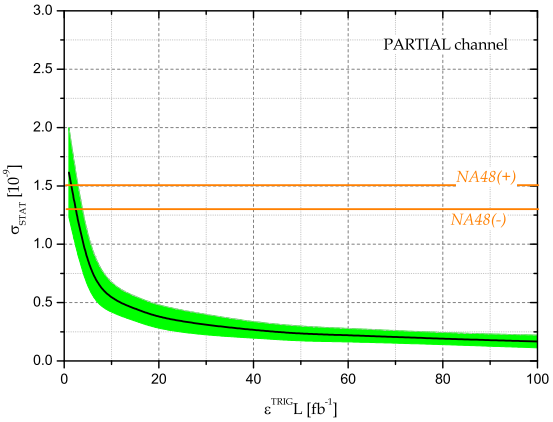

Fig. 33: Projected LHCb reach for $\mathcal{B}(K_S^0 \to \pi^0\mu^+\mu^-)$ as a function of the integrated luminosity times trigger efficiency (which is expected to be $\mathcal{O}(1)$ in LHCb Upgrade II. Figure adapted from Ref. [300].

4.4.1 Lepton flavor universality violation in $K^\pm \to \pi^\pm\ell^+\ell^-$

The coefficients a_+ and b_+ can be used to test for LFUV. If lepton flavour universality applies, each of the two coefficients, averaged over different experiments, have to be equal for the ee and $\mu\mu$ channels. Within errors this is indeed the case, see Table 22. Since the SM interactions are lepton flavour universal, deviations from zero in differences, such as $a_+^{\mu\mu} - a_+^{ee}$, would be a sign of NP. Such a test is especially interesting in view of the B-physics anomalies (see Sec. 7), with rare kaon decays providing a complementary role in testing the NP explanations. Our analysis [333] is based on the observation that at low energy scales, $\mu \ll m_{t,b,c}$, the strangeness-changing transitions are described in terms of the effective Lagrangian [323]

$$\mathcal{L}_{\rm eff}^{|\Delta S|=1} = -\frac{G_F}{\sqrt{2}} V_{ud}V_{us}^* \sum_i C_i(\mu)Q_i(\mu) + \text{h.c.}\,, \tag{64}$$

which contains semileptonic operators

$$Q_{7V} = [\bar{s}\gamma^\mu(1-\gamma_5)d] \sum_{\ell=e,\mu} \left[\bar{\ell}\gamma_\mu\ell\right], \quad \text{and} \quad Q_{7A} = [\bar{s}\gamma^\mu(1-\gamma_5)d] \sum_{\ell=e,\mu} \left[\bar{\ell}\gamma_\mu\gamma_5\ell\right], \tag{65}$$

that are the $s \to d$ analogues of the $b \to s$ operators, $Q_{9,10}^B$. In the framework of minimal flavour violation (MFV), the Wilson coefficients of the two sectors are correlated. We use this feature to convert knowledge of $C_{7V,7A}$ into bounds on $C_{9,10}^B$.

To convert the allowed range on $a_+^{\rm NP}$ into a corresponding range in the Wilson coefficients $C_{7V}^{\ell\ell}$, we make use of the $\mathcal{O}(p^2)$ chiral realization of the $SU(3)_L$ current

$$\bar{s}\gamma^\mu(1-\gamma_5)d \leftrightarrow i f_\pi^2 (U\partial^\mu U^\dagger)_{23}\,, \qquad U = U(\pi, K, \eta)\,, \tag{66}$$

to obtain

$$a_+^{\rm NP} = \frac{2\pi\sqrt{2}}{\alpha} V_{ud}V_{us}^* C_{7V}^{\rm NP}\,. \tag{67}$$

Contributions due to NP in $K^+ \to \pi^+\ell^+\ell^-$ can then be probed by considering the difference between the two channels

$$C_{7V}^{\mu\mu} - C_{7V}^{ee} = \alpha \frac{a_+^{\mu\mu} - a_+^{ee}}{2\pi\sqrt{2}V_{ud}V_{us}^*}\,. \tag{68}$$

Assuming MFV, this can be converted into a constraint on the NP contribution to C_9^B,

$$C_9^{B,\mu\mu} - C_9^{B,ee} = -\frac{a_+^{\mu\mu} - a_+^{ee}}{\sqrt{2}V_{td}V_{ts}^*} \approx -19 \pm 79\,, \tag{69}$$

where we have averaged over the two electron experiments listed in Table 22.

The determination of $a_+^{\mu\mu} - a_+^{ee}$ needs to be improved by an $\mathcal{O}(10)$ factor in order to probe the parameter space relevant for the B-anomalies, which require Wilson coefficients $C_{9,10}^B = \mathcal{O}(1)$ [334]. Improvements of this size may be possible at NA62, especially for the experimentally cleaner dimuon mode which currently has the larger uncertainty.

4.5 $K_S \to \pi^+\pi^- e^+ e^-$

The $K_S \to \pi^+\pi^- e^+ e^-$ decays can be interesting, if one can test beyond the dominant bremsstrahlung contribution, performing ChPT tests. In principle, CP violation is also of interest for NP searches. So far, NA48 has, using 676 events, obtained a measurement $\mathcal{B}(K_S \to \pi^+\pi^- e^+ e^-) = (4.79 \pm 0.15) \times 10^{-5}$, [310] to be compared with the theoretical prediction [335]

$$\mathcal{B}(K_S \to \pi^+\pi^- e^+ e^-) = \underbrace{4.74 \cdot 10^{-5}}_{\text{Brems.}} + \underbrace{4.39 \cdot 10^{-8}}_{\text{Int.}} + \underbrace{1.33 \cdot 10^{-10}}_{\text{DE}}\,. \tag{70}$$

Similarly, one can predict for the dimuon channel,

$$\mathcal{B}(K_S \to \pi^+\pi^- \mu^+ \mu^-) = \underbrace{4.17 \cdot 10^{-14}}_{\text{Brems.}} + \underbrace{4.98 \cdot 10^{-15}}_{\text{Int.}} + \underbrace{2.17 \cdot 10^{-16}}_{\text{DE}}\,. \tag{71}$$

The LHCb upgrade expects a yield of up to 5×10^{-4} events per fb-1 [336].

4.6 LFV modes

Modes with LFV, such as $K \to (n\pi)\mu^\pm e^\mp$, provide null tests of the SM. The interest on such processes has been renewed because they can receive sizable contributions from BSM addressing the hints for LFUV in $B \to K^{(*)}\ell^+\ell^-$. Both types of processes can arise from NP contributions to the product of the two neutral currents, composed of the down-type quarks and charged leptons. The only difference between the two is the strength of the flavour couplings involved. Using general EFT arguments, the amount of LFUV hinted at in $B \to K^{(*)}\ell^+\ell^-$ decays, generically imply $B \to K^{(*)}$ LFV rates of the order of 10^{-8} [337]. (More quantitative estimates require introduction of flavour models [265, 333, 338–348].)

As discussed in Ref. [301], such arguments can be extended to $K \to (\pi)\mu^\pm e^\mp$, with fairly general assumptions on different flavour couplings involved. Expected rates can be as large as $10^{-10} - 10^{-13}$ for the $K_L \to \mu^\pm e^\mp$ mode and a factor of ~ 100 smaller for the $K^+ \to \pi^+\mu^\pm e^\mp$ one. Taking into account the suppression mechanisms at play, such "large" rates are a non-trivial finding. The relatively wide predicted ranges are due to the inherent model dependence, especially in the choice of the leptonic coupling and of the overall scale of the new interaction, typically between 5 and 15 TeV [301]. On the experimental side, the limits on $K \to (\pi)\mu^\pm e^\mp$ modes are, somewhat surprisingly, decades-old

$$\begin{aligned} &\mathcal{B}(K_L \to e^\pm\mu^\mp) < 4.7 \times 10^{-12} \quad [349]\,, && \mathcal{B}(K_L \to \pi^0 e^\pm\mu^\mp) < 7.6 \times 10^{-11} \quad [350]\,, \\ &\mathcal{B}(K^+ \to \pi^+ e^-\mu^+) < 1.3 \times 10^{-11} \quad [351]\,, && \mathcal{B}(K^+ \to \pi^+ e^+\mu^-) < 5.2 \times 10^{-10} \quad [352]\,. \end{aligned} \tag{72}$$

These modes can be profitably pursued at the upgraded LHCb, which will benefit from huge yields. Ref. [301] presented a feasibility study for the modes in Eq. (72), taking $K^+ \to \pi^+\mu^\pm e^\mp$ as a benchmark. The expected reach is displayed in Fig. 34 as a function of the integrated luminosity and for different

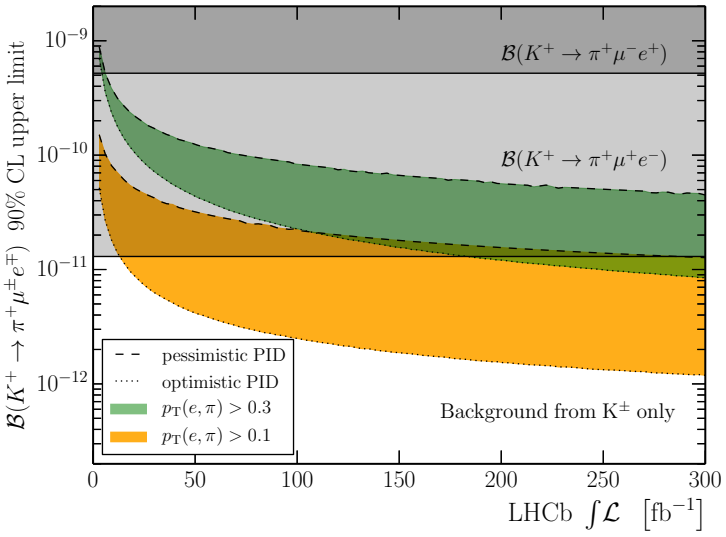

Fig. 34: Expected reach for $K^+ \to \pi^+\mu^\pm e^\mp$ as a function of the integrated luminosity with 13 TeV pp collisions based on a fast simulation of LHCb. Different scenarios in terms of PID performance and p_T thresholds of the π^+ and $e^\pm$ candidates are shown. Combinatorial background is neglected in the study. Figure adapted from Ref. [301].

scenarios of detector performance. This shows that LHCb Upgrade II could update some of the existing limits, a result that per se already makes these searches promising. Even more interestingly, LHCb Upgrade II could probe part of the parameter space for LFV kaon decays suggested by the B-physics anomalies. This conclusion in turn calls attention to other running and upcoming facilities, including Belle-II, NA62 [353], as well as the newly proposed TauFV [354]. Dedicated sensitivity studies for these facilities are required in order to make more quantitative statements. Yet, the experimental outlook for all these modes is certainly promising.

4.7 Hyperons at HL-LHC

The LHCb can contribute significantly to the strangeness-physics programme with measurements of hyperon decays. There is vast room for improvement in this sector as most of the data for the standard modes, both in nonleptonic and semileptonic decays, is about 40 years old, and many of the rare decays sensitive to SD physics have not even been searched for. An exploratory study of the LHCb's potential in hyperon physics was presented in [355]; here we summarize the main conclusions.

Current experimental data on the semileptonic hyperon decays $\Lambda \to p\mu^-\bar{\nu}$, $\Xi^- \to \Lambda\mu^-\bar{\nu}$ and $\Xi^- \to \Sigma^0\mu^-\bar{\nu}$ is quite poor, with relative uncertainties in the range of 20%-100%. These decay modes can be partially reconstructed at the LHCb, where the kinematic distributions allow one to discriminate from the peaking backgrounds of $\Lambda \to p\pi^-$ and $\Xi^- \to \Lambda\pi^-$. Besides testing lepton-universality by comparing with the semi-electronic modes, these decays are sensitive to BSM scalar and tensor currents [356]. If percent precision is achieved in the measurement of semi-muonic branching fractions, they could contribute to a better determination of the CKM matrix element $|V_{us}|$ from hyperon decays [357–360].

A golden mode among the rare hyperon decays is $\Sigma^+ \to p\mu^+\mu^-$, to which LHCb recently contributed with an evidence for the decay at 4.1σ and a di-muon invariant distribution consistent with the SM [361], thus challenging the HyperCP anomaly [362]. With dedicated triggers and the upgraded LHCb detector in the HL phase about a thousand events per year of data-taking could be measured, which will allow one to measure angular distributions or direct CP asymmetries that have been shown to be sensitive to SD physics [262, 363]. The equivalent channel with lepton number violation, $\Sigma \to \bar{p}\mu^+\mu^+$ can also be searched for, with potential sensitivities at the 10^{-9} level. Other $\Delta S = 1$ semileptonic rare hyperon

decays, except those of the Ω^- (which will be produced at a rate similar to that of a B-meson), must have electrons in the final state due to phase space. Sensitivity to $\mathcal{B}(\Sigma^+ \to pe^+e^-) \sim 10^{-6}$ should be accessible at LHCb, whereas other modes like $\Lambda \to p\pi^-e^+e^-$ suffer from low electron reconstruction efficiency. More exotic modes, probing baryon-number violation, lepton-flavor violation, or $\Delta S = 2$, can also be measured with projected sensitivities improving by orders of magnitude the current limits [355]. Radiative decays such as $\Lambda \to p\pi\gamma$ are also accessible to LHCb.

5 Tau leptons

Authors (TH): Vincenzo Cirigliano, Martin Gonzalez-Alonso, Adam Falkowski, Emilie Passemar.

The physics of the tau lepton is an exceptionally broad topic, both experimentally and theoretically. A large variety of processes involving taus have been used in the last decades to learn about fundamental physics [364]. In some cases the results obtained in e^+e^- machines [365] are very hard to improve in the LHC environment, due to large backgrounds, even if the number of taus produced is much larger. This is the case, *e.g.*, for the study of basic tau properties (mass, lifetime, etc.) or the standard tau decay channels. However, there are also many processes involving taus that are relevant for HL/HE-LHC. Here we focus on those that are more directly connected to flavour and that are not covered by other sections (for instance $h \to \tau\tau$, $h \to \tau\ell$, Sec. 9 or heavy meson decays to taus, Sec. 7).

To simplify the discussion we will assume that the scale of New Physics (NP) relevant for the processes under consideration is much heavier than the energy scales probed by the LHC. We can then use the SMEFT framework [366]. We first discuss lepton flavour conserving observables, where the SM contribution has to be calculated with some accuracy in order to probe NP. In contrast, the SM contribution is negligible for lepton flavour violating processes, where the challenges are purely experimental. As a result, the NP scales that are probed are much higher in the latter case.

5.1 Lepton-flavour-conserving processes

Collider phenomenology is usually very different for the so-called vertex corrections and contact interactions. For vertex corrections the NP contributions mimic the structure of the SM gauge couplings, $Z\tau\tau$ and $W\tau\nu$. Their study requires, in most cases, very precise measurements, which are challenging in a hadron collider. On the other hand, four-fermion contact interactions (generated for example by the tree-level exchange of a heavy mediator) give a contribution to high-energy observables qualitatively different from the SM one. For instance, a contribution from an off-shell mediator grows with the partonic center of mass energy, and thus one does not require very high precision in order for the measurements to probe interesting NP scales [367, 368]. For these contact interactions, we focus on flavour-diagonal couplings involving first-generation quarks and third-generation leptons.

5.1.1 High-energy tails

LHC measurements of differential distributions in the Drell-Yan lepton production can be sensitive to new effective interactions between leptons and quarks [367, 368]. As an example, consider that the following dimension-6 interaction is added to the SM Lagrangian,

$$\mathcal{L} \supset \frac{C_{lq}^{(3)}}{\Lambda^2}(\bar{L}_3\gamma_\mu\sigma^i L_3)(Q_1\gamma^\mu\sigma^i Q_1), \tag{73}$$

where σ^i are the Pauli matrices, $L_3 = (\nu_L^\tau, \tau_L)$ is the 3rd generation lepton doublet, and $Q_1 = (u_L, d_L)$ is the 1st generation quark doublet. This interaction term can be interpreted as an effective field theory (EFT) description of a more fundamental theory, for example an exchange of an $SU(2)$ triplet of vector bosons with masses $m_V = \Lambda \gg v$ that couples to L_3 and Q_1 with coupling strength $g_V \approx 2|C_{lq}^{(3)}|^{1/2}$. Even when m_V is too heavy to be directly produced at the LHC, the effective interaction in Eq. (73) may produce observable effects, and therefore provide information about the theory that completes the SM.

At the LHC, contact interactions between quarks and 3rd generation leptons can be probed via the processes $pp \to \tau^+\tau^- X$ and $pp \to \tau\nu X$ [369, 370]. Here we focus on the latter, taking as a template the existing Run-2 ATLAS analysis in Ref. [371]. This measured the $\tau\nu$ transverse mass distribution, where the transverse mass is given by $m_T = \sqrt{2p_{\rm T}E_T(1-\cos\phi)}$, with $\vec{p_{\rm T}}$ the transverse momentum of the (hadronic) tau candidate, $\vec{E}_T$ the missing transverse momentum, and ϕ the azimuthal angle between the two. The effects of the interaction in Eq. (73) are most pronounced at higher m_T.

To estimate the current and future sensitivity, we pick $m_T > 1.8$ TeV as our signal region (a more elaborate analysis with a wider, binned, m_T range would lead to stronger bounds [370]). Using the `Madgraph` [372]/`Pythia 8` [373]/`Delphes` [374] simulation chain and imposing the selection cuts we can estimate the expected number of events in the presence of the interaction in Eq. (73):

$$N_{pp\to\tau\tau}^{m_T>1.8\ \text{TeV}} \approx \left(\frac{\mathcal{L}}{36.1\ \text{fb}^{-1}}\right)\left[0.36 + 4.0\times 10^3 \frac{C_{lq}^{(3)} v^2}{\Lambda^2} + 3.6\times 10^5 \left(\frac{C_{lq}^{(3)} v^2}{\Lambda^2}\right)^2\right], \qquad (74)$$

where $\mathcal{L}$ is the integrated luminosity, $v \approx 246$ GeV, and we will ignore the theoretical error of this estimation. The ATLAS collaboration observed 0 events in $\mathcal{L} = 36.1\ \text{fb}^{-1}$ [371], from which one can derive the 68% CL limit on the Wilson coefficient in Eq. (73): $-(5.3\ \text{TeV})^{-2} \le C_{lq}^{(3)}/\Lambda^2 \le (7.7\ \text{TeV})^{-2}$. For the HL-LHC with $\mathcal{L} = 3000\ \text{fb}^{-1}$, assuming the observed number of events will be exactly equal to the SM prediction, the expected limit becomes

$$-\frac{1}{(17.5\ \text{TeV})^2} \le \frac{C_{lq}^{(3)}}{\Lambda^2} \le \frac{1}{(20.5\ \text{TeV})^2} \qquad @\ 68\%\ \text{CL}. \qquad (75)$$

Compared to the present LHC bound, this represents an $\mathcal{O}(10)$ stronger bound on $C_{lq}^{(3)}/\Lambda^2$, or $\mathcal{O}(3)$ times improvement in the reach for the mass scale of NP. Assuming maximally strongly coupled NP, $g_V \sim 4\pi$, the HL-LHC can probe particles even as heavy as $m_V \sim 100$ TeV.

There are 3 more independent dimension-6 operators that can be probed by the $pp \to \tau\nu$ process: $O_{ledq} = (\bar{L}_3\tau_R)(\bar{d}_R Q_1)$, $O_{lequ} = (\bar{L}_3\tau_R)(Q_1 u_R)$, and $O_{lequ}^{(3)} = (\bar{L}_3\sigma_{\mu\nu}\tau_R)(\bar{Q}_1\sigma^{\mu\nu}u_R)$ [367, 375]. We estimate that the HL-LHC will be sensitive to $C/\Lambda^2 \sim (10\ \text{TeV})^{-2}$ through a one-bin analysis like the one presented above. The slightly smaller sensitivity than for the operator in Eq. (73) follows from the fact that these do not interfere with the SM amplitudes, and thus their effect enters only at quadratic order in C/Λ^2. [3]

We expect that our simple analysis provides a good qualitative estimate of the HL-LHC reach. However, a more sophisticated analysis using the full information about the m_T distribution (such as in Ref. [370]), and possibly also about the τ polarization, should lead to a further $\mathcal{O}(1)$ increase of sensitivity. Ideally, the optimal analysis should be able to distinguish between different dimension-6 operators (except between O_{ledq} and O_{lequ}, which give exactly the same contribution to the $pp \to \tau\nu$ cross section), and provide constraints on the Wilson coefficients in the situation when all the independent operators are simultaneously present. Furthermore, the process $pp \to \tau^+\tau^-$ probes a large set of dimension-6 operators: $O_{lq} = (\bar{L}_3\gamma_\mu L_3)(Q_1\gamma^\mu Q_1)$, $O_{lu} = (\bar{L}_3\gamma_\mu L_3)(\bar{u}_R\gamma^\mu u_R)$, $O_{ld} = (\bar{L}_3\gamma_\mu L_3)(\bar{d}_R\gamma^\mu d_R)$, $O_{eq} = (\bar{\tau}_R\gamma_\mu\tau_R)(\bar{Q}_1\gamma^\mu Q_1)$, $O_{eu} = (\bar{\tau}_R\gamma_\mu\tau_R)(\bar{u}_R\gamma^\mu u_R)$, and $O_{ed} = (\bar{\tau}_R\gamma_\mu\tau_R)\ (\bar{d}_R\gamma^\mu d_R)$, in addition to the operators discussed above. We expect comparable sensitivity of $pp \to \tau^+\tau^-$ to C/Λ^2 as in the case of $pp \to \tau\nu$ [367]. It is unlikely that the LHC alone can discriminate between all these operators; to this end combining with low energy precision measurements of τ decays will be necessary. Finally, we mention that $\tau\tau$ and $\tau\nu$ production also probes analogous operators with heavier (s, c, b) quarks instead of the 1st generation ones [369, 377, 378]. The presence of such operators in the Lagrangian can be motivated by the anomalies observed by BaBar and LHCb in the $B \to D^{(*)}\tau\nu$ decays [379–381] (see Sec 7).

5.1.2 Beyond tails: lepton flavour universality

It has been pointed out recently that there is an interesting complementarity between the high-energy searches and low-energy precision studies, presented above, and hadronic tau decays [370]. The latter

[3] Contributions from SMEFT dim-8 operators are assumed to be subleading with respect to dim-6 squared terms. Although not true in general, this is indeed the case for strongly coupled UV completions [376].

are equally sensitive to vertex and contact interactions, and thus effectively become model-independent probes of LFU violations in the $W\tau\nu$ vertex once the strong LHC bounds described above are taken into account. This is interesting because the only low-energy model-independent measurement of this effect, which was carried out at LEP2, found a $\sim 2\sigma$ tension with LFU [382, 383]. Including also hadronic tau decays and LHC bounds on contact interactions, the result is improved by a factor of two, but the (dis)agreement with LFU remains at the $\sim 2\sigma$ level: $\delta g_L^{W\tau} - \delta g_L^{We} = 0.0134(74)$ [370].

Finally, it is interesting to mention the possibility of accessing LFU violations in the vertex corrections at the (HL/HE) LHC. In the ratio of $W \to \tau\nu$ and $W \to \ell\nu$ many experimental and QCD uncertainties cancel, which make a per-cent level extraction a bit less complicated. In fact, past studies carried out by the D0 collaboration [384] showed that such precision is indeed possible in a collider environment.

5.2 Lepton Flavour Violation

Lepton Flavour Violating (LFV) processes involving charged leptons are very interesting because their observation would be a clear indication of physics beyond the SM. While lepton family number is an accidental symmetry of the SM, we know it must be broken in order to account for neutrino masses and mixings. If the only low-energy manifestations of LFV are neutrino masses and mixings (which corresponds to a very high scale for LFV), then charged LFV amplitudes are suppressed by the GIM mechanism and the predicted rates are un-observably small, e.g., $\mathcal{B}(\mu \to e\gamma) \sim 10^{-52}$, $\mathcal{B}(\tau \to \mu\gamma) \sim 10^{-45}$ and $\mathcal{B}(\tau \to 3\mu) \sim 10^{-54}$ [385–388]). However, if the breaking of the lepton family symmetry happens not too much above the electroweak symmetry breaking scale, as borne out in many NP scenarios, then one can expect charged LFV BRs quite close to existing limits, and therefore within reach of ongoing searches. In fact in some cases experimental limits are already excluding regions of parameter space in specific weak scale NP models. While less severe than in the quark sector, one has a "flavour problem" in the lepton sector as well.

A rich literature exists on this topic, including studies in supersymmetric extensions of the SM, little Higgs models, low-scale seesaw models, leptoquark models, Z' models, left-right symmetric models, and extended Higgs models. For recent reviews on both theoretical and experimental aspects we refer the reader to Refs. [389, 390]. Current limits on BRs in μ-e transitions are at the level of 10^{-13} (e.g. $\mathcal{B}(\mu^+ \to e^+\gamma) < 4.2 \times 10^{-13}$ (90% CL) [391]), while τ-μ and τ-e BRs are bound at the 10^{-8} level [197]. As discussed below, improvements in LFV τ decays will offer the opportunity to explore *(i)* correlations with μ-e transitions, probing underlying sources of flavour breaking; *(ii)* correlations among different LFV τ decays, probing the nature of the underlying mechanism. In parallel to the ambitious programme constraining LFV for tau lepton, a similar programme exists in the muonic sector improving the limit on $\mu \to e\gamma$ with MEGII [392, 393], $\mu \to 3e$ with Mu3e [394, 395], and $\mu \to e$ conversion on Aluminium target with Mu2e [396] at Fermilab and COMET [397] at JPARC and on silicon-carbide and graphite target with DeeMe at JPARC [398, 399]. LFV studies can also be performed in B and D decays, as well as the decays of $c\bar{c}$ and $b\bar{b}$ quarkonia, though the effective NP scale reach is lower, see, e.g., [400, 401]. Probing the relative strength of $\mu \to e$ and $\tau \to \mu$ LFV transitions will shed light on the underlying sources of family symmetry breaking in the lepton sector and their link to the quark sector in grand unified scenarios.

Finally, LFV decay modes of the Z^0 are also of considerable interest. Their BRs in the SM are again negligible, $\mathcal{B}(Z \to e^\pm\mu^\mp) \sim \mathcal{B}(Z \to e^\pm\tau^\mp) \sim 10^{-54}$, $\mathcal{B}(Z \to \mu^\pm\tau^\mp) \sim 10^{-60}$ and the LHC can obtain competitive bounds in some of these channels [402]. The current upper limits are due to LEP measurements (at 95% CL) [403–406],

$$\mathcal{B}(Z \to e^\pm\mu^\mp) < 1.7 \times 10^{-6}, \quad \mathcal{B}(Z \to e^\pm\tau^\mp) < 9.8 \times 10^{-6}, \quad \mathcal{B}(Z \to \mu^\pm\tau^\mp) < 1.2 \times 10^{-5}, \tag{76}$$

while the ATLAS Collaboration has recently obtained the following 95% CL upper limits: $\mathcal{B}(Z \to e^\pm\tau^\mp) < 5.8 \times 10^{-5}$ [407], and $\mathcal{B}(Z \to \mu^\pm\tau^\mp) < 1.3 \times 10^{-5}$ [407]. The HL/HE LHC will therefore

provide the best limit on LFV Z decays. The detection of a signal in the $Z^0 \to \ell\ell'$ channel, in combination with the information from charged lepton LFV decays, would also allow one to learn about features of the underlying LFV dynamics. An explicit example is provided by the Inverse Seesaw (ISS) and "3+1" effective models which add one or more sterile neutrinos to the particle content of the SM [408] (see also, e.g., Ref. [409–411]).

5.2.1 Lepton Flavour Violation in τ decays

Tau decays offer a rich landscape to search for CLFV. The τ lepton is heavy enough to decay into hadrons. Until now already 48 LFV modes have been bounded at the level of 10^{-8} [197], as can be seen in Fig. 35.

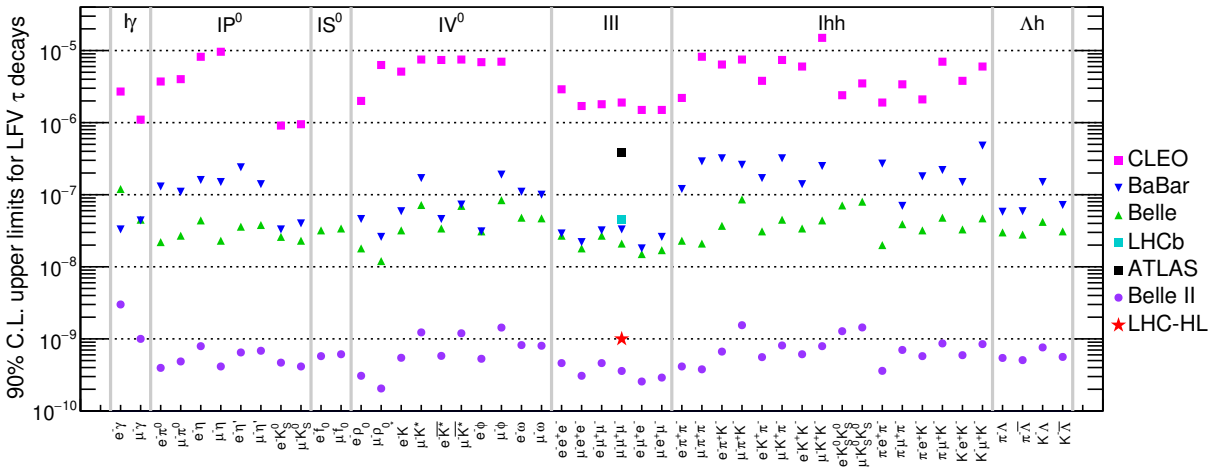

Fig. 35: Bounds on Tau Lepton Flavour Data from the existing experiments are compiled by HFLAV [197]; projections of the Belle-II bounds were performed by the Belle-II collaboration assuming 50 ab^{-1} of integrated luminosity [196].

The B factories, BaBar and Belle, have improved by more than an order of magnitude [412–424] the previous CLEO bounds [425–427] for a significant number of modes. Some of the modes, for instance, $\tau \to \ell\omega$, have been bounded for the first time [413].

Table 23 shows a list of limits obtained for the $\tau \to 3\mu$ channel by different experiments. The strongest limits come from the B-factories, with a competitive limit obtained by LHCb [428]. Table 23 also contains the recent measurement by ATLAS [429], as well as the expected limit from the Belle-II experiment at the SuperKEKB collider, which will improve current limits by almost two orders of magnitude [196]. Finally, Table 23 also summarizes the expected limits from the HL-LHC that we discuss in more detail below.

The physics reach and model-discriminating power of LFV tau decays is most efficiently analyzed above the electroweak scale using SMEFT, and in a corresponding low-energy EFT when below the weak scale [430]. Several classes of dimension-six operators contribute to LFV tau decays at the low-scale, with effective couplings denoted by C_i/Λ^2. Loop-induced dipole operators mediate radiative decays $\tau \to \ell\gamma$ as well as purely leptonic $\tau \to 3\ell$ and semi-leptonic decays. Four-fermion – both four-lepton and semi-leptonic – operators with different Dirac structures can be induced at tree-level or loop-level, and contribute to $\tau \to 3\ell$ and $\tau \to \ell + \text{hadrons}$. As a typical example, we note that current limits on $\tau \to \mu\gamma$ probe scales on the order of $\Lambda/\sqrt{C_{\text{Dipole}}} \sim 500$ TeV. Besides probing high scales, LFV τ decays offer two main handles to discriminate among underlying models of NP, i.e., to identify which operators are present at low energy and what is their relative strength: (i) correlations among different LFV τ decay rates [430]; (ii) differential distributions in higher multiplicity decays, such as the $\pi\pi$ invariant mass in $\tau \to \mu\pi\pi$ [430] and the Dalitz plot in $\tau \to 3\mu$ [431, 432].

Table 23: Actual and expected limits on BR($\tau \to 3\mu$) for different experiments and facilities. The ATLAS projections are given for the medium background scenario, see main text for further details.

BR($\tau \to 3\mu$) (90% CL limit)	Ref.	Comments
3.8×10^{-7}	ATLAS [429]	Actual limit (Run 1)
4.6×10^{-8}	LHCb [428]	Actual limit (Run 1)
3.3×10^{-8}	BaBar [417]	Actual limit
2.1×10^{-8}	Belle [423]	Actual limit
3.7×10^{-9}	CMS HF-channel at HL-LHC	Expected limit (3000 fb^{-1})
6×10^{-9}	ATLAS W-channel at HL-LHC	Expected limit (3000 fb^{-1})
2.3×10^{-9}	ATLAS HF-channel at HL-LHC	Expected limit (3000 fb^{-1})
$\mathcal{O}(10^{-9})$	LHCb at HL-LHC	Expected limit (300 fb^{-1})
3.3×10^{-10}	Belle-II [196]	Expected limit (50 ab^{-1})

In addition to Belle-II, HL/HE LHC will be able to search for the "background-free" $\tau \to 3\mu$. A detailed summary of projected sensitivities is given below. This is a particularly crucial discovery mode when LFV is introduced at tree-level, for example by the exchange of Z' or doubly charged Higgs bosons. Efforts should also go into understanding the backgrounds and improving the sensitivity in semi-leptonic three-body decays $\tau \to \mu\pi^+\pi^-$ and $\tau \to \mu K\bar{K}$, which have a particularly high discovery potential in Higgs-mediated [433–435] or leptoquark-mediated LFV. If LFV is discovered, these modes also have significant model-diagnosing power because of their Dalitz structure, and therefore also probe a wider class of models than the dominant one-loop-induced LFV process $\tau \to \mu\gamma$. Of particular interest is the sensitivity of $\tau \to \mu\pi\pi$ to extended Higgs sectors and to non-standard Yukawa couplings of the SM Higgs to light quarks and leptons [430, 434]. This channel also allows a particularly robust theoretical interpretation thanks to advances in the calculation of all the relevant hadronic form factors [434].

5.2.2 HL-LHC experimental prospects

The LHC proton collisions at 13 TeV produce τ leptons with a cross-section five orders of magnitude larger than at Belle II. As a result, during the HL-LHC running period, about 10^{15} τ leptons will be produced in 4π. Most will be produced in the decay of heavy flavour hadrons, specifically D_s meson decays. This high production cross-section compensates for the higher background levels and lower integrated luminosity, in particular for the $\tau \to 3\mu$ golden mode. Background events arise dominantly from badly reconstructed heavy flavour decays like $D_s^+ \to \eta(\mu^+\mu^-\gamma)\mu^+\nu_\mu$, lepton fakes from hadrons ($c\bar{c}/b\bar{b} \to X\mu\mu$), and pile-up. A particular challenge for this production channel is the soft momentum spectrum of the τ decay products, which places stringent requirements on both the trigger and offline reconstructions of all the HL-LHC experiments.

W and Z bosons offer a complementary source of τ leptons. Their production cross sections are considerably smaller than those for B and D mesons, but τ leptons from W and Z afford much cleaner experimental signatures with far better signal-to-background ratios for CMS and ATLAS; the LHCb forward geometry is less well suited to exploting these decays. For instance, in a $\tau \to 3\mu$ search relying on $W \to \tau\nu$ decays as a source of τ leptons, one can benefit from τ leptons having relatively large transverse momenta and being isolated, from large missing transverse momentum $p_{\mathrm{T}}^{\mathrm{miss}}$ in an event, and from the transverse mass of the τ-$p_{\mathrm{T}}^{\mathrm{miss}}$ system being close to the W mass.

Detector improvements planned for the HL-LHC period will significantly enhance the capabilities of all three experiments in this area. In the case of ATLAS, the installation of a new tracking system will improve the vertex and momentum resolution. The trigger system upgrade will include additional capabilities, ultimately improving the online selection, and allowing to maintain a low muon triggering

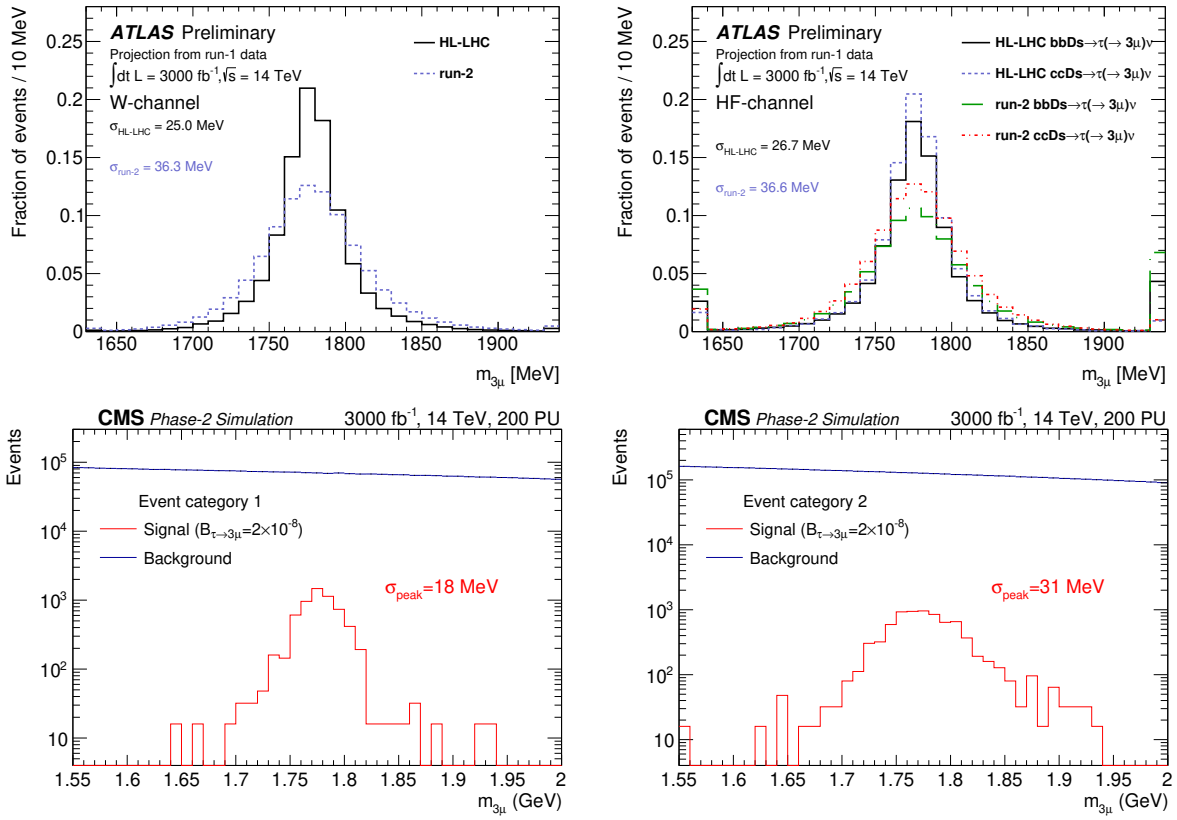

Fig. 36: (Top) Comparison of ATLAS tau mass resolutions in the W- (left) and HF-channels (right) in Run-2 and under HL-LHC detector conditions. Widths are estimated from a double-Gaussian fit. (Bottom) CMS trimuon invariant mass $m_{3\mu}$ for the $\tau \to 3\mu$ signal (red) and background (blue) after all event selection cuts, for Category 1 (left) and Category 2 (right) events, as defined in the text. The signal is shown for $\mathcal{B}(\tau \to 3\mu) = 2 \times 10^{-8}$. CMS results refer to the HF channel; plots are taken from [436] .

threshold. The CMS upgraded muon system, whose coverage is extended from $|\eta|$ = 2.4 to 2.8, increases the signal fiducial acceptance by a factor of two and, also, enhances the capability to trigger on and reconstruct low momentum muons [436]. The additional events with muons at high $|\eta|$ have worse trimuon mass resolution. Hence, two event categories are introduced: Category 1 for events with all three muons reconstructed only with the Phase-1 detectors, and Category 2 for events with at least one muon reconstructed by the new triple Gas Electron Multiplier (GEM) detectors, which will be installed in the first station of the upgraded muon system. The impact of the proposed ATLAS detector upgrades and CMS event categories is shown in Fig. 36. In the case of LHCb, the deployment of a fully software trigger will remove one of the key sources of inefficiency in the current analysis. In addition, the proposed calorimeter improvements during the LHCb Upgrade II will play an important role in suppressing backgrounds such as $D_s^+ \to \eta(\mu^+\mu^-\gamma)\mu^+\nu_\mu$.

The extrapolated sensitivities for ATLAS and CMS are shown in Fig. 37 and Tables 24 and 25. The ATLAS sensitivities [437] are extrapolated based on the Run 1 measurement [429] taking into account the expected detector improvements. Three scenarios for the acceptance, efficiency and background yields are considered. Systematic uncertainties are extrapolated from the Run-1 measurement scaling down by the increased statistics with preserved constant terms for the reconstruction efficiency. A 15% systematic uncertainty dominated by the background estimation is derived. Varying the systematic uncertainty by 5% translates into a 10% change of the expected upper limit. Limits of up to $\mathcal{B}(\tau \to 3\mu) = 1.03(5.36) \times$

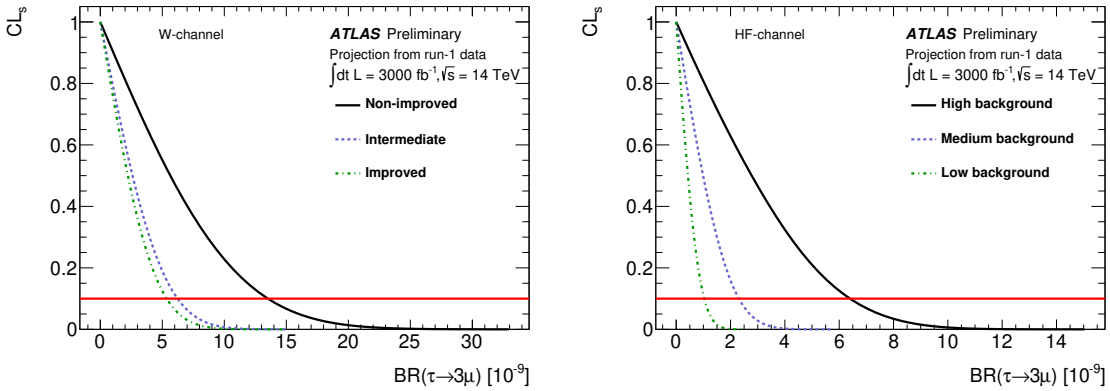

Fig. 37: ATLAS extrapolated CL_s versus the $\tau \to 3\mu$ branching fraction, BR($\tau \to 3\mu$) for each of the discussed scenarios in the W-channel (left) and HF-channel (right). The horizontal red line denotes the 90% CL. The limit is obtained from the intersection of the CLs and this line.

Table 24: Summary of the ATLAS expected 90% CL upper limit on $\mathcal{B}(\tau \to 3\mu)$ for an assumed luminosity of 3 ab^{-1} of pp collisions at $\sqrt{s} = 14$ TeV in the W and Heavy Flavour (HF) channels, for different signal and background yield scenarios.

Scenario	W-channel 90% CL UL [10^{-9}]	HF-channel 90% CL UL [10^{-9}]
ATLAS High	5.4	1
ATLAS Medium	6.2	2.3
ATLAS Low	13.5	6.4

10^{-9} are derived in the HF-(W-)channel. In the case of CMS, the absence of tails in the signal trimuon mass distribution, shown in Fig. 36, demonstrates the robustness of the reconstruction even at the high pileup (PU=200) of HL-LHC. The projected exclusion sensitivity in the absence of a signal is $\mathcal{B}(\tau \to 3\mu) < 3.7 \times 10^{-9}$ at 90% CL, while the expected 5 σ-observation sensitivity is $\mathcal{B}(\tau \to 3\mu) = 1.1 \times 10^{-8}$. CMS studies focusing on τ leptons originating from W boson decays are ongoing.

Extrapolations based on the current LHCb $\tau \to 3\mu$ result [428] and assuming no detector or trigger improvements show that, similarly to Belle II, CMS, and ATLAS, Upgrade II LHCb would also be able to probe branching ratios down to $\mathcal{O}(10^{-9})$. This will allow Upgrade II LHCb to independently confirm any earlier Belle II discovery, or to significantly improve the combined limit.

Table 25: (Top) The expected numbers of signal and background events in the mass window 1.55 -2.0 GeV for CMS. An integrated luminosity of 3000 fb^{-1} and a signal $\mathcal{B}(\tau \to 3\mu)$ = 2 $\times 10^{-8}$ is assumed. (Bottom) The search sensitivities for the combined categories.

	Category 1	Category 2
Number of background events	2.4 $\times 10^{6}$	2.6 $\times 10^{6}$
Number of signal events	4580	3640
Trimuon mass resolution	18 MeV	31 MeV
$\mathcal{B}(\tau \to 3\mu)$ limit per event category	4.3 $\times 10^{-9}$	7.0 $\times 10^{-9}$
$\mathcal{B}(\tau \to 3\mu)$ 90% C.L. limit	3.7×10^{-9}	
$\mathcal{B}(\tau \to 3\mu)$ for 3-σ evidence	6.7×10^{-9}	
$\mathcal{B}(\tau \to 3\mu)$ for 5-σ observation	1.1×10^{-8}	

6 Hadron spectroscopy and QCD exotica

Authors (TH): Angelo Esposito, Feng-Kun Guo, Juan Nieves, Alessandro Pilloni, Antonio Polosa, Sasa Prelovsek.

Determination of hadron spectrum is key to understanding the strong interactions, in particular the mechanisms underlying color confinement. While BESIII is the leading experiment in the charm region, and Belle II will make a major impact in the study of excited mesons and lighter exotic hadrons, only the HL-LHC experiments have the potential to comprehensively study the full range of possible excited hadronic states. Such a comprehensive understanding and characterisation of quark structures would not only, in some sense, greatly enhance the taxonomy of the SM particles, but would also sharpen our understanding of QCD in a particularly difficult energy regime. Moreover, while not directly probing BSM physics, spectroscopy measurements will continue to make essential contributions to the interpretation of any observed BSM effects in the flavour sector. In addition, spectroscopy can provide tools to probe BSM effects by using a new observed state as a tagger [438], [439].

While the Upgrade II of LHCb will by design offer unparalleled capabilities in this area, the legacy of HL-LHC for spectroscopy will be much stronger, if ATLAS and CMS are also able to continue to pursue this work in the HL-LHC period. The planned hardware tracking triggers and much higher data rates sent to their software triggers are promising in this respect, and we encourage further study of what capabilities they might bring to this area of physics. In particular, heavy-ion experiments might have an advantage for doubly-heavy exotics, if they can improve their particle identification.

Gauge theories play a major role in BSM and some of them might be strongly coupled. In this sense, QCD serves as a prototype of a strongly-coupled gauge theory. By studying hadron spectroscopy and the QCD exotica we learn about the range of possibilities of analogous states in BSM theories.

6.1 Open questions in spectroscopy

A large number of "exotic" experimental discoveries, which did not fit the expectations of the (until then) very successful valence quark model, as well as the unprecedented statistical precision obtained by LHCb, BESIII, and other experiments, have led to a recent renaissance of hadron spectroscopy. For recent reviews, see [196, 310, 440–448]. Understanding strong interactions at low energies requires an explanation of how the emergent hadron spectrum is organized, which can shed light on the confinement property of QCD.

To answer this question, a joint effort by experimental and theoretical communities is needed, making a combined use of all available tools, including lattice QCD results and effective field theory (EFT) methods, as well as phenomenological tools. The spectra of weakly decaying hadrons, as postdicted or predicted by lattice QCD, generally agree with the observed ones. Valuable conclusions can be drawn from the lattice also for several strongly decaying resonances, where the challenge increases with the number of open strong decay channels. From the phenomenological side, quark potential models, inspired by QCD, describe mesons as bound states of a valence quark-antiquark pair, and baryons as bound states of three valence quarks. One would expect these models [449–451] to work particularly well in describing the heavy quarkonium sector. They indeed do a very good job for the spectrum of charmonia and bottomonia below their respective open-flavor thresholds. This success can be connected with QCD by using nonrelativistic EFTs such as the ones described in Refs. [452–455].

However, other color configurations are allowed, such as mesons with two quarks and two antiquarks, and baryons with four quarks and one anti-quark, dubbed tetraquarks and pentaquarks, respectively.[4] These are examples of the so-called exotic hadrons which also include glueballs and hybrid hadrons with gluonic excitations. As already mentioned, their search has been an important theme in high-energy experiments, although plagued by several ambiguous claims. The key questions are: Can

[4] In fact, such configurations were already suggested in Gell-Mann's seminal paper on the quark model [456]. Multiquark configurations are also suggested, but not listed, in Zweig's original paper [457]. The name of "pentaquark" and a pioneering dynamical model first appeared in Ref. [458].

new states be unambiguously extracted from the experimental data? Are exotic hadrons really allowed by QCD? If yes, what kinds are allowed? Why are they so scarce? Can lattice QCD predict their spectrum? Is it possible to construct QCD-based phenomenological models for (at least) some of them?

The situation dramatically changed in 2003, when the charm-strange mesons $D^*_{s0}(2317)$, $D_{s1}(2460$ and the charmonium-like $X(3872)$ were discovered by the BaBar, CLEO and Belle Collaborations, respectively. None of them is in line with the predictions from potential quark models. For instance, their masses are lower than the predictions by Godfrey and Isgur by about 160 MeV, 70 MeV and 80 MeV, respectively [451]. As time passed, more and more unknown resonant structures were reported from various high-energy experiments, mostly BaBar, Belle, BESIII and LHCb. Many new structures, not compatible with predictions, have been found in the charmonium mass region. These are traditionally called XYZ states.[5] In particular, the isovector Z states are explicitly exotic, because they have nonzero isospin and at the same time contain a heavy $Q\bar{Q}$ pair. Similarly, LHCb [459] reported two structures in the $J/\psi\, p$ spectrum. If these were produced by real QCD baryon resonances (P_c), these states would contain at least five valence quarks/antiquarks. So far, there has been no consensus about the nature of these resonances, and some of the related experimental peaks might even receive large contributions from kinematical effects, making their interpretation as real states ambiguous. To resolve these issues, high statistics data and the search for signatures of these states in several different processes are highly desirable.

Next, we introduce briefly a few main types of models beyond the naive quark model for these intriguing exotic hadron candidates.

6.1.1 Tetraquarks

Two quarks and two antiquarks can lead to color singlets in different ways, which are difficult to choose from first principles. One possibility is for the constituents to be bound in a compact tetraquark (see, e.g., [460, 461]). For experimental reasons, the most studied systems are of the form $Q\bar{Q}q\bar{q}'$, where $Q = c, b$ and $q^{(\prime)}$ are light quarks. Their spectrum is well described in terms of diquarks, with a spin-spin interaction between the constituents given by $H_I = 2\kappa_{Qq}\big(\boldsymbol{S}_Q \cdot \boldsymbol{S}_q + \boldsymbol{S}_{\bar{Q}} \cdot \boldsymbol{S}_{\bar{q}'}\big)$, with no coupling between the constituents of different diquarks [461]. The chromomagnetic couplings κ are extracted from observed masses. It is found that two quasi-degenerate 1^{++} and 1^{+-} states are expected (identified with the $X(3872)$ and $Z_c(3900)$), together with a higher 1^{+-} state (the $Z'_c(4020)$). The same pattern should be replicated in the beauty system, where the two $Z_b(1^{+-})$'s have been discovered but the $X_b(1^{++})$ is still missing. The Z_c's and Z_b's are expected to fill in triplets of states, as confirmed experimentally. The X is an exception: only the neutral state is observed. This could be due to its accidental vicinity to threshold [462]. Moreover, the remarkable isospin violation observed in its decays can be explained by the fact that, being $\alpha_s(2m_c)$ small, the mixing between the mass eigenstates is suppressed [460, 463]. The $X^{\pm}$ components are forced to decay only into charmonia, and the computed rates lie below the current exclusion limits set experimentally. Decay modes such as, for example, $X^{\pm} \to J/\psi\rho^{\pm}$ should be eagerly sought in data.

Radial excitations are also possible, the charged $Z(4430)$ being the most remarkable example [460, 464, 465]. Its mass and decay modes fit perfectly a picture where it is the first radial excitation of the Z_c. Lastly, one also has orbital excitations, allowing for a 1^- spectroscopy. Prominent candidates are the observed $Y(1^-)$ states. An example is the $Y(4630) - Y(4660)$ system (identified as a single particle in [466]). Its mass fits the diquarkonium spectroscopy and its strong preference to decay into two baryons is easily explained by the breaking of the QCD string between the diquarks. For reviews see [440, 442, 443, 445, 467]. Remarkably, the X, $Z_c^{(\prime)}$ and $Z_b^{(\prime)}$ resonances are found experimentally

[5] Note that the naming scheme was changed in the 2018 edition of the Reviews of Particle Physics (RPP) by the Particle Data Group [310]. For charmonium(-like) states, the isoscalar states with quantum numbers J^{--}, J^{++} are called ψ_J, χ_{cJ}, respectively, and the isovector states with J^{--}, J^{+-} are called R_{cJ}, Z_{cJ}, respectively.

$\delta \lesssim 10$ MeV *above* their related meson-meson thresholds ($D^0\bar{D}^{*0}$ for the X, etc.). Their measured widths follow a $\Gamma = A\sqrt{\delta}$ law, with the same coefficient A for both charm and beauty states, as first observed in [468].

The above feature, the suppression of the interactions across different diquarks and the preference for decaying into open-flavour mesons, can be qualitatively explained with a separation in space of the two diquarks due to a (tiny) potential barrier between the two [462, 469–471]. With this conjecture, one can also understand why the discrepancy between the decay into quarkonia and open flavor is more prominent in the bottom sector than in the charm one. This would also make these exotic hadrons slightly larger than the standard ones (≈ 1.3 fm) [471]. The idea of the diquark–antidiquark pair being slightly separated in space has also been presented in [472], where it was shown that considering diquarks as dynamical and moving with respect to each other leads to an interesting way of computing tetraquark decays. The same picture has also been employed to study the spectrum of tetraquarks and possible selection rules for their decays [473], as well as to study pentaquarks [474]. Among other proposals to calculate the tetraquark spectrum, we recall the Born-Oppenheimer approximation, where the tetraquark is described as a heavy $Q\bar{Q}$ pair in color octet, immersed into an effective potential generated by the light pair, again in color octet. Under the assumption that the effective potential is the same as the one calculated on the lattice for heavy hybrids, the spectrum is derived [475]. Lastly, it was also proposed that the scaling of the tetraquark exclusive production cross section with the center-of-mass energy might reveal important information on the composite nature of these states [476, 477]. It follows that the study of production of exotic states is crucial.

6.1.2 Hadronic molecules

These are complex systems for which the dominant components are two or more interacting hadrons. For a review of theoretical and phenomenological aspects of hadronic molecules, with a focus on the new heavy-flavour hadrons, we refer to [444]. For a review focusing on the $X(3872)$, see [478].

The simplest hadronic molecule would be a loosely bound state of two hadrons (H_1, H_2) with a sizable extension. Such an object would be the analog to a neutron-proton pair bound to form a deuteron. If the physical state is located slightly below an S-wave threshold of two hadrons H_1 and H_2, the scattering length (a) and effective range (r) of the continuum $H_1 + H_2 \to H_1 + H_2$ scattering amplitude would be approximately given by

$$a = -2\frac{1-\lambda^2}{2-\lambda^2}\frac{1}{\gamma} + \mathcal{O}(\gamma/\beta), \qquad r = -\frac{\lambda^2}{1-\lambda^2}\frac{1}{\gamma} + \mathcal{O}(\gamma/\beta), \tag{77}$$

where $\gamma = \sqrt{2\mu E_B}$, with μ the H_1, H_2 reduced mass and $E_B > 0$ the binding energy of the physical state (i.e., the difference between the H_1, H_2 threshold and its mass), β the inverse range of forces and λ^2 the wave function renormalization constant, which for a pure molecule vanishes. There is also a relation for the effective coupling of the physical state to H_1 and H_2, given by (using the non-relativistic normalization)

$$g^2_{\text{NR,eff}} = \frac{2\pi\gamma}{\mu}(1-\lambda^2) + \mathcal{O}(\gamma/\beta). \tag{78}$$

The $(1-\lambda^2)$ factor gives the molecular probability, i.e., the probability of finding the H_1H_2 component in the physical state (the Weinberg compositeness criterion [479]). Thus, for a pure molecule ($\lambda^2 = 0$), one finds that the scattering length takes its maximum value, $a = -1/\gamma$, and in addition $r = \mathcal{O}(1/\beta)$, while for a compact state ($\lambda^2 = 1$) one gets $a = \mathcal{O}(1/\beta)$ and $r \to -\infty$. In addition, the effective coupling takes the maximal value for a pure molecule and it vanishes when there is no H_1H_2 component in the physical state. These differences produce distinctive signatures in the line shapes of near-threshold states (see, e.g., the discussion in [444, 480]) and not-so-near-threshold states [481]. In the case of coupled-channel dynamics, one might also find states that can decay into some of the open channels. These may

still qualify as hadronic molecules, were they to couple strongly to one of the channels considered in the dynamical space. A detailed review on weak decays of heavy hadrons leading to molecular states in the final state is given in [482].

The hadron-hadron interactions are usually taken from EFTs based on exact or approximate QCD symmetries, which are employed to construct amplitudes satisfying unitarity in coupled channels. The undetermined low-energy constants (LECs) are fitted to data or lattice QCD results, both in the perturbative expansion (implicit in the EFT) and in the unitarization procedure.

6.1.2.1 Effect of meson-meson channels on naive quark-antiquark bound states

Many of the hadronic structures discovered since 2003 appear close to hadron-hadron thresholds, and thus their dynamics can be strongly dictated by the nearby multiquark hadron-hadron channels. In fact, the discovery of the XYZ particles is opening the door to systematically explore higher Fock components of the hadron wave function [483–485]. When the hadron-hadron channels dominate, one gets states that can be approximately by hadronic molecules introduced above. Within quark models, the hadron-hadron effects can be calculated as pioneered in Refs. [449, 450, 486].

Within the quark model picture, the coupling between the quark-antiquark and meson-meson sectors requires that the hadronic state is written as [487, 488]

$$|\Psi\rangle = \sum_\alpha c_\alpha |\psi_\alpha\rangle + \sum_\beta \chi_\beta(P)|\phi_A\phi_B\beta\rangle, \tag{79}$$

where $|\psi_\alpha\rangle$ are eigenstates of the quark-antiquark Hamiltonian [489, 490], $|\phi_A\phi_B\beta\rangle$ is the two-meson state with β quantum numbers and $\chi_\beta(P)$ is the relative wave function between the two mesons. In principle one should couple with an infinite number of hadron-hadron channels. However, it has been argued in Refs. [491, 492] that the only relevant thresholds are those close to the naive states, while the rest have only little effect, which can be absorbed in the quark model parameters. The reason is that the energy nonanalyticity at thresholds does not cause any nontrivial behavior, if the thresholds are far away.

The meson-meson interaction can be derived from the quark-antiquark one using the resonating group method (RGM) [493, 494]. The coupling between the quark-antiquark and meson-meson sectors requires the creation of a light quark-antiquark pair, and thus the operator associated with this should describe also the open-flavor meson strong decays of heavy quarkonia. The most simple decay model is the well-known $^3P_0$ model [495–497], in which the transition potential between quark-antiquark and meson-meson sectors can be defined as

$$\langle\phi_A\phi_B\beta|T|\psi_\alpha\rangle = P\, h_{\beta\alpha}(P)\, \delta^{(3)}(\vec{P}_{\rm cm})\,, \tag{80}$$

where P denotes the relative momentum of the two-meson state.

Using Eq. (79) and the transition potential in Eq. (80), one gets the coupled equations

$$c_\alpha M_\alpha + \sum_\beta \int h_{\alpha\beta}(P)\chi_\beta(P)P^2 dP = E\, c_\alpha\,, \tag{81}$$

$$\sum_\beta \int H_{\beta'\beta}(P', P)\chi_\beta(P)P^2 dP + \sum_\alpha h_{\beta'\alpha}(P')\, c_\alpha = E\, \chi_{\beta'}(P')\,, \tag{82}$$

where M_α are the masses of the bare quark-antiquark mesons and $H_{\beta'\beta}$ is the RGM Hamiltonian for the two-meson states. Solving the coupled-channel equations, Eqs. (81) and (82), as indicated, e.g., in Ref. [498], allows to study hadronic states as poles of the S-matrix in any possible Riemann sheet.

6.2 Hadrons with a single heavy quark

6.2.1 Mesons

The lowest positive-parity states include the very narrow charm-strange mesons $D_{s0}^*(2317)$, $D_{s1}(2460)$, and the very broad charm-nonstrange mesons $D_0^*(2400)$ and $D_1(2430)$ [310]. Their bottom partners are still waiting for discovery, likely by LHC experiments. Bottom partners of the first two might be also accessible at Belle-II, though being at the upper edge of its energy reach.

6.2.1.1 Phenomenology

There were attempts trying to interpret the $D_{s0}^*(2317)$ and $D_{s1}(2460)$ as $c\bar{s}$ mesons, see, e.g., [499–502], or as the positive-parity chiral partners of the ground-state D_s and D_s^* [503, 504]. In these cases, the isospin-breaking hadronic decay widths are predicted to be of the order of only 10 keV. Predictions for the radiative decays can be found in [499, 503]. An updated calculation of the excited $c\bar{q}$ ($q = u, d, s$) meson spectrum and the decay properties in the relativized quark model can be found in [505].

The $D_{s0}^*(2317)$ and $D_{s1}(2460)$ states could be compact tetraquarks, namely $[cq][\bar{s}\bar{q}']$ states, where the two quarks and the two antiquarks are coupled to form a color singlet, see, e.g., [460, 506]. Having a single heavy quark, the mechanism driving isospin violation described in [460, 463] is expected not to be as effective as for the $X(3872)$, making the D_{sJ} states isosinglet. The only kinematically allowed hadronic decay channel is the isovector $D_s^{(*)}\pi$ state. Hence, the lack of isospin violation, together with the predilection for tetraquarks to decay into baryons, explains the narrowness of the states. Using the mass of the $X(3872)$ to fix the chromomagnetic coupling in the tetraquark model, one can indeed accommodate both of them. Of course, this predicts other similar states with quantum numbers $(0, 1, 2)^+$, all expected to decay into $D_s^{(*)+}\pi^0$. The $D^{(*)}K$ mode should be open for the heavier members in the multiplet.

Another possibility is to describe the $D_{s0}^*(2317)$ and $D_{s1}(2460)$ as DK and D^*K molecules [507, 508]. Dynamically they can be generated from charmed-meson–light-meson scattering in unitarized heavy-meson chiral effective theory (UHMChPT) [509–512], using as input the scattering lengths calculated on the lattice [513]. Such scheme predicts a (strangeness, isospin) $(S, I) = (1, 0)$ state with a mass 2315^{+18}_{-28} MeV, in agreement with that of the $D_{s0}^*(2317)$ resonance. Applying the Weinberg's compositeness condition allows one to estimate the size of the molecular component to be about 70% [513]. Such a picture is supported by the lattice energy levels reported in [514, 515], as discussed in [516, 517].

A decisive measurement is that of the width of the $D_{s0}^*(2317)$, which is expected to be around 100 keV in the molecular picture and smaller in other models [499, 500]. So far, only an upper limit has been provided. It would be difficult to measure such a tiny width at LHC experiments for two reasons: because it requires a very high mass resolution, and because there is a neutral pion in the dominant decay mode $D_s^+\pi^0$. However, it could be possible to measure the width of its spin partner $D_{s1}(2460)$, which carries similar information, through the decay mode $D_s\pi^+\pi^-$ and the Dalitz decay $D_{s1}(2460) \to D_s\gamma(\to \mu^+\mu^-)$. Dalitz decays have already been probed successfully for the χ_c states [518]. Both decay modes benefit from a very good mass resolution (~ 1 MeV), given the small Q values of the reactions. Though a measurement of the width with a precision of 100 keV might be optimistic, LHCb should at least be able to improve on the current upper limit (< 3.5 MeV). The proposed decay modes suffer from tiny branching fractions, but the large integrated luminosity in the HL-HE era would help cope with that.

In the $(S, I) = (0, 1/2)$ sector, UHMChPT suggests the presence of two broad D_0^* states at about $2.10 - i\,0.10$ GeV and $2.45 - i\,0.13$ GeV [519], which would have masses different from the $D_0^*(2400)$ given in the RPP [310], determined from fitting to the $D\pi$ mass distributions using a single Breit–Wigner function. Ref. [520] showed that these amplitudes can reproduce well the $B^- \to D^+\pi^-\pi^-$ process measured by the LHCb Collaboration [521]. The combination of angular moments, $\langle P_1\rangle - \frac{14}{9}\langle P_3\rangle$, is particularly sensitive to the $D\pi$ S-wave, and a higher-statistics measurement in the energy range between 2.4 and 2.5 GeV will provide invaluable information on the $D\pi$–$D\eta$–$D_s\bar{K}$ coupled-channel dynamics. Ref. [520] also finds two broad D_1 states at $2.25 - i\,0.11$ GeV and $2.56 - i\,0.20$ GeV, in addition to

the relatively well-understood narrow $D_1(2420)$. A precise study of $\langle P_1\rangle - \frac{14}{9}\langle P_3\rangle$ for the $D^*\pi$ S-wave is needed in the $\bar{B} \to D^*\pi\pi$ channel, as well as in $\bar{B} \to D^{(*)}\eta\pi$, $\bar{B} \to D_s^{(*)}\bar{K}\pi$, $\bar{B} \to D_s^{(*)}\bar{K}\bar{K}$, $\bar{B}_s \to D^{(*)}\bar{K}\pi$, $\bar{B}_s \to D_s^{(*)}\eta\pi$, etc. In particular, signals of the predicted higher D_0^* and D_1 states, coupled dominantly to $D_s^{(*)}\bar{K}$, could be near-threshold enhancements in the $D_s^{(*)}\bar{K}$ spectrum. Such enhancements exist in low-statistics data by BaBar [522] and Belle [523,524], and need to be investigated at LHCb using data sets with much higher statistics.

Heavy-quark flavour symmetry allows one to predict the bottom partners of charmed mesons. The lowest B_{s0}^* and B_{s1} are predicted to be at about 5.72 GeV and 5.77 GeV [519, 520], consistent with lattice results [525]. A good channel to search for both of them is $B_s^*\gamma$ [503, 526]. They can also decay into the isospin-breaking hadronic channels $B_s^{(*)}\pi^0$, whose widths are expected to be smaller than those of their charm partners because the isospin splitting between B^0 and $B^\pm$ is an order of magnitude smaller than that between D^0 and $D^\pm$. The axial state B_{s1} can decay into $B_s\gamma$ as well. Both the $B_s\gamma$ and $B_s^*\gamma$ decay modes should appear in the $B_s\gamma$ spectrum with similar efficiencies (similarly to the $B_{s2}^*(5840) \to B^*K$ decay, which peaks in the BK spectrum as well [527]). Large integrated luminosity will cope with the low efficiency for detecting soft photons, and the LHCb experiment will have sensitivity to observe such states for the first time. The predicted poles for the B_0^* mesons are at about $5.54 - i\,0.11$ GeV and $5.85 - i\,0.04$ GeV, while those for the B_1 mesons they are at about $5.58 - i\,0.12$ GeV and $5.91 - i\,0.04$ GeV [519, 520]. The bottom meson spectrum in quark models is different. For an updated calculation of the excited $b\bar{q}$ ($q = u, d, s$) meson spectrum and the decay properties in the relativized quark model can be found in [528]. And the predictions of bottom mesons in the parity-doubling model can be found in [503]. These resonances can be searched for in $B\pi$ and, for higher excited states, in $B_s\bar{K}$ final states.

The $D_{sJ}(2860)$ discovered by BaBar [529] was split into a 1^- state, the $D_{s1}^*(2860)$, and a 3^- state, the $D_{s3}^*(2860)$ by the LHCb measurement with higher statistics [530]. Yet, the ratio of two branching fractions $\mathcal{B}(D^*K)/\mathcal{B}(DK) = 1.10 \pm 0.24$ [531] is assigned to the spin-1 $D_{s1}^*(2860)$ in the RPP2018 [310]. This value is much larger than the expectations in Ref. [532], based on heavy quark spin symmetry (HQSS) and the leading order chiral Lagrangian, for the D-wave $c\bar{s}$ mesons, which are the only available quark-model option in that mass region. The predictions in [532] are 0.06 and 0.39 for the 1^- and 3^- D-wave states, respectively. However, the quark-model calculation in Ref. [533] gives larger values, 0.72 and 0.68 for the 1^- and 3^- D-wave states, respectively. On the other hand, in the picture for the $D_{s1}^*(2860)$ as mainly a $D_1(2420)K$ bound state, the ratio is predicted to be 1.23 as a natural consequence of HQSS [534]. Heavy quark symmetries allow to predict several related mesons in this picture: a 2^- spin partner at about 2.91 GeV, decaying into D^*K and $D_s^*\eta$; the bottom partners at about 6.15 GeV and 6.17 GeV, decaying into $B^{(*)}\bar{K}$ and $B_s^{(*)}\eta$ [534].

6.2.1.2 Lattice QCD

The most extensive spectrum of higher-lying D and D_s mesons on the lattice [535] was obtained in the single-hadron approximation, in which the decays of resonances and the effects of thresholds are not taken into account. This lattice study predicts a large number of states with $J \leq 4$ [535], most of which have not been discovered yet. Some of them might contain substantial gluonic components (hybrid mesons).

A proper treatment of a strongly decaying resonance $R \to H_1H_2$, with one open channel, requires simulations of single-channel H_1H_2 scattering. This has been accomplished recently by several lattice collaborations for a series of resonances. Mostly, resonances composed of u, d, s were considered. The infinite-volume scattering matrix $T(E)$ is extracted from the energies of H_1H_2 eigenstates on the finite lattice via the rigorous Lüscher's formalism [536]. The resulting scattering matrix $T(E)$ renders resonance masses, M, and decay widths, Γ, via Breit–Wigner-type fits. A related strategy is to analytically continue $T(E_c)$ to the complex-energy plane, where the pole positions, $E_c \simeq M - \frac{i}{2}\Gamma$, are related to the

resonance parameters. The resonances that strongly decay to several final states require simulation of coupled-channel scattering, which is much more challenging. The Hadron Spectrum Collaboration managed to extract the coupled-channel scattering matrix for a few selected channels, while most channels are awaiting future simulations.

Strong decays of resonances containing a single heavy quark were considered only for the low-lying charmed resonances with $J^P = 0^+, 1^\pm, 2^+$ [537, 538]. The $N_f = 2$ simulation of $D\pi$ scattering [537] finds a broad D_0^*, in rough agreement with experiment. As commented above, a reanalysis of $D\pi$–$D\eta$–$D_s\bar{K}$ coupled channels [538] for $N_f = 2 + 1$ suggests two D_0^* states, with masses located around 2.10 and 2.45 GeV [519].

The strongly stable states that lie closely below the H_1H_2 threshold might be sensitive to threshold effects. A proper way to treat these is to simulate H_1H_2 scattering. The mass of a shallow bound state corresponds to an energy $E < m_1 + m_2$, of which the scattering matrix, $T(E)$, has a pole. In this way, the effects of D^*K thresholds were found to push the masses of the D_{s0}^* and D_{s1}^* down, bringing them close to the experimental values [514, 515]. Analogously, the yet-undiscovered strongly stable B_{s0}^* and B_{s1}^0 were predicted at 5.71 and 5.75 GeV, respectively [525]. For the decay modes that can be used in searching, we refer to the discussion in 6.2.1.1.

6.2.2 Baryons

The most extensive spectrum of yet-undiscovered singly charmed baryons was predicted in 2013 [539]. It predicted five Ω_c baryons in the region 3.0-3.2 GeV, in impressive agreement with the 2017 LHCb discovery [540]. This work predicted also up to ten Λ_c, Σ_c, Ω_c, Ξ_c states in each channel with $J \leq 7/2$, where resonances are treated in a simplified single-hadron approach. A follow-up precision lattice study of the five discovered Ω_c resonances confirms their most likely quantum numbers [541].

The experimental discovery of the five Ω_c states has triggered extensive theoretical activity, with some of the quark models revisited in view of the new result [542–547]. The role of diquarks in the Ω_c spectrum was discussed in [542, 548, 549], while the odd-parity molecular interpretation for two or three of the states seen by LHCb was proposed in Refs. [550–552]. The meson-baryon interactions used in the molecular schemes, derived in [550, 552], are consistent with both chiral and heavy-quark spin symmetries, and lead to successful descriptions of the observed lowest-lying odd parity $\Lambda_c(2595)$, $\Lambda_c(2625)$ [553–556] and $\Lambda_b(5912)$, $\Lambda_b(5920)$ [557] resonances. Some of the Ω_c states observed by LHCb could thus be spin-flavour symmetry partners of these $\Lambda_{Q=c,b}^*$ baryons. However, the masses and decay widths of $\Lambda_{Q=c,b}^*$, at least the charmed ones, can also be accommodated within usual constituent quark models (see for instance [558, 559]), and thus the importance of the molecular components in their structure has not been settled yet. Information obtained from the $\Lambda_b \to \bar{\nu}_\ell \ell \Lambda_c(2595)$, $\Lambda_b \to \bar{\nu}_\ell \ell \Lambda_c(2625)$, and related reactions will put some constraints on these models, as shown in [560].

Molecular schemes also predict partners of the Ω_c baryons in the bottom sector (see for instance, Ref. [561]). LHCb recently reported [562] a peak in both the $\Lambda_b^0 K^-$ and $\Xi_b^0\pi^-$ invariant mass spectra that might correspond to either a radially or orbitally excited quark-model $\Xi_b^-(6627)$ resonance with quark content bds, or to a hadron molecule. In the latter, it would be dynamically generated from the coupled-channel interaction between Goldstone bosons and the lowest even-parity bottom baryons [557, 563–565]. For a review of recent observations and phenomenological models of open-flavour heavy hadrons, we refer to [566].

6.3 Hadrons containing $\bar{c}c$, $\bar{b}b$ or $\bar{c}b$

The current experimental status for the hadrons containing a heavy quark-antiquark pair can be found in several recent reviews [196, 310, 440–448], and will not be repeated here. In the following, we discuss isospin-scalar quarkonium(-like) states and, separately, exotic charged states, and focus on a few selected important issues.

6.3.1 Quarkonia

6.3.1.1 Phenomenology

The $J^{PC} = 1^{++}$ $X(3872)$ state has several salient features: the central value of its mass coincides with the $D^0\bar{D}^*$ threshold within a small uncertainty of 180 keV [310]; despite the tiny phase space, its decay branching fraction into $D^0\bar{D}^0\pi^0$ is larger than 40% [310]; it decays into $\omega J/\psi$ ($I = 0$) and $\rho J/\psi$ ($I = 1$) with similar partial decay widths.

This state could be interpreted in terms of a $[cq][\bar{c}\bar{q}]$ compact tetraquark. In this case, the isospin violation is explained by the smallness of $\alpha_s(m_c)$ [460, 463], which suppresses the mixing between the almost degenerate mass eigenstates $X_u = [cu][\bar{c}\bar{u}]$ and $X_d = [cd][\bar{c}\bar{d}]$. Isospin symmetry predicts a degenerate charged partner X^+– experimental search for which has so far been unsuccessful. Similarly, degenerate isoscalar and isovector states with signature 0^{++}, $0^{++\prime}$ and 2^{++} are expected, with masses around $M(0^{++}) \simeq 3.8$ GeV and $M(0^{++\prime}) \simeq M(2^{++}) \simeq 4$ GeV [461]. Were the $Z_c(4050)$ a scalar or a tensor, it would have been a suitable candidate for one of the above isovector states (see e.g. [567]). If confirmed, another possible candidate for the heavier scalar state could be the resonance observed by LHCb in $\eta_c\pi$ [568]; see also Ref. [475].

Given the expected mass, the charged partner predicted in the tetraquark picture, X^+, might only decay into a charmonium and a light meson. As discussed in Sec. 6.1.1, a potential barrier between the diquarks has been conjectured [462, 469–471]. This would solve the issue about the elusive X^+: the decay into J/ψ plus hadrons would be largely suppressed by the tunneling factor for a heavy quark, and could make the hadronic decay comparable to the electromagnetic one, as is indeed observed in data. Although physically and phenomenologically motivated, such a picture awaits experimental confirmation. Specifically, the charged partners of the X could be searched in the $J/\psi\rho^\pm$ channel.

The properties of the $X(3872)$, on the other hand, indicate that it couples strongly to $D\bar{D}^*$. This leads to the proposal that it could have a large $D\bar{D}^*$ molecular component [569–571]. The isospin violation in this case stems from the difference of masses between the neutral $D^0\bar{D}^{*0}$ and charge D^+D^{*-} in the loops [572–574]. The line shapes of the $X(3872)$ in both $J/\psi\pi^+\pi^-$ and $D^0\bar{D}^{*0}$ modes are crucial to reveal its nature and binding mechanism [575–579] (for a review, see [478]). Improved measurements at the LHC experiments are foreseen. In the hadronic molecular picture, the 2^{++} heavy-quark spin partner of the X, dubbed X_2, would decay into $D\bar{D}^*$ and $D\bar{D}$ in a D wave, and it is expected to be narrow [580, 581]. However, it has been suggested [582] that the mixing of the $D^*\bar{D}^*$ molecule with bare charmonium $\chi_{c2}(2P)$ might destabilize the X_2 [583], making it hardly visible. Better experimental information on the 2^{++} spectrum around 4 GeV is hence of great importance, and the X_2 can be searched for in $D\bar{D}$ and $J/\psi\omega$. So far, there is only one observed state, $\chi_{c2}(3930)$, compatible with a standard charmonium assignment, and its mass is lower than what is normally expected for the X_2. No evidence for an additional 2^{++} state that could be identified as the X_2 has been observed so far. Hence, the existence of the $\chi_{c1}(2P)$ and/or the X_2, in addition to the $X(3872)$ and $\chi_{c2}(2P)$ states, respectively, are still open questions which need to be addressed and that will definitely shed light into the dynamics of the mysterious $X(3872)$ [582].

The 0^{++} spectrum is also still unclear: the spin of the narrow $X(3915)$ is not fixed, and the broad $X(3860)$ [584,585] needs confirmation. Since the $(0, 1, 2)^{++}$ and 1^{+-} heavy quarkonia differ from each other only by the quark polarization, it is necessary to consider systematically physical states with these quantum numbers [582, 586]. Thus, searching for an isoscalar 1^{+-} state around 3.9 GeV is also of high interest [587]. Its important decay modes include $D\bar{D}^*$, $J/\psi\eta$ and $J/\psi\pi\pi$. Hints for such a state have been seen by COMPASS [588], albeit with low statistics.

The $X(3872)$ could emerge as a dynamically generated mixed state of a DD^* molecule and the $\chi_{c1}(2P)$ as shown in [589], see also Refs. [484, 576, 586, 590–594]. The $c\bar{c}$ mixture is less than 10% but it is important to bind the molecular state. The proposed structure would allow to understand the origin of its prompt production rate and to describe correctly its isospin violating decays and radiative

transitions. The original $c\bar{c}(2^3P_1)$ state is dressed by meson-meson coupled-channel effects and goes up in the spectrum allowing its identification with the $X(3940)$. Within the same coupled-channels scheme, Ref. [583] analyzes the $J^{PC} = 0^{++}$ and 2^{++} charmonium sectors. The two hadron states found in the 0^{++} channel were assigned to the $Y(3940)$ and to the recently identified resonance $X(3860)$ [584, 585]. The bound state with quantum numbers 2^{++} found in [583] is interesting because, within the uncertainties of the model, its mass and decay properties suggest that the $X(3915)$ and $X(3930)$ meson-like structures could correspond to the same state, as also claimed in Ref. [595].

It is also crucial to look for the analogue of the $X(3872)$ in the bottom sector. Such a state could decay, for example, into $B\bar{B}\gamma$, $\chi_{bJ}\pi\pi$, $\Upsilon\pi\pi\pi$ and $\Upsilon\gamma$ [596–598]. The $X_b \to \Upsilon\rho$ channel has already been investigated, with no observation [599,600]. It should be noticed, however, that this channel should be highly suppressed due to G-parity violation. There is an important difference between the $X(3872)$ and the X_b: The mass difference between the charged and neutral charmed mesons is one order of magnitude larger than that for the bottom mesons, because of the different interference between the QCD and QED contributions [601], and thus the X_b should be a well-defined isoscalar state [596]. The null results of Refs. [599, 600] are perfectly consistent with the existence of an isoscalar X_b [597, 598]. Note that in the tetraquark model one would expect isospin violation, while the opposite is true in a molecular scheme. The isospin-conserving channel $X_b \to \Upsilon\omega$ has found no evidence for the state either [602]. The spin-2 bottomonium-like X_{b2} and B_c-like state X_{bc2} [596] can instead be searched for in D-wave $B\bar{B}$ and DB final states, respectively.

Vector 1^{--} states have also been observed at e^+e^- colliders (see, e.g., [603–607]). The number of observed vector charmonium-like states far exceeds the predictions in the $c\bar{c}$ potential quark models, and thus some of them must have an exotic origin. In the tetraquark model these are diquarkonia with orbital angular momentum $L = 1$, and their spectrum easily matches the experimental observations [461] (see also [608]), which also leads to a distinctive spectrum with a low-mass 3^{--} state [609]. Complexity in understanding these structures also comes from the many S-wave thresholds of hadron pairs, such as the $\bar{D}D_1(2420)$ for the $Y(4260)$ [610] and $\psi' f_0(980)$ for the $Y(4660)$ [611]. Effects of open charm channels for the $Y(4260)$ are considered in a quark model framework in Ref. [612]. The $Y(4260)$ is also widely regarded as a candidate for a hybrid charmonium [613–617]. The hadro-charmonium model for the $Y(4260)$ and $Y(4360)$ [618] can hardly explain why the $Y(4260)$ was seen in several different channels including $J/\psi\pi^+\pi^-$, $h_c\pi^+\pi^-$, $\chi_{c0}\omega$ and $D^0D^{*-}\pi^+ + c.c.$ (the data are nicely summarized in Ref. [448] and a combined fit in these channels leads to a lower mass around 4.22 GeV for the $Y(4260)$ [619]. The search for these states in, for example, prompt production and/or B decays can help to understand their nature.

6.3.1.2 Lattice QCD

The lattice spectrum of bottomonia presented in [620] contains almost all the observed $\bar{b}b$ states up to the $\bar{B}B$ threshold. It also predicts a plethora of undiscovered states where the $\bar{b}b$ pair carries an orbital angular momentum $L = 2, 3, 4$, and total angular momentum $J \leq 4$. Fourteen B_c mesons with $J \leq 3$ are predicted up to the BD threshold [620]. Only two of them have been discovered so far.

All the charmonia below the $D\bar{D}$ threshold have been experimentally discovered, while the treatment of strongly decaying resonances is much more challenging. The most extensive spectrum obtained in the simplified single-hadron approach predicts several excited $\bar{c}c$ states, as well as $\bar{c}cg$ hybrids up to 4.7 GeV, carrying $J \leq 4$ [535], also including exotic 1^{-+}, 0^{+-}, 2^{+-} quantum numbers. Most of them have not been observed yet. Only one exploratory study considered the resonant nature of charmonia above the open-charm threshold [621], and underlines the need to experimentally explore further $\bar{D}D$ in S and D waves. A neutral is found as a state slightly below $D\bar{D}^*$ [622].

Table 26: Expected data samples at LHCb Upgrade II and Belle II for key decay modes for the spectroscopy of heavy flavoured hadrons. The expected yields at Belle II are estimated by assuming similar efficiencies as at Belle.

		LHCb		Belle II
Decay mode	$23\,\text{fb}^{-1}$	$50\,\text{fb}^{-1}$	$300\,\text{fb}^{-1}$	$50\,\text{ab}^{-1}$
$B^+ \to X(3872)(\to J/\psi\pi^+\pi^-)K^+$	14k	30k	180k	11k
$B^+ \to X(3872)(\to \psi(2S)\gamma)K^+$	500	1k	7k	4k
$B^0 \to \psi(2S)K^-\pi^+$	340k	700k	4M	140k
$B_c^+ \to D_s^+ D^0 \overline{D}^0$	10	20	100	—
$\Lambda_b^0 \to J/\psi p K^-$	340k	700k	4M	—
$\Xi_b^- \to J/\psi \Lambda K^-$	4k	10k	55k	—
$\Xi_{cc}^{++} \to \Lambda_c^+ K^-\pi^+\pi^+$	7k	15k	90k	< 6k
$\Xi_{bc}^+ \to J/\psi \Xi_c^+$	50	100	600	—

6.4 Experimental prospects

The LHCb Upgrade II detector will have a large impact on sensitivity in searches for heavy states. Aside from the much larger integrated luminosity, many of the detector improvements planned for LHCb Upgrade II may have significant benefits for spectroscopy studies. For example, the potential removal of the VELO RF foils, together with the improved particle identification provide by the TORCH, will enhance the reconstruction efficiency for multibody B decays, such as $B_c^+ \to D_s^+ D^0 \overline{D}^0$; the selection of short-lived particles (*e.g.*, B_c^+, Ξ_{cc}, Ω_{cc}^+, Ξ_{bc}, etc) will also benefit from an improved vertex resolution; the Magnet Side Stations will help in studying di-pion transitions such as $X(3872) \to \chi_{c1}\pi^+\pi^-$ or $B_c^{**+} \to B_c^+\pi^+\pi^-$; improved π^0 and η mass resolutions will increase the sensitivity in searching for the C-odd and charged partners of the $X(3872)$ meson by $X(3872)^{C-\text{odd}} \to J/\psi\,\eta$ and $X(3872)^{\pm} \to J/\psi\,\pi^0$. A summary of the expected yields in certain important modes, and a comparison with Belle II, is given in Table 26. Below we give further details on the prospects for specific studies and analyses.

6.4.1 Taxonomy of tetraquarks and pentaquarks

To advance our understanding of the $X(3872)$ state, it will be very important to learn even more about its decay pattern. In particular, if it really has a strong $\chi_{c1}(2P)$ component, it should have $\pi^+\pi^-$ transitions to the $\chi_{c1}(1P)$ state. Unfortunately at LHCb, the reconstruction efficiency for the dominant $\chi_{c1}(1P)$ decay to $\gamma J/\psi$ decay is low, making this prediction hard to test. The very large data set of LHCb Upgrade II will allow one to overcome this problem, and will be essential in detecting or refuting such transitions. Studies of the $X(3872)$ lineshape by a simultaneous fit to all detected channels are important for pinning down the location of its resonant pole and determining its natural width; both are very important inputs in helping with the understanding of the state. Therefore a very large data set will be essential for the statistical precision of such studies and reconstruction of decays to $D^0\overline{D}^{*0}$, which are relevant given the proximity of the $X(3872)$ mass to the $D^0\overline{D}^{*0}$ threshold.

Searching for prompt production of any known exotic hadron candidates at the LHC remains an important task, since its detection would signify a compact component, either conventional quarkonium, or a tightly bound tetraquark or pentaquark. To date, the $X(3872)$ is the only exotic hadron candidate with $Q\overline{Q}$ content that has been confirmed to be produced promptly. However, it will be important to quantify the upper limits in negative searches to allow more rigorous phenomenological analysis.

Many puzzling charged exotic meson candidates (e.g., $Z(4430)^+$) decaying to J/ψ, $\psi(2S)$ or χ_{c1} plus a charged pion have been observed in B decays. Some of them are broad, and none can be satisfactorily explained by any of the available phenomenological models. The hidden-charm mesons, observed

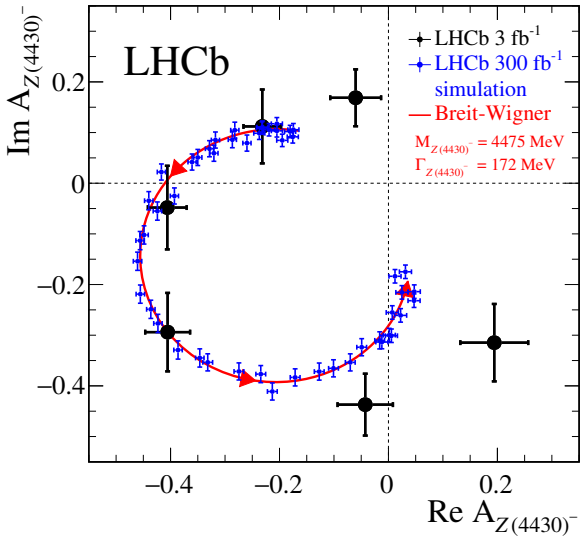

Fig. 38: Argand diagram of the $Z(4430)^-$ amplitude ($\mathrm{A}_{Z(4430)^-}$) in bins of $m^2_{\psi(2S)\pi^-}$ from a fit to the $B^0 \to \psi(2S)K^+\pi^-$ decays. The black points are the results based on Run 1 data [737] while the blue points correspond to an extrapolation to an integrated luminosity of 300 fb^{-1} expected at the LHCb Upgrade II. The red curve is the prediction from the Breit-Wigner formula with a resonance mass (width) of 4475 (172) MeV. Units are arbitrary.

in the $J/\psi\,\phi$ decay [738–740], also belong to this category. The determination of their properties, or even the claim of their existence, relies on an advanced amplitude analysis, which allows the exotic contributions to be separated from the typically dominant non-exotic components. Further investigation of these $Q\overline{Q}q\overline{q}$ structures will require much larger data samples and refinement of theoretical approaches to parametrisations of hadronic amplitudes. Similar comments apply to improvements in the determination of the properties of the pentaquark candidates $P_c(4380)^+$ and $P_c(4450)^+$ and to the spectroscopy of excited Λ baryons in $\Lambda_b^0 \to J/\psi\,pK$ decays. The large data set collected during the LHCb Upgrade II would allow one to test further the resonant character of the $P_c(4380)^+$, $P_c(4450)^+$ and $Z(4430)^+$ states (Fig. 38), while improvements in calorimetry would help in searching for new decay modes (e.g., $P_c^+ \to \chi_{c1,2}(\to J/\psi\,\gamma)p$) by amplitude analyses of $\Lambda_b^0 \to \chi_{c1,2}pK^-$ decays [657, 741].

6.4.2 *Searches for further tetra- and pentaquarks*

Though the true nature of the $X(3872)$ meson is still unclear, both the molecular [742] and tetraquark [460] models predict that a C-odd partner ($X(3872)^{C-\mathrm{odd}}$) and charged partners ($X(3872)^{\pm}$) may exist and decay to $J/\psi\,\eta/\gamma\chi_{cJ}$ and $J/\psi\,\pi^0\pi^{\pm}$ respectively.

Similarly, the existence of the $P_c(4380)^+$ and $P_c(4450)^+$ pentaquark states raises the question of whether there is a large pentaquark multiplet. The observed states have an isospin 3-component of $I_3 = +\frac{1}{2}$. If they are part of an isospin doublet with $I = \frac{1}{2}$, there should be a neutral $I_3 = -\frac{1}{2}$ state decaying to $J/\psi\,n$ [474]. However this final state does not lend itself well to observation. Instead, the search for the neutral pentaquark candidate can be carried out using decays into pairs of open charm, in particular in the process $\Lambda_b^0 \to \Lambda_c^+ D^- \overline{K}^{*0}$, where the neutral pentaquark states would appear as resonances in the $\Lambda_c^+ D^-$ subsystem (Fig. 39 left). Such decays can be very well reconstructed, but the total reconstruction efficiency suffers from the large number of tracks and the small branching fractions of Λ_c^+ and D^- reconstructable final states; the total reconstruction efficiency is about a factor 50 smaller than the efficiency for the $\Lambda_b^0 \to J/\psi\,pK^-$ channel. If there could exist pentaquarks of an isospin quadruplet,

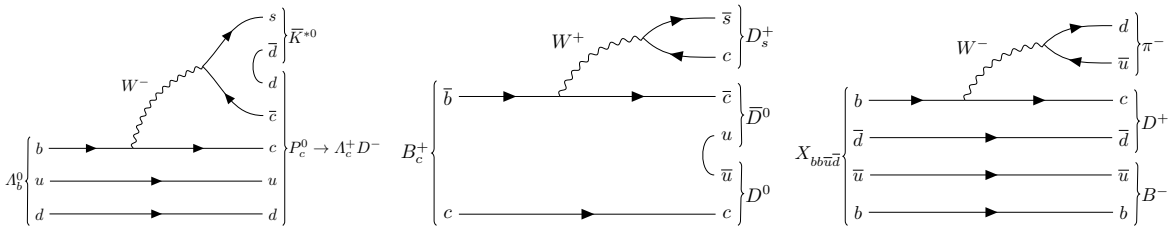

Fig. 39: Schematic Feynman diagrams for decays of $\Lambda_b^0 \to \bar{K}^{*0}\Lambda_c^+ D^-$, $B_c^+ \to D^0 \bar{D}^0 D_s^+$, and $X_{bb\bar{u}\bar{d}} \to B^- D^+ \pi^-$ (from left to right).

then there is the interesting possibility to find doubly charged pentaquarks decaying into $\Sigma_c^{++}\overline{D}^0$. Channels such as these require very large data sets to offset the low efficiency. The magnet side stations will also improve the reconstruction efficiency of such decay modes with several tracks in the final states.

The relative coupling of the pentaquark states to their decays into the double open-charm channels will depend on their internal structure and the spin structure of the respective decay. For that reason it is important to study decays involving D^{*+} resonances as well (e.g., $P_c^+ \to D^{*-}\Sigma_c^{++}$) to investigate the internal structure of pentaquarks [665]. Since these decays require the reconstruction of slow pions from the D^{*+} decays, the proposed tracking stations inside the magnet, enhancing the acceptance for low-momentum particles, will be highly beneficial for this study.

Invoking $\mathrm{SU}(3)$ flavour symmetry, one would expect the existence of pentaquarks with strangeness, which would decay into channels like $J/\psi\,\Lambda$ or $\Lambda_c^+ D_s^-$. Such states and their decays into these channels were investigated in [649, 743]. To explore the potential of the former case, the decay $\Xi_b^- \to J/\psi\,\Lambda K^-$ has been studied using Run 1 data at LHCb, with about 300 signal decays observed [744]. Complementary information can be achieved by a study of the $\Lambda_b^0 \to J/\psi\,\Lambda\phi$ decays. An increase of the available integrated luminosity by a factor of 100 would allow detailed amplitude analyses to be performed for these final states, with a similar sensitivity as was the case for the pentaquark discovery channel.

The history of $X(3872)$ studies illustrates well the difficulty of distinguishing between exotic and conventional explanations for a hidden-charm state. Therefore, it is appealing to search for states with uncontroversial exotic signatures. A good candidate in this category would be a $\mathcal{T}_{cc}$ doubly charmed tetraquark [443, 643, 696, 702–704, 745–755], being a meson with constituent-quark content $cc\overline{q}\overline{q}'$, where the light quarks q and q' could be u, d or s. If the masses of the doubly charmed tetraquarks are below their corresponding open-charm thresholds, they would manifest as weakly decaying hadrons with properties including masses, lifetimes and decay modes not too different from the recently observed Ξ_{cc}^{++} baryons [756], and, as for the Ξ_{cc} baryons, the most promising searches are in prompt production. Instead, if the masses of $\mathcal{T}_{cc}$ states are above the open-charm threshold and their widths are broad, it will be very challenging to observe these states via prompt production. Instead, B_c^+ decays to open-charm mesons can offer unique opportunity to test for their existence. In Run 5 the B_c^+ mesons will be copiously produced at the LHC, because of the large production cross-sections of $b\bar{b}$ and $c\bar{c}$ pairs and of the enormous data sample. Similarly to the amplitude analysis of the $\Lambda_b^0 \to J/\psi\,pK^-$ decay, which led to the observation of the P_c^+ pentaquark candidates [757], studying the angular distributions of the multi-body final states of the B_c^+ meson has the potential of indicating new states, e.g., $\mathcal{T}_{cc}$, inaccessible through decays of lighter hadrons. It also allows for the determination of the spin-parity quantum numbers of any state that is observed. A good example is to study the $\mathcal{T}_{cc}^+$ state in the decay mode $B_c^+ \to D_s^+ D^0 \overline{D}^0$ (Fig. 39 middle) through the decay chain $B_c^+ \to \mathcal{T}_{cc}^+ \overline{D}^0$ and $\mathcal{T}_{cc}^+ \to D_s^+ D^0$, as discussed in Ref. [702].

The decay $B_c^+ \to D_s^+ D^0 \overline{D}^0$ has not been observed with the Run 1 data, and predictions on the branching fractions of B_c^+ decays are subject to very large uncertainties. Estimates of the integrated luminosity needed to perform a full amplitude analysis are therefore imprecise, and can only be formulated through considerations of other decay modes such as $B_c^+ \to J/\psi\,D_s^+$. The signal yield of $B_c^+ \to J/\psi\,D_s^+(\to \phi\pi^+)$ decays observed in Run 1 data is 30 ± 6 [758]. Considering the branching

fraction of the decay of the additional charm hadron and the lower efficiency due to the higher track multiplicity, the estimated number of signal of $B_c^+ \to D_s^+ D^0 \overline{D}^0$ decays is $\mathcal{O}(10^2)$ in a future dataset corresponding to an integrated luminosity of 300 fb^{-1}, collected with $\mathcal{O}(100\%)$ trigger efficiency [758]. Since the D^0 and D_s^+ mesons are pseudoscalars, the amplitude analysis simplifies, and can provide conclusive results already with a few hundred decays.

Finally, strongly decaying doubly charmed tetraquarks with a narrow decay width, as predicted by pure tetraquark models with spin-parity quantum numbers of 0^+, 1^+ and 2^+, can also be searched for in prompt production. The expected yields can be estimated by the associated production of open-charm mesons measured with a fraction of the Run 1 data [759]. With a data sample of 300 fb^{-1}, the yield for D^+D^+ ($D^+D_s^+$) associated production is around 750k (150k), which is a very promising sample in which to search for narrow $\mathcal{T}_{cc}$ states.

If the coincidence of the $\chi_{c1}(2P)$ charmonium state with the $D^0\overline{D}^{*0}$ threshold is responsible for the $X(3872)$ state, there is likely no bottomonium analogue of it, since the $\chi_{b1}(3P)$ state was detected well below the $B\overline{B}^*$ threshold, and the $\chi_{b1}(4P)$ state is predicted to be too far above it. However, if molecular forces dominate its dynamics, there could be an isosinglet state below this threshold decaying to $\omega\Upsilon(1S)$, where ω could be reconstructed via the decay to $\pi^+\pi^-\pi^0$. Unfortunately, its prompt production would likely be very small unless driven by tightly bound tetraquark dynamics or by the $b\bar{b}$ Fock-state component of the same quantum numbers [597]. The improved π^0 reconstruction in the LHCb Upgrade II will help for these searches.

The prompt production at the LHC remains the best hope for unambiguously establishing the existence of a stable, weakly decaying $bb\bar{u}\bar{d}$ tetraquark predicted by both lattice QCD and phenomenological models. However, the inclusive reconstruction efficiencies for such states are tiny due to the small branching fractions of B and D meson decays to low-multiplicity final states (Fig. 39c). Recently, there have been also several predictions for an exotic state with quark composition $b\bar{b}b\bar{b}$ [711–721] with a mass below the $2m_{\eta_b}$ threshold, which implies that it can decay to $\Upsilon\mu^+\mu^-$. However, lattice QCD calculations do not find evidence for such a state in the hadron spectrum [710]. Given the presence of four muons in the final state, LHCb will have good sensitivity for observing the first exotic state composed of more than two heavy quarks [760].

Motivated by the discovery of the hidden-charm pentaquarks, theorists have extended the respective models for multiplet systems to include beauty quarks. In Ref. [668] $Q\overline{Q}qqq$ ground states were investigated in an effective-Hamiltonian framework assuming a colour-magnetic interaction between colour-octet qqq and $Q\overline{Q}$ subsystems. Several resonant states are predicted. Such beautiful pentaquarks could be searched for in the Υp, $\Upsilon\Lambda$, $B_c^\pm p$ and $B_c^\pm\Lambda$ mass spectra. In analogy with the popular $\Sigma_c\overline{\Lambda}_c^-$ molecular model, Refs. [669] and [670] investigate similar dynamics in the hidden-bottom sector and predict a large number of exotic resonances. Indeed, in the hidden-beauty sector the theory calculations are found to be even more stable than for hidden charm, motivating searches for resonances close to the $B^*\Sigma_b$, $B\Sigma_b^*$, $B^*\Sigma_b^*$ and $B\Lambda_b^{*0}$, $B^*\Lambda_b^0$ thresholds.

Another possibility is the existence of pentaquarks with open beauty and quark contents such as $\bar{b}duud$, $b\bar{u}udd$, $b\bar{d}uud$ and $\bar{b}suud$ [761, 762]. If those states lie below the respective baryon-meson thresholds containing beauty, then they could be stable against strong decay and would predominantly decay through the weak transition $b \to c\bar{c}s$. A search using a 3 fb^{-1} data set in four decay channels $J/\psi p h^+ h^-$ (h = K, π) has been performed in Ref. [763]. No signals were found and 90% CL limits were set on the production cross section times branching fraction relative to the Λ_b^0 in the $J/\psi pK^-$ mode. The obtained limits are of the order of 10^{-3}, which does not yet rule out the estimates for the production of such an object provided in Ref. [761]. Similar searches in channels with open-charm hadrons in the final state again lead to large multiplicities and the respective small reconstruction efficiencies, but could profit from favoured branching fractions. Investigations of a large number of channels will maximise sensitivity for weakly decaying exotic hadrons. It has also been proposed to search for excited Ω_b^- states [561] in analogy to the recently discovered excited Ω_c^0 states [764]. Such open-beauty excited

states could be searched for in decays to the $\Xi_b K$ final state.

6.4.3 Study of doubly-heavy baryons

The discovery of the Ξ_{cc}^{++} baryon has opened an exciting new line of research that LHCb is avidly pursuing. Measurements of the lifetime and relative production cross-section of Ξ_{cc}^{++}, searches for additional decay modes, and searches for its isospin partner Ξ_{cc}^{+} and their strange counterpart Ω_{cc}^{+} are underway.

A signal yield of 313 ± 33 $\Xi_{cc}^{++} \to \Lambda_c^+ K^- \pi^+ \pi^+$ decays was observed by LHCb in $1.7\,\text{fb}^{-1}$ of Run 2 data [756]. Improvements in the trigger for the LHCb Upgrade II detector are projected to increase selection efficiencies by a factor two for most charm decays, with decays to high-multiplicity final states, such as those from the cascade decays of doubly charmed baryons, potentially benefiting much more [765, 766]. Thus the Run 5 sample will contain more than 90 000 decays of this mode. The branching fraction for $\Xi_{cc}^{++} \to \Lambda_c^+ K^- \pi^+ \pi^+$ is theoretically estimated to be up to 10%, making it one of the most frequent nonleptonic decay modes. Several other lower multiplicity modes with $\mathcal{O}(1\%)$ predicted branching fractions will yield samples of comparable size [295, 681, 767, 768].

The efficiency with which LHCb can disentangle weak decays of doubly charmed baryons from prompt backgrounds depends on the lifetime of the baryon [769]. Although the predicted lifetimes for the Ξ_{cc}^{+}, Ξ_{cc}^{++}, and Ω_{cc}^{+} baryons span almost an order of magnitude, the relative lifetimes of Ξ_{cc}^{+} and Ω_{cc}^{+} are expected to be approximately $1/3$ that of the Ξ_{cc}^{++} baryon [674, 679, 770–775]. Assuming a relative efficiency of 0.25 with respect to Ξ_{cc}^{++} due to the shorter lifetimes and an additional production suppression of $\sigma(\Omega_{cc}^{+})/\sigma(\Xi_{cc}^{++}) \sim 0.2$ for Ω_{cc}^{+} [674], LHCb will have Run 5 yields of around 25 000 for Ξ_{cc}^{+} and 4500 for Ω_{cc}^{+} in each of several decay modes.

LHCb will be the primary experiment for studies of the physics of doubly charmed baryons for the foreseeable future, and its potential will not be exhausted by the end of Run 5. With the data collected in Run 2, LHCb should observe all three weakly decaying doubly charmed baryons and characterise their physical properties. Run 5 will supply precision measurements of doubly differential cross sections that will provide insight into production mechanisms of doubly heavy baryons. In addition Run 5 will allow the spectroscopy of excited states and bring studies of the rich decay structure of doubly charmed hadrons into the domain of precision physics.

The production cross section of the Ξ_{bc} baryons within the LHCb acceptance is expected to be about 77 nb [776]. This value is about 1/6 of the expected production cross-section of a B_c^+ meson [777, 778]. It should be noted that the relative Λ_b^0 production rate is $p_{\rm T}$-dependent. In the typical $p_{\rm T}$ range in the LHCb acceptance, a ratio of production rates, $\sigma(pp \to \Lambda_b^0 X)/\sigma(pp \to \overline{B}^0 X) \sim 0.5$ [779, 780] is measured. It is therefore conceivable that the Ξ_{bc} production rates are also larger than predicted by the above calculations.

It is quite challenging to observe and study Ξ_{bc} and Ω_{bc}^0 baryons because of the low production rates, the small product of branching fractions and the selection efficiencies for reconstructing all of the final-state particles. To collect a large sample of Ξ_{bc} baryons will require the higher integrated luminosity and detector enhancements planned for in the LHCb Upgrade II. Using the notation that X_c is a charmed baryon containing a single charm quark, some of the most promising decay modes to detect Ξ_{bc} and Ω_{bc}^0 baryons are: *(i)* $J/\psi\, X_c$ modes $J/\psi\, \Xi_c^+$, $J/\psi\, \Xi_c^0$, $J/\psi\, \Lambda_c^+$, $J/\psi\, \Lambda_c^+ K^-$; *(ii)* Ξ_{cc} modes $\Xi_{cc}\pi^-$; *(iii)* doubly charmed modes $D^0 \Lambda_c^+$, $D^0 \Lambda_c^+ \pi^-$, $D^0 D^0 p$; *(iv)* penguin-topology modes $\Lambda_c^+ K^-$, $\Xi_c^+ \pi^-$; *(v)* the Ξ_b , B^0 or Λ_b^0 modes $\Xi_b \pi^+$, $\Lambda_b^0 \pi^+$, $B^0 p$, using fully reconstructed or semileptonic B^0, Λ_b^0 or Ξ_b decays [781]; *(vi)* the decays due to W-exchange between b-c quarks, that is not helicity suppressed, and which can give rise to a final state with just one charmed particle, *e.g.*, $\Lambda_c^+ K^-$.

To put this in context, the LHCb collaboration observed 30 ± 6 $B_c^+ \to J/\psi\, D_s^+ (\to \phi\pi^+)$ decays with $3\,\text{fb}^{-1}$ data at 7 and 8 TeV [758]. With looser selections about 100 signal decays can be obtained with reasonably good signal-to-background ratio. The $\Xi_{bc}^+ \to J/\psi\, \Xi_c^+$ decay is kinematically

very similar. Assuming $f_{\Xi_{bc}^+}/f_{B_c^+} \sim 0.2$, with $\mathcal{B}(\Xi_{bc}^+ \to J/\psi\,\Xi_c^+)/\mathcal{B}(B_c^+ \to J/\psi\,D_s^+) \sim 1$, while $\mathcal{B}(\Xi_c^+ \to pK^-\pi^+)/\mathcal{B}(D_s^+ \to K^+K^-\pi^+) \sim 0.1$, and $\epsilon_{\Xi_{bc}^+}/\epsilon_{B_c^+} \sim 0.5$, a signal yield of about 600 $\Xi_{bc}^+ \to J/\psi\,\Xi_c^+$ decays is expected in Run 5, albeit with sizeable uncertainties. Other modes could also provide sizeable signal samples. It is likely LHCb will observe the Ξ_{bc} baryons in Run 3/4, and further probe the spectrum of other doubly heavy baryons with the large samples accessible in the proposed Upgrade II.

6.4.4 Precision measurements of quarkonia

The correct interpretation of the experimental polarisation results for S-wave quarkonia requires a rigorous analysis of the feed-down contributions from higher excited states [782, 783]. The direct measurement of the polarisation for χ_c and χ_b states is necessary to decrease this model dependence. Since P-wave states are practically free from the feed-down from higher excited states, any χ_c and χ_b polarisation measurements could be interpreted in a robust manner without additional model assumptions.

The recent discovery of the $\chi_{c1,2} \to J/\psi\,\mu^+\mu^-$ decays [784] opens the possibility to perform a detailed study of χ_c production, allowing almost background-free measurements even for a very low transverse momentum of χ_c candidates. Due to the excellent mass resolution, the vector state χ_{c1} and the tensor state χ_{c2} are well separated, eliminating the possible systematic uncertainty caused by the large overlap of these states in the $\chi_c(\chi_b) \to J/\psi\,(\Upsilon)\gamma$ decay [782, 783, 785–788]. An integrated luminosity of 300 fb^{-1} will allow one to probe the high-multipole contributions to the $\chi_c \to J/\psi\,\mu^+\mu^-$ amplitude, namely the magnetic-dipole contribution for χ_{c1} decays and the magnetic-dipole and electric-octupole contributions for χ_{c2} decays. Use of the Run 5 data set is also necessary to measure the $(p_{\rm T}, y)$ dependence of χ_c polarisation parameters. In addition, the effect of the form factor in the decays $\chi_c \to J/\psi\,\mu^+\mu^-$ [789, 790] could be probed with the precision of several percent from the shape of the $m(\mu^+\mu^-)$ spectra.

Studies of double quarkonia production allows independent tests for the quarkonia production mechanism, and in particular for the role of the colour octet. So far the LHCb collaboration has analysed double-J/ψ production in 7 TeV and 13 TeV data with relatively small datasets [791, 792]. Using 280 pb^{-1} of data collected at $\sqrt{s} = 13$ TeV, $(1.05 \pm 0.05) \times 10^3$ signal $J/\psi\,J/\psi$ events are observed. However, even with the larger sample of $J/\psi\,J/\psi$ events now available, it is not possible to distinguish between different theory descriptions of the single-parton scattering (SPS) mechanism [793–801], nor to separate the contributions from the SPS and double-parton scattering (DPS) mechanisms [802, 803]. Though the larger samples collected during Runs 3 and 4 will allow some progress on these questions, the measurement of the correlation of J/ψ polarisation parameters will only be possible with the Upgrade II data set.

In addition, while it is likely that $\Upsilon\Upsilon$ and $J/\psi\,\Upsilon$ production will be observed in the near future (assuming the dominance of the DPS mechanism), the determination of the relative SPS and DPS contributions, as well as the discrimination between different SPS theory models, will require precision measurements only possible with Run 5 data.

7 Bottom-quark probes of new physics and prospects for B-anomalies

A key contribution of the HL-LHC data sets will be a comprehensive global picture of rare and (semi)-leptonic quark transitions. This has value whether or not the current "flavour anomalies" are confirmed with Run 2 or Run 3 LHC data. If the improvements on statistically limited observables, $R_{K^{(*)}}$ and $R(D^{(*)})$, confirm the anomalies, a global analysis of all related channels may discriminate between different BSM explanations. Such a global analysis will also help to constrain the mass scale of the BSM particles and mediators, which, together with the direct HL-LHC searches, will further restrict the range of possible explanations for the anomalies. On the other hand, if the signifcance of the anomalies decreases, or they even disappear with Run 2 and Run 3 data, we should still search for small BSM effects on top of the dominant SM amplitudes. In this case, global analyses of the data would lead to improved bounds on the BSM affecting these flavor observables. The statistical power of the HL-LHC datasets will also enable a unique reach for other BSM signatures such as Lepton-Flavour Violation (LFV) and Baryon-Number Violation (BNV), particularly in the baryon and heavy-meson sectors.

We would like to stress that, in the HL-LHC era, many rare beauty decays will become abundant and enter the precision-measurement regime. Therefore, it will become increasingly important that the LHC collaborations and Belle II publish results in such a way that systematic uncertainties can be treated in a coherent manner and their correlations taken into account. A good example of this is the treatment of the ratio of hadronization fractions f_s/f_d in any LHC $B_q \to \ell\ell$ combination, discussed in Sec. 7.3. It will also be important to correctly treat systematic uncertainties due to the use of common software packages, e.g., the use of `PHOTOS` by the LHC experiments and Belle II, in future lepton universality measurements.

While much of the power of the HL-LHC and Belle II datasets will lie in the breadth of precisely measured rare and (semi-)leptonic decays, practical considerations mean that experiments will continue to publish analyses of individual decay modes as each is completed. Systematically publishing experimental likelihoods, efficiency maps, and resolution unfoldings, as already done for some of the most important analyses, should be strongly encouraged even now. This facilitates both the combination of results between experimental collaborations, and the inclusion of the results in global fits and in tests of phenomenological models [804–806].

7.1 Phenomenology of $b \to s\ell\ell$ decays

Authors (TH): Wolfgang Altmannshofer, David Straub, Javier Virto.

In this section we discuss the status of the interpretation of $b \to s$ transitions in and beyond the SM, the prospects for future sensitivities at the LHC, and the complementarity with Belle-II. All current and planned measurements of processes involving $b \to s$ transitions are related to weak decays of b-hadrons. At present, most of the data is on B decays, with a smaller fraction on B_s decays. LHCb has already provided a few measurements on Λ_b decays, with data sets that will increase dramatically in future runs, including a significant output on decays of other b-hadrons such as Ω_b or Ξ_b [807] (see Sec. 7.3).

Theoretically, the decays of b-hadrons are best described within the Weak Effective Theory (WET), where flavor-changing transitions are mediated by "effective" dimension-six operators with Wilson coefficients (WCs) that encapsulate all SM and heavy NP effects. Thus all observables can be calculated in full generality, model-independently in terms of the WCs and hadronic matrix elements. The relevant effective Lagrangian for $b \to s$ transitions at low-energies in the SM is [808]

$$\mathcal{H}_{\text{eff}}^{\text{SM}} = \frac{4G_F}{\sqrt{2}} \sum_{p=u,c} \lambda_{ps} \left(C_1 O_1^p + C_2 O_2^p + \sum_{i=3}^{10} C_i O_i \right), \tag{83}$$

with $\lambda_{ps} = V_{pb} V_{ps}^*$. As defined in Ref. [808], the $O_{1,2}^p$, $O_{3,\ldots,6}$, and O_8 are the so-called "current-current", "QCD-penguin" and "chromo-dipole" operators, respectively, and they contribute to the $b \to s\gamma$ and $b \to$

$s\ell\ell$ transitions via an electromagnetic interaction. The $O_{7\gamma}$ and $O_{9,10}$ are the "electromagnetic dipole" and the "semileptonic" operators, respectively. The BSM can enter through the WCs $C_1, \ldots, C_{10}$, or the chirally-flipped versions, $P_{L(R)} \to P_{R(L)}$, giving $O'_{7\gamma,\ldots,10}$, or through scalar and tensor semileptonic operators [809]. Furthermore, beyond the SM, semileptonic operators can induce lepton-flavor universality violation (LFUV) or charged-lepton flavor violation (CLFV). For the purpose of this Section, the relevant operators for the interpretation of $b \to s\gamma$ and $b \to s\ell\ell'$ data are

$$\begin{aligned} O_{7\gamma}^{(\prime)} &= \frac{e\, m_b}{16\pi^2}(\bar{s}\sigma_{\mu\nu}P_{R(L)}b)F^{\mu\nu}, \\ O_9^{\ell\ell'(\prime)} &= \frac{\alpha_{\rm em}}{4\pi}(\bar{s}\gamma_\mu P_{L(R)}b)(\bar{\ell}\gamma^\mu \ell'), \qquad O_{10}^{\ell\ell'(\prime)} = \frac{\alpha_{\rm em}}{4\pi}(\bar{s}\gamma_\mu P_{L(R)}b)(\bar{\ell}\gamma^\mu\gamma_5 \ell'), \end{aligned} \tag{84}$$

where we have added leptonic flavor labels ($C_i^\ell \equiv C_i^{\ell\ell}$).

By calculating and measuring a large set of independent observables, one can perform global fits to all the relevant WCs, and by comparing with their SM values, extract information on NP model-independently. This programme has been carried out since the start of the LHC, and culminated in the current $b \to s\ell\ell$ anomalies [810–820]. The future runs of the LHC will allow either to establish the anomalies or to refine our understanding of these transitions.

7.1.1 Observables and Hadronic Matrix Elements

7.1.1.1 $B_q \to \ell^+\ell^-$

From a theoretical perspective the purely leptonic decay, $B_s \to \ell^+\ell^-$, is the cleanest exclusive $b \to s\ell\ell$ process. Up to QED corrections [821], all QCD effects are contained in a decay constant, which is precisely and reliably computed using lattice QCD, giving $f_{B_s} = 230.7(1.3)$ MeV [822]. [6] Going beyond this accuracy in f_{B_s} is difficult (see Sec. 11), and the current theoretical error is less than 5% [821, 822],

$$\mathcal{B}(B_s \to \mu^+\mu^-)_{\rm SM} = (3.64 \pm 0.11) \cdot 10^{-9}, \tag{85}$$

which is dominated by the uncertainties of the relevant CKM parameters. The latest measurements by LHCb and ATLAS [15, 825], have an error of $\sim 25\%$ (see Sec. 7.3 for HL-LHC prospects). Beyond the SM, the decay $B_s \to \mu^+\mu^-$ gives very strong constraints on the scalar and pseudoscalar operators [826, 827], and also on $C_{10}^{\mu(\prime)}$, which has an impact on the fits and the $b \to s\mu\mu$ anomalies. Searches for the CLFV channels $B_s \to \tau\mu$ and $B_s \to \mu e$ are important, because an observation would be an unambiguous signal of NP, which can be connected to the LFUV signals in $R_{K^{(*)}}$ [337, 339, 341, 828, 829]. Besides the branching fractions, an effective lifetime observable and the CP-violating observable $S_{\mu\mu}$ are accessible by exploiting the nonvanishing width difference, $\Delta\Gamma_s$, in the B_s system [320, 830]. This provides complementary constraints on the WCs [831], and a precise measurement will be possible at the LHCb.

These measurements are simultaneously sensitive to the decay $B_d \to \mu^+\mu^-$, although its branching fraction is further suppressed by a CKM factor [822, 832],

$$\mathcal{B}(B_d \to \mu^+\mu^-)_{\rm SM} = (1.00 \pm 0.03) \cdot 10^{-10}. \tag{86}$$

The ratio $\mathcal{B}(B_s \to \mu^+\mu^-)/\mathcal{B}(B_d \to \mu^+\mu^-)$ can be predicted more accurately in the SM and models with Minimal-Flavor Violation (MFV) than the single branching ratios, testing the flavor structure of the short-distance dynamics. In particular, it is related to the ratio $\Delta m_s/\Delta m_d$ [833] with small uncertainties from hadronic inputs and none from CKM ones. A similar comment applies to the ratios $\mathcal{B}(B_q \to$

[6] The average of lattice $N_f = 2 + 1$ results from FLAG 2016 [66] and other recent $N_f = 2 + 1 + 1$ lattice calculations of the decay constant [823, 824] give similar central values but with larger errors.

$\mu^+\mu^-)/\Delta m_q$ [833]. It is important to emphasize that the measurements of $\mathcal{B}(B_d \to \mu^+\mu^-)$ that can be done at the LHC are of utmost importance as they cannot be done in any other facility in the coming decade.

Finally, the $m_{\mu^+\mu^-}$ spectrum is sensitive to the decay $B_s \to \mu^+\mu^-\gamma$ (where the photon is not detected) [834]. Theoretically, this mode is interesting because the extra photon lifts the chiral suppression of the leptonic mode and gives access to the WC C_9^μ. However, it is also challenging to predict because of long-distance hadronic contributions [835].

7.1.1.2 $B_q \to M\ell^+\ell^-$

The most prominent semileptonic decay modes are $B \to K^{(*)}\mu^+\mu^-$ and $B_s \to \phi\mu^+\mu^-$. These are sensitive to all the WCs and they currently dominate the global fits to $b \to s\ell\ell$ data because of the experimental precision achieved and the large number of observables they give access to. This allows one to constrain some independent combinations of WCs and hadronic parameters. Since there is no experimental information related to the polarization of the final-state leptons, the measurable observables arise from the kinematic differential distributions of the final-state momenta. These are customarily written as angular distributions with coefficients that depend on the dilepton invariant mass squared q^2, measured in specific bins of q^2.

In the case of the three-body mode $B \to K\mu^+\mu^-$, there are three observables: the differential branching fraction, $d\mathcal{B}/dq^2$, the forward-backward asymmetry, $A_{\rm FB}(q^2)$, and the "flat term", $F_H(q^2)$ [809]. The kinematic distribution of the four-body decay, $B \to V(\to M_1M_2)\ell^+\ell^-$, contains many more independent angular coefficients, up to 11 in the most general case (plus the total rate), called $I_i(q^2)$ or $J_i(q^2)$ [836–838]. Normalizing these by the total differential rate $d\Gamma/dq^2$ and symmetrizing or antisymmetrizing with respect to the two charge-conjugate modes leads to the observables S_i, A_i [837]. A subset of these observables can also be constructed for $B_s \to \phi\mu^+\mu^-$ [839]. It is convenient to define certain combinations of angular observables where form-factor uncertainties largely cancel in the heavy-quark limit, called "optimized observables". An independent set of these, optimized at low-q^2, is given by the $P_i^{(\prime)}$ basis [838, 840, 841]. Optimized observables at large-q^2 also exist [841, 842].

The observables in exclusive semileptonic decays, $B \to M\ell^+\ell^-$, are specified by transversity (or helicity) amplitudes. They depend on two types of hadronic matrix elements: "local" (form factors) and "non-local" (see, e.g., [843–845]). Local form factors for $B \to K$, $B \to K^*$ and $B_s \to \phi$ transitions can be calculated at low-q^2 in two different versions of light-cone sum rules (LCSRs) [846–849], and at large-q^2 using Lattice QCD [850, 851] (LQCD). A comparison between both determinations can be done by parametrizing the q^2 dependence via the z-expansion [852–854], which is based on the analytic structure of the matrix elements. Future prospects for the theoretical precision of the form factors rely on improvements in LQCD calculations. Note that both LQCD and LCSRs work in the narrow-width limit for vector mesons. A calculation beyond this approximation is possible within the LCSRs [855, 856], and points to a correction of up to 10%. There are prospects for treating hadronic resonances on the lattice [857], and calculating directly the $B \to K\pi$ form factors should play an important role in the next decade.

Non-local effects are significantly more difficult to estimate [858–860]. Data-driven methods might be able to reduce the uncertainties on these hadronic contributions and will benefit significantly from the high statistics collected by LHCb in the HL phase. All of these methods are based on precise measurements of the q^2 spectra in conjunction with a theoretically motivated parametrization of the q^2 dependence of the amplitudes and a theory benchmark that allows one to separate short-distance contributions from long-distance contributions.

At low q^2, the theory input is based on the light-cone Operator Product Expansion (OPE) at very low (or negative) q^2 [858, 859], an expansion that breaks down at the perturbative $c\bar{c}$ threshold $q^2 \simeq 4m_c^2$. Parametrizations of the q^2 dependence are based on a Taylor expansion in powers of q^2 [819, 844] or on

dispersion relations [859] such as in the z-expansion [845]. The latter two parametrizations implement analyticity constraints and use extra information, such as data on (or in between) the $B \to \psi K^*$ decays, with $\psi = \{J/\psi, \psi(2S)\}$. Short- and long-distance effects are disentangled by the experimental input from $B \to \psi K^*$, the fixed q^2 dependence of the NP contribution, and by the theory constraints at negative q^2. The experimental prospects for this data-driven approach were studied in [861], showing that future LHC data could provide a higher level of control over the long-distance contribution at low q^2.

At high q^2, the theory input is based on the low-recoil OPE [842, 860, 862]. This method relies on the theoretical assumption that resonant effects from "above-threshold" charmonia average out within sufficiently broad q^2 bins ("quark-hadron duality"). Thus, only a single bin in the whole high-q^2 region is typically considered in the global fits. The q^2 spectrum can be used to give estimates and test models of the intrinsically nonperturbative "duality-violating" effects. Currently, these analyses are carried out within the "Krüger-Sehgal" (naive factorization) approach [863], which allows one to use data on the $R(s)$ ratio in e^+e^- annihilation [860, 864, 865]. Ref. [865] uses all currently available data on $B \to K^*\mu^+\mu^-$ at low recoil and finds agreement with the OPE within $\sim 20\%$ in all the bins. Notably, future precision data from the LHC with the expected fine binning will be essential in refining these data-driven methods and to disentangle NP contributions. As in the low-q^2 case, combined fits to hadronic parameters and NP are also beneficial [865].

Hadronic uncertainties largely cancel in the SM in lepton-universality ratios such as $R_{K^{(*)}}$ [866],

$$R_{K^{(*)}} = \frac{\mathcal{B}(B \to K^{(*)}\mu^+\mu^-)}{\mathcal{B}(B \to K^{(*)}e^+e^-)}. \tag{87}$$

The SM predictions are thus limited only by the size of the electromagnetic corrections [867]. Current LHCb measurements show tensions with the SM in R_K [868] and in two bins of R_{K^*} [869] at approximately $\sim 2.5\,\sigma$ each. Much higher precision will be achieved with future data at LHCb [807]. and, independently, with Belle-II, which can confirm R_K at $5\,\sigma$ with $20\,\text{ab}^{-1}$ [196] at the current experimental central value. In the presence of LFUV contributions the predictions are less precise and "optimized" observables based on angular analyses of muonic and electronic modes can improve the sensitivity to different BSM scenarios [870, 871]. In fact, LFUV and CLFV can be connected, and decays such as $B \to K^{(*)}\tau\mu$ and $B \to K^{(*)}\mu e$ become clear targets for the HL-LHC. Semitauonic decays $B \to K^{(*)}\tau^+\tau^-$ are very challenging at the LHC but theoretically interesting because their branching fractions can receive enhancements of several orders of magnitude in BSM [341, 872] (see also [873] and [874]). Assuming that the LFUV anomalies persist and the BSM contributions are in the muonic WCs, as the global fits to $b \to s\mu\mu$ currently suggest, one can use future precise and fine-binned measurements in $b \to se^+e^-$ exclusive modes to fit the hadronic parameters directly [875].

Other measurements with potential impact on the $b \to s\ell\ell$ fits will be possible at the HL-LHC. The LHC experiments have a unique opportunity to measure the $\Lambda_b \to \Lambda\mu^+\mu^-$ decays [186], probing the $b \to s\mu^+\mu^-$ transition in a baryonic system [876–878]. For $B_s \to \phi\mu^+\mu^-$, a flavor-tagged time-dependent analysis allows one to access independent observables [879] sensitive to BSM. The expected sensitivity to the B_s and Λ_b decay measurements will make it possible to extend the global fit programme, outlined above, to these modes. Finally, the study of exclusive $b \to d\mu^+\mu^-$ transitions will reach the level of precision we have now in $b \to s\mu^+\mu^-$ (see Sec. 7.3). This will allow one to extend the programme of the global fits to $b \to d\mu^+\mu^-$ transitions, setting constraints in a different flavor sector or, if the $b \to s\ell\ell$ anomalies remain, to give further insights on the BSM flavour structure. The $b \to d\mu^+\mu^-$ modes are theoretically more challenging than their $b \to s\ell\ell$ counterparts, since new large long-distance contributions appear at low q^2, e.g., in the form of light resonances [880].

7.1.1.3 Radiative decays: $B_s \to \phi\gamma$ and related modes

Radiative decays are obvious probes of the electromagnetic dipole operators. Strategies to determine with these decays the helicity of the photon (and therefore the presence of BSM WC $C'_{7\gamma}$ have intensively been investigated [881–886]. Approaches based on the CP-averaged exclusive decay rates are prone to hadronic uncertainties and depend quadratically on $C'_{7\gamma}$ [885–887]. In contrast, interference between helicity amplitudes of the $B^0_{(s)}$ and $\bar{B}^0_{(s)}$ decays is directly sensitive to the photon polarization. This can be measured by constructing time-dependent CP-asymmetries in $B \to V\gamma$ (the $S_{V\gamma}$ observable), or those induced by the width-differences $\Delta\Gamma_q$, shown to be clean null tests of the SM [881, 888]. Experimentally, $S_{K^*\gamma}$ has been measured in the B-factories [889, 890], while a measurement of the width-difference effects has been achieved at LHCb [891]. Prospects in the HL-LHC include reaching a few-percent precision in this observable, which will provide a strong constraint on the chirality of the electromagnetic dipole operators.

The $B \to K^{(*)}\ell^+\ell^-$ decays are also sensitive to the interference of the two helicities through the angular observables P_1 (also called $A_{\rm T}^{(2)}$) and P_3^{CP} close to the photon pole $q^2 \simeq 0$, region where these observables are particularly clean from hadronic uncertainties [844]. Thus, the electronic mode is especially suited for these measurements, providing a theoretically clean window to right-handed currents beyond the SM. This has been measured by LHCb with a $\sim 20\%$ precision with data of Run 1 [892] and will be improved to a few-percent precision in the HL-LHC.

7.1.1.4 Interplay with Belle-II: Inclusive B decays and $B_q \to M\nu\bar{\nu}$

Apart from contributing to the above-mentioned measurements [196], Belle-II will also measure decays which are very challenging in the LHC environment. This comprises inclusive decays and the $b \to s\nu\bar{\nu}$ transitions. The inclusive observables used in the current fits are $\mathcal{B}(B \to X_s\gamma)$ and $\mathcal{B}(B \to X_s\ell^+\ell^-)$. Belle-II will improve these, including precise measurements of the forward-backward asymmetry in $B \to X_s\ell^+\ell^-$, which will impact the fits [196]. In particular, Belle-II measurements of $B \to X_s\mu^+\mu^-$ will be able to test the LHCb anomalies independently by 2024 [196]. Theoretically, these inclusive rates can be calculated perturbatively in terms of the partonic decay of the b quark up to small non-perturbative effects [893, 894]. These include local power corrections, non-local shape function-like effects, and additional contributions to the absence of an OPE for some operator insertion. The latter effects represent irreducible uncertainties which cannot be removed by relaxing the experimentally necessary cuts in the hadronic mass spectrum [894]. Calculations of both rates have been done with high accuracy [895, 896]. The exclusive decays $B \to K^{(*)}\nu\bar{\nu}$ and related modes [897], on the other hand, depend only on local form factors. Belle-II is expected to provide measurements of these modes with an uncertainty of about 10%, assuming the rates are SM-like [196]. These decays do not probe directly the WCs entering the $b \to s\nu\bar{\nu}$ transitions. However, they can be correlated through $SU(2)_L$ gauge invariance in the SMEFT if the BSM is realized above the EW scale, and direct correlations are obtained in specific models of NP (see e.g. [341, 898]).

7.1.2 Model-Independent Fits

Existing measurements show hints of deviations from the SM expectations in three different classes of measurements: in $B \to K^*\mu^+\mu^-$ angular observables [899], in branching fractions of exclusive $b \to s\mu^+\mu^-$ decays (in particular $B_s \to \phi\mu^+\mu^-$ [900]), and in μ-e universality (LFU) tests [5, 6]. None of the individual measurements is in tension with the SM by more than 4σ. However, a global significance of the tensions can be defined in a specific framework of NP, such as the model-independent framework provided by the weak effective Hamiltonian.

Several groups have performed global fits of the WCs to existing $b \to s\ell\ell$ data (see [815–820, 827] for recent fits). Three classes of fits can be distinguished: fits to $b \to s\mu\mu$ data only, fits to μ-e LFU ratios only, and combined fits assuming no NP in $b \to see$ transitions. All these fits agree – up to differences

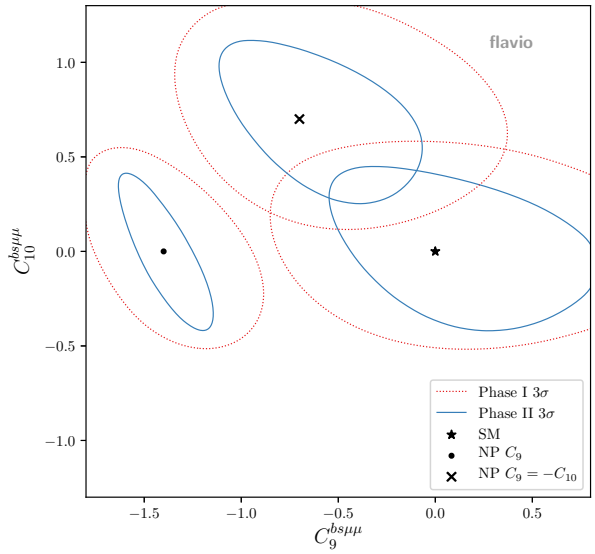

Fig. 40: Potential sensitivity to the SM and to NP scenarios motivated by the anomalies of LHCb, ATLAS and CMS combined after the HL-LHC phase. These scenarios are $C_9 = -1.4$ (vector current) and $C_9 = -C_{10} = -0.7$ (pure left-handed current). The observables included are the branching fraction of $B_s \to \mu^+\mu^-$ and the angular observables of the decay $B^0 \to K^{*0}\mu^+\mu^-$ in the low-q^2 region (e.g., P_5'). To produce the P_5' expectation for ATLAS and CMS in Phase I, the result from a CMS projection was scaled by $1/\sqrt{2}$, assuming that the two experiments have the same sensitivity and the uncertainties are uncorrelated. This plot has been done using the `flavio` software package [903].

that can be attributed to different theoretical inputs or different selection of observables – and arrive at two basic conclusions. First, there is a tension in $b \to s\mu\mu$ data alone, and could be explained by a NP shift in the WC C_9^μ [811] (maybe combined with C_{10}^μ), or by a not well understood hadronic effect. Second, the LHCb measurements of $R_{K^{(*)}}$, if combined,are already in tension with the SM and lepton-flavor universality at 4σ, assuming there is no experimental correlation between R_K and R_{K^*}. This cannot be explained by hadronic effects. Assuming that it is due to NP coupling only to muons, one finds that it is consistent with the NP contribution needed to accommodate the $b \to s\mu\mu$ anomaly [826]. Singling out the WC C_9^μ in the muonic transition and performing a global fit to all the data, the log-likelihood ratio between the best-fit point and the SM hypothesis corresponds to a deviation ranging from 4σ to more than 6σ, depending on the theoretical assumptions [815–820].

Clearly, future experimental efforts that can clarify the origin of the above tensions are of utmost importance. If LFU is indeed violated in $b \to s\ell\ell$ transitions, then R_K and R_{K^*} are theoretically clean smoking guns that allow one to establish a possible deviation from the SM. At the same time, global fits to all the relevant observables will remain relevant for several reasons: *(i)* if the hints for LFUV disappear with more statistics, LFU new physics effects [820, 901, 902] might still hide in observables that are theoretically less clean ; *(ii)* to identify the nature of NP (and not just its presence), the values of the BSM Wilson coefficients have to be determined; *(iii)* in particular, if LFUV persists, to understand whether the NP effects are due to the muons, the electrons, or to which part of admixture one needs to perform lepton specific measurements and corresponding global fits; and *(iv)* they allow one to simultaneously determine poorly known hadronic effects from the data.

Extrapolations of global fits to the LHC data after the HL phase, in the (C_9^μ, C_{10}^μ) plane, are shown in Fig. 40. Further improvements beyond those taken into account in projections in Fig. 40 are: *(i)* $B \to K^* e^+ e^-$ angular analysis can be included, where for LFUV NP a simultaneous amplitude analysis of $B \to K^*\mu^+\mu^-$ and $B \to K^* e^+ e^-$ decays is more powerful than separate analyses [875];

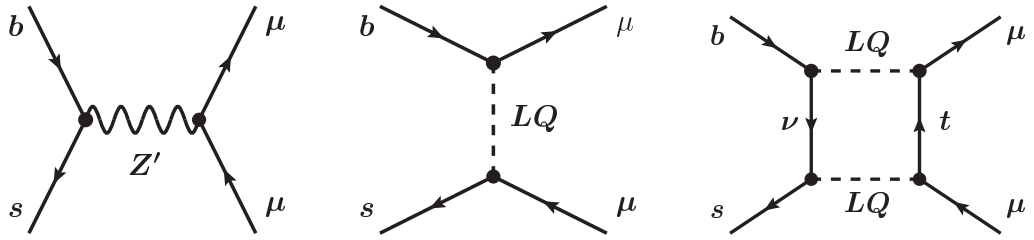

Fig. 41: Examples of NP contributions to $b \to s\mu\mu$ transitions. Left: tree-level Z' contribution. Center: tree-level leptoquark contribution. Right: One-loop leptoquark contribution.

(ii) combined fits to semi-leptonic and non-leptonic decays as well as the precise dilepton invariant mass spectra will allow one to better disentangle long- and short-distance effects in $B \to K^* \mu^+ \mu^-$ [861]; *(iii)* unbinned determination of Wilson coefficients [804] will fully exploit the experimental potential.

7.1.3 Models of NP for $b \to s\ell\ell$

Finally, we briefly review the NP models that can explain the $b \to s\ell\ell$ anomalies, assuming these become statistically significant. The model-independent analysis gives for the NP scale of a tree-level mediator with couplings of $\mathcal{O}(1)$,

$$\Lambda_{\rm NP} = \frac{4\pi}{e} \frac{1}{\sqrt{|V_{tb}V_{ts}^*|}} \frac{1}{\sqrt{|\Delta C_9^\mu|}} \frac{v}{\sqrt{2}} \simeq \frac{35\ \text{TeV}}{\sqrt{|\Delta C_9^\mu|}}\,, \tag{88}$$

where ΔC_i^ℓ denotes the NP contribution to C_i^ℓ. The actual mass of the NP degrees of freedom responsible for the anomalies can be much smaller if the NP couplings are small and/or if the NP contributions arise at loop level, instead of at tree level.

At tree level there are two types of NP particles that can contribute to $b \to s\ell\ell$ transitions: Z' and leptoquarks (see left and center diagrams in Fig. 41). Loop-level contributions of leptoquarks have been studied extensively in the literature (see right diagram in Fig. 41). Other loop-level models have been put forward, see, e.g., Refs. [342, 904–908], but we will not discuss them in detail.

7.1.3.1 Z' models

Models with a Z' that has flavour-violating couplings to quarks and that couples non-universally to leptons can explain the observed anomalies in $b \to s\ell\ell$. In a "simplified model" approach, treating the Z' mass and its couplings to the SM fermions as free parameters, irreducible constraints arise from B_s mixing, neutrino-trident production and LEP bounds on four-lepton contact interactions.

Combining these constraints gives the following maximal values for the Z' contributions to the relevant Wilson coefficients $\Delta C_{9,10}^{e,\mu}$ in the case of *(i)* left-handed lepton couplings (89), or *(ii)* in the case of vectorial lepton couplings (90) [909],

$$|\Delta C_9^\mu| = |\Delta C_{10}^\mu| \lesssim 5.4\,, \quad |\Delta C_9^e| = |\Delta C_{10}^e| \lesssim 0.64\,, \tag{89}$$

$$|\Delta C_9^\mu| \lesssim 9.3\,, \quad |\Delta C_9^e| \lesssim 0.72\,, \quad \Delta C_{10}^\mu = \Delta C_{10}^e = 0\,. \tag{90}$$

The Z' coupling to muons can comfortably explain the anomalies in R_K and R_{K^*} and the other anomalies in $b \to s\mu\mu$ transitions. Addressing R_K and R_{K^*} through a Z' coupling to electrons is possible only in the parameter region close to the current upper bounds from B_s meson mixing and four-lepton contact interactions. The sensitivity to NP of B_s-mixing [910, 911] will become stronger at the time scale of the HL/HE-LHC due to improved lattice predictions of hadronic matrix elements (see Secs. 2 and 11). The Z' mass can be at most several TeV; otherwise an explanation of the anomalies requires couplings to

leptons that are non-perturbatively large. If the Z' has very weak couplings to light quarks and electrons, its production cross section at colliders is tiny. Therefore the Z' could in principle be light, for example at the electroweak scale, or in certain models even much lighter [912–914].

A popular class of UV-complete Z' models is based on gauging the difference of muon-number and tau-number, $L_\mu - L_\tau$. Once physics is introduced that generates flavor-violating couplings of the Z' to quarks, the observed tensions in $b \to s\ell\ell$ decays can be explained [915–922]. $L_\mu - L_\tau$ models predict

$$\Delta C_9^e = 0\,, \quad \Delta C_9^\mu = -\Delta C_9^\tau\,, \quad \Delta C_{10}^e = \Delta C_{10}^\mu = \Delta C_{10}^\tau = 0\,. \tag{91}$$

Besides $L_\mu - L_\tau$, various other combinations of gauged flavor symmetries have been used to construct Z' models that can address the $b \to s\ell\ell$ anomalies [340, 923–936]. Also, scenarios where the Z' couples to both quarks and leptons indirectly through the mixing with heavy vectorlike fermions have been considered [347, 937, 938].

In models with partial compositeness the Z' can be identified with a heavy neutral spin-1 resonance of the composite sector, typically denoted as ρ. Such a resonance generically features flavor-violating couplings to quarks. A large degree of compositeness of the left-handed muons is required to explain the B-decay anomalies [939–944]. The generic expectation in models with partial compositeness is that the ρ couplings are strongest to SM fermions of the third generation, reflecting the mass hierarchy of the SM fermions that is related to their degree of compositeness. Assuming the dominance of couplings to left-handed leptons, these models suggest the pattern

$$\Delta C_9^e \simeq -\Delta C_{10}^e \ll \Delta C_9^\mu \simeq -\Delta C_{10}^\mu \ll \Delta C_9^\tau \simeq -\Delta C_{10}^\tau\,. \tag{92}$$

Models in which the Z' is part of a $SU(2)_L$ triplet have been suggested as a simultaneous explanation of the $b \to s\ell\ell$ anomalies and hints for LFUV in semileptonic charged-current decays, $R(D)$ and $R(D^*)$ [265, 925, 926, 945–948].

Different Z' models predict different patterns of NP effects in $b \to s\ell\ell$ and the related $b \to s\nu\nu$ transitions. Future measurements of these transitions at LHCb and Belle II will therefore allow one to narrow down viable Z' models. For example, the Z' models based on the gauged $L_\mu - L_\tau$ symmetry predict effects in the semileptonic $b \to s\mu^+\mu^-$ and $b \to s\tau^+\tau^-$ transitions of opposite sign, while $b \to se^+e^-$ transitions remain SM-like. In these models, the purely leptonic $B_s \to \mu^+\mu^-$ and $B_s \to \tau^+\tau^-$ decays, as well as the neutrino modes $B \to K^{(*)}\nu\bar{\nu}$, are predicted to be SM-like [915].

A markedly different pattern arises in the Z' scenarios based on dominant couplings to left-handed fermions of the third generation. In those models the $b \to s\tau^+\tau^-$ and $B \to K^{(*)}\nu\bar{\nu}$ rates are typically enhanced compared to the SM predictions by a factor of a few. The $B_s \to \mu^+\mu^-$ rate is predicted to be suppressed by approximately 25% compared to the SM prediction. Finally, in contrast to the $L_\mu - L_\tau$ models, rare lepton flavor-violating decays like $B \to K^{(*)}\tau\mu$ are predicted at levels of $O(10^{-8})$ [337] which might be in reach at the HL-/HE-LHC.

7.1.3.2 Leptoquark models

There are seven quantum number assignments for leptoquarks that allow tree-level couplings to down-type quarks and charged leptons of the SM. These are [264] $S_3 = (\bar{3}, 3, 1/3)$, $R_2 = (3, 2, 7/6)$, $\tilde{R}_2 = (3, 2, 1/6)$, $\tilde{S}_1 = (\bar{3}, 1, 4/3)$, $U_3 = (3, 3, 2/3)$, $V_2 = (\bar{3}, 2, 5/3)$ and $U_1 = (3, 1, -1/3)$. Among these, the couplings of R_2, $\tilde{R}_2$, $\tilde{S}_1$, and V_2 necessarily involve right-handed currents and therefore cannot explain the anomalies. Thus one is left with the triplet scalar S_3, the singlet vector U_1, and the triplet vector U_3. They all contribute at tree level to the operator $(\bar{s}\gamma_\alpha P_L b)(\bar{\mu}\gamma^\alpha P_L \mu)$ and can explain the $b \to s\ell\ell$ anomalies.

In a simplified model approach the constraints on the leptoquark models are very weak. While the leptoquarks S_3, U_1, and U_3 contribute to B_s-mixing, they only do so at the 1-loop level. Correspondingly,

the bounds on the leptoquark couplings from B_s mixing allow leptoquark masses as high as several 10's of TeV. Lower bounds on the leptoquark masses come from direct searches at hadron colliders. All leptoquarks are charged under color and can be pair-produced through strong interactions in pp collisions. Bounds from direct searches at the LHC are currently above 1 TeV in all different channels [949].

There is an additional leptoquark that has been identified as a possible explanation of the rare B-decay anomalies. With the appropriate couplings, the scalar-doublet leptoquark $R_2 = (3, 2, 7/6)$ can contribute to $b \to s\ell\ell$ transitions through 1-loop box diagrams [346] (for an earlier attempt with the scalar singlet leptoquark S_1 see [950]). The R_2 model largely avoids constraints from the neutrino modes $B \to K^{(*)}\nu\bar{\nu}$, and B_s mixing as well as from lepton universality in $b \to c\mu\nu$ and $b \to ce\nu$ transitions. If R_2 is responsible for the anomalies, it is expected to be very close to the current sensitivity of direct searches.

Most studies treat leptoquarks in the simplified-model approach [341, 344, 947, 948, 950–955]. Going beyond simplified models, one finds that the leptoquark couplings required to explain the anomalies are likely not of Minimal-Flavor Violation type [956], and constitute new sources of flavor violation beyond the SM Yukawa couplings. Both scalar and vector leptoquarks could arise, for example, in composite models [957, 958]. The vector leptoquarks could also be the gauge bosons of an enlarged gauge group that is broken not far above the TeV scale [348, 959–965]. The scalar-singlet leptoquark that contributes to $b \to s\ell\ell$ transitions at the loop level can be identified with the right-handed sbottom in the Minimal Supersymmetric Standard Model with R-parity violation [966, 967].

Some leptoquark scenarios are also able to address simultaneously the $b \to s\ell\ell$ anomalies as well as the hints for LFUV in $R(D^{(*)})$ [265, 348, 947, 948, 950, 954, 955, 958, 959, 962–964, 968]. However, many of the models that attempt a simultaneous explanation are strongly constrained by measurements of the $\tau^+\tau^-$ invariant mass spectrum at the LHC [369]; by existing bounds on $B \to K\nu\nu$ and $B \to K^*\nu\nu$ from BaBar and Belle; by existing bounds on LFV tau decays like $\tau \to 3\mu$; from precision measurements of the leptonic couplings of the Z at LEP [969–971], and by lepton-universality tests in leptonic tau decays $\tau \to \ell\nu_\tau\bar{\nu}_\ell$ [969–971].

7.2 Phenomenology of $b \to c\ell\nu$ decays

Authors (TH): Marat Freytsis, Martin Jung, Dean Robinson, Stefan Schacht.

7.2.1 $B \to D^{(*)}l\nu$ form factors and anatomy of $R(D^{(*)})$

Signs of LFUV have not only been seen in loop-suppressed flavor-changing neutral currents discussed above, but also in tree-level decays, namely, in tensions with the SM predictions for the ratios

$$R(D^{(*)}) = \frac{\mathcal{B}(B \to D^{(*)}\tau\nu)}{\mathcal{B}(B \to D^{(*)}l\nu)}, \qquad (l = \mu,\ e). \tag{93}$$

Assuming for the moment the SM particle content only, the $b \to c\ell\nu_{\ell'}$ transitions at scales near m_b can be described by an $SU(3) \times U(1)$-invariant effective Hamiltonian,

$$\mathcal{H}_{\text{eff}}^{b\to c\tau\nu} = \frac{4G_F}{\sqrt{2}} V_{cb} \sum_{\ell\ell'} \Big((\delta_{\ell\ell'} + C_L^{\ell\ell'}) O_{V_L}^{\ell\ell'} + \sum_i C_i^{\ell\ell'} O_i^{\ell\ell'} + \text{h.c.} \Big), \tag{94}$$

where $\ell, \ell' = e, \mu, \tau$ denotes the charged-lepton and neutrino flavor, respectively, and the sum over i runs over the following operators,

$$\begin{aligned} O_{V_{L,R}}^{\ell\ell'} &= (\bar{c}_{L,R}\gamma^\mu b_{L,R})(\bar{\ell}_L\gamma_\mu\nu_{\ell' L}), \qquad & O_{S_{L,R}}^{\ell\ell'} &= (\bar{c}_{R,L} b_{L,R})(\bar{\ell}_R\nu_{\ell' L}), \\ O_T^{\ell\ell'} &= (\bar{c}_R\sigma^{\mu\nu} b_L)(\bar{\ell}_R\sigma_{\mu\nu}\nu_{\ell' L}). \end{aligned} \tag{95}$$

The NP coefficients $C_i^{\ell\ell'}$ depend, in general, on both charged-lepton and neutrino flavor. These operators arise from more fundamental interactions at a higher scale Λ which, in accordance with available LHC data, can be taken to be larger than the electroweak scale v˜. The operators of Eq. (95) should then be embedded into $SU(2)_L \times U(1)$ invariant operators composed of the full SM field content. For C_{V_R} there is no contribution violating lepton-universality at dimension-6, leading to a parametric suppression of at least v^2/Λ^2 for tree-level ultraviolet (UV) completions. Linearly realized electroweak symmetry breaking, captured by the Standard Model effective field theory (SMEFT) [366,375], also yields the prediction $C_{V_R}^{\ell\ell'} \equiv C_{V_R}\delta_{\ell\ell'}$ [972,973]. In this case, sizable contributions to C_{V_R} are excluded by $b \to c(e,\mu)\nu$ [974]. While deviations from this prediction are possible in a non-linear realization of electroweak symmetry breaking [973], at least one of the above-named sources of suppression always remains and right-handed currents do not play a role.

The relevant hadronic matrix elements of the SM operator $O_{V_L}^{\ell\ell}$, i.e., $\langle D|\,\bar{c}\gamma^\mu b\,|\bar{B}\rangle$, $\langle D^*|\,\bar{c}\gamma^\mu b\,|\bar{B}\rangle$, and $\langle D^*|\,\bar{c}\gamma^\mu\gamma_5 b\,|\bar{B}\rangle$, are parametrized using one, two, and three form factors, respectively [975]. The helicity form factors obey unitarity bounds which can be written in an elegant way using the parametrization of Boyd-Grinstein-Lebed (BGL) [976]. The contributions of the helicity form factors S_1 and P_1 (as defined in [975]) to the branching ratios of $B \to Dl\nu$ and $B \to D^*l\nu$ are suppressed by the mass of the final-state lepton. In view of the lack of experimental information on these form factors we need input from theory. In the case of $B \to D$, we are in the fortunate position that lattice results for both V_1 and S_1 at $w \geq 1$ exist [66,977,978], where $w = (m_B^2 + m_{D^{(*)}}^2 - q^2)/(2m_B m_{D^{(*)}})$. This is the reason for the very good agreement of all SM predictions in this case, see Table 27. Recently, also soft photon corrections to $R(D)$ have been discussed [979]. For $B \to D^*$, we have only one data point from lattice, namely $A_1(w=1)$ [980,981] so that it is necessary to use Heavy Quark Effective Theory (HQET) [975,982–988] to relate the $B \to D$ and $B \to D^*$ form factors order-by-order in the heavy quark expansion in terms of Isgur–Wise functions in order to obtain a prediction for P_1 and hence $R(D^*)$.

At NLO in the heavy-quark expansion, i.e., expanding to linear order in α_s/π and $1/m_{c,b}$, there is sufficient differential information in the $B \to D^{(*)}l\nu$ decays to fit to the four Isgur-Wise functions that arise at this order [982,989]. In the literature the theoretical error from using NLO HQET results is under discussion, leading to different results for the error of the SM prediction. HQET can also be used to obtain a stronger version of the unitarity bounds (see Refs. [70,976] for details). Additional model-dependent theoretical input at maximal w can be provided by Light Cone Sum Rules (LCSR) [849,990], or at zero recoil by QCD sum rules [985–988]. We give a summary of theoretical predictions for $R(D^{(*)})$ in Table 27.

Since lattice data is presently available only at zero recoil for $B \to D^*$ and the kinematic suppression requires $d\Gamma[B \to D^*l\nu]/dw$ to vanish at $w = 1$, $|V_{cb}|$ can be obtained from $B \to D^*l\nu$ only by extrapolating $d\Gamma[B \to D^*l\nu]/dw$ back to zero recoil. This procedure can be highly sensitive to the chosen form-factor parameterization and other theoretical inputs; for recent analyses, see Refs. [31,32,69,70,981,982,989,991,992]. Lattice data beyond zero recoil is expected soon (see [993] for preliminary results) from both domain wall and AsqTad ensemble approaches. Combined with abundant future data for $B \to D^*l\nu$ from HL-LHC, extractions of $|V_{cb}|$ that are less sensitive to theoretical inputs will become possible, thereby either resolving or more concretely establishing tensions between exclusive and inclusive measurements of $|V_{cb}|$.

With future experimental data and lattice QCD results (see Sec. 11 and Table 41 therein) the SM prediction of $R(D^*)$ will improve considerably. For an estimate, one may note that the dependence of $d\Gamma/dw$ on the P_1 form factor arises only incoherently, via a contribution of the form $m_l^2|P_1(w)|^2$. This P_1 term contributes approximately 10% of the total integrated $B \to D^*\tau\nu$ rate, which suggests that the dependence of $R(D^*)$ on this form factor should be limited. Assuming a 1% future precision for P_1, using the 50 ab^{-1} which Belle II will presumably gather by 2025, and taking into account the expected improvement of the form factors $A_{1,5}$ and V_4 from the lattice, it is hence reasonable to assume that an

Table 27: Current SM $R(D^{(*)})$ theory predictions and their deviation from experiment $R(D)^{\rm exp} = 0.407(39)(24)$ [197,379,380,994] and $R(D^*) = 0.306(13)(7)$ [16,17,197,379–381,994–997] (HFLAV 2018 summer update). For older SM predictions see Refs. [998–1000]. Table adapted and extended from Ref. [992].

error of 0.001 for the SM value of $R(D^*)$ might be achieved.

7.2.2 Excited states and other b hadrons: $R(D^{**})$, $R(J/\psi)$, $R(\Lambda_c^{(*)})$ and $R(X_c)$

Measurements of $|V_{cb}|$ and lepton universality can also be probed via B decays to the D^{**} excited states, as well as decays of strange or charmed b hadrons, including $B_s \to D_s^{(*)}$, $B_c \to J/\psi$, and the baryonic $\Lambda_b \to \Lambda_c^{(*)}$ transitions. In comparison to the $B \to D^{(*)}\ell\nu$ decay modes, these modes may variously exhibit higher sensitivities to specific NP operators or, in some cases, may be theoretically cleaner than the decays to the $D^{(*)}$ ground states. These modes can also be important downfeed or crossfeed backgrounds to the $B \to D^{(*)}\ell\nu$ decays and, to the extent they are affected by the same NP operators, must also be understood and measured carefully. The HL-LHC is the only experiment planned that will yield significant samples of these heavier b-hadrons, with precision analyses anticipated from the LHCb experiment. In this subsection we present the motivations and theoretical prospects for the measurement of each of these exclusive decay modes, as well as for measurement of inclusive semileptonic B decays.

The D^{**} excited states comprise four different charmed hadrons: The D_0^*, D_1^*, D_1, D_2^*. In the language of HQET, these furnish two doublets, $\{D_0^*, D_1^*\}$ and $\{D_1, D_2^*\}$, with spin-parity $s_\ell^{\pi_\ell} = \frac{1}{2}^+$ and $\frac{3}{2}^+$, respectively. (In the heavy-quark limit, spin-parity is a conserved quantum number.) The $\frac{3}{2}^+$ states are narrow, with $\Gamma \sim 30$–$50\,\text{MeV}$, because their hadronic decays to $D^{(*)}\pi$ either proceed via a D-wave or violate heavy quark-symmetry, while the $\frac{1}{2}^+$ states are quite broad. Although isolating these excited-state decays will likely be simpler at e^+e^- B factories, which can more easily reconstruct π^0's and photons, analyses of $B \to D^{**}\ell\nu$ decays are also feasible at LHCb Upgrade II, especially for the narrow $\frac{3}{2}^+$ states subsequently decaying to charged hadrons.

The crucial attractive feature of the $B \to D^{**}$ transitions is that various leading-order contributions to the form factors vanish in the heavy-quark limit at zero recoil ($w = 1$), so that $\mathcal{O}(\alpha_s)$ and $\mathcal{O}(1/m_{c,b})$ corrections become important [1002–1005]. The richer structure of the subleading form-factor contributions has the consequence that sensitivity to various NP currents can be much larger than in the ground state decays [1005, 1006]. For example, including only a NP tensor operator, $O_T^{\ell\ell'}$, one finds the ratios $R(X)/R(X)_{\rm SM} \simeq \{1.5, 1.3\}$ for $X = \{D, D^*\}$ at the best fit to the $R(D^{(*)})$ data. However, the same Wilson coefficients result in $R(X)/R(X)_{\rm SM}$ greater than 4.0 or less than 0.5 for $X = \{D_0^*, D_1^*, D_1, D_2^*\}$. Interference between different $B \to D^{**}$ transitions also offers the possibility to probe for new CP-violating phases in the NP operators [1007]. The current SM predictions for all four modes, from fits to Belle data including NLO HQET contributions, are [1006]

$$R(D_0^*) = 0.08\pm0.03, \quad R(D_1^*) = 0.05\pm0.02, \quad R(D_1) = 0.10\pm0.02, \quad R(D_2^*) = 0.07\pm0.01\,. \tag{96}$$

Decays of B mesons to these excited states have total SM branching ratios comparable to the $B \to D^{(*)}\ell\nu$ decays themselves. Combined with the possible large enhancement of the semitauonic

modes by NP contributions, this means that the subsequent $D^{**} \to D^{(*)}X$ decays can then induce important downfeed backgrounds to the $D^{(*)}$ measurements. Analyses of $B \to D^{(*)}\ell\nu$ will therefore typically have to fold in contributions from these excited states. Moreover, anticipated analyses for the inclusive $B \to D\pi\ell\nu$ decays provide an opportunity to probe these excited-state decays and their associated larger NP sensitivities collectively with the ground-state decays. In this context, rather than being thought of as a background, these contributions should be more properly thought of as additional sources of (NP) signal. The large data sets from HL-LHC will then provide a very sensitive set of channels for probing NP contributions to $b \to c\ell\nu$.

The B_s and B_c mesons have production ratios $\sigma(B_s)/\sigma(b\bar{b}) \sim 10\%$ [1008] and $\sigma(B_c)/\sigma(b\bar{b}) \sim 0.2\%$ [1009] in Run 1 LHC. A much smaller sample of B_s mesons may also be produced at B factories running on the $\Upsilon(5S)$ resonance. However, for the B_c the only significant sample of mesons will be produced at HL-LHC. At first glance, the theoretical structure of $B_s \to D_s^{(*,**)}\ell\nu$ can be mapped directly from $B \to D^{(*,**)}\ell\nu$ via the approximate $SU(3)$ flavor symmetry. Some crucial differences are that $\mathcal{B}(D_s^* \to D_s\gamma) \simeq 94\%$, which will be difficult to see at LHCb Upgrade II, while the four D_s^{**} excited states are all narrow, and therefore may be easier to resolve.

The leptonic $B_c \to (J/\psi \to \mu\mu)\ell\nu$ decay mode is reasonably clean experimentally, with measurements for $R(J/\psi)$ already available from LHCb Run 1 data, $R(J/\psi) = 0.71 \pm 0.17\,(\text{stat}) \pm 0.18\,(\text{sys})$ [18], albeit with large uncertainties at present. A central difficulty in probing this mode lies in the large theoretical uncertainties for the $B_c \to J/\psi$ form-factor parameterizations. Predictions for the form factors are typically hadronic-model-dependent, making use of either perturbative QCD, the constituent-quark model, the (non)relativitistic quark model, or QCD sum rules [1010–1018]. The LHCb results have motivated several studies of the form factors [1019–1022]. A recent, more model-independent result combines preliminary lattice QCD results with dispersive bounds and zero-recoil heavy-quark relations, leading to the prediction $0.20 \leq R(J/\psi) \leq 0.39$ [1023], at 95% CL, implying a mild tension at the 1.3σ level with the data.

Abundant samples of Λ_b's will be produced only at (HL-)LHC, with a production cross-section $\sigma(\Lambda_b)/\sigma(b\bar{b}) \sim 10\%$ [779]. From an HQET point of view, the $\Lambda_b \to \Lambda_c$ transitions are theoretically cleaner than the $B \to D^{(*)}$ decays, because the "brown muck" dressing the heavy quark lies in the $s_\ell^{\pi\ell} = 0^+$ ground state. A consequence of this is a relatively simpler form-factor structure, where not only the $\mathcal{O}(\alpha_s)$ but also the $\mathcal{O}(1/m_{c,b})$ and $\mathcal{O}(\alpha_s/m_{c,b})$ subleading contributions are fully fixed by the leading-order HQET structure, reducing the number of free parameters in the form-factor fits. These modes are therefore promising, clean candidates for testing the behavior of the HQET expansion itself, by e.g., assessing the impact of $\mathcal{O}(1/m_c^2)$ contributions. Fitting the subsubleading $\mathcal{O}(\alpha_s, \alpha_s/m_{c,b}, 1/m_c^2)$ HQET structure to existing LHCb data [77] and lattice form factor results [71] implies such terms are of the expected size [1024]. More $\Lambda_b \to \Lambda_c\ell\nu$ data from LHCb will improve the precision of these results, allowing access to other subleading terms. Moreover, with precision lattice calculations of the form factors (see, e.g., Ref. [71]), additional data for these modes may permit precision measurement of $|V_{cb}|$ in an environment with reduced theoretical uncertainties.

The heavy quark expansion is also applicable to Λ_b transitions into excited $\Lambda_c^* = \Lambda_c(2595)$, $\Lambda_c(2625)$ states [1025]. The complexity of the HQET description lies between that of $\Lambda_b \to \Lambda_c$ and $B \to D^{(*)}$ transitions, with two unknown functions up to $\mathcal{O}(1/m_{c,b})$. It was recently demonstrated that simultaneous binned likelihood fits to the rich angular distributions of $\Lambda_b \to \Lambda_c^*\mu\bar{\nu}$ decays can determine these two functions and produce data-driven predictions of $R(\Lambda_c^*)$ [1026]. The projected precision due to parametric effects reaches $\sim 2\%$ for the LHCb Upgrade 1 data set. Due to the spin structure of the Λ_c^* states, these decays provide a complementary LFU probe with a different set of systematic uncertainties when compared to $R(D^{(*)})$ and $R(\Lambda_c)$. More data from LHCb will similarly improve the precision of these results.

Also of interest is the measurement of the inclusive process $B \to X_c\ell\nu$, where X_c can be a

multibody charmed state of arbitrary invariant mass, and the associated ratio $R(X_c)$. In the heavy quark limit $m_b \to \infty$, the amplitude for this process corresponds simply to that of the free quark decay $b \to c\ell\nu$. Corrections to the heavy quark limit are obtained via an OPE in terms of local heavy-quark operators: SM predictions exist at $\mathcal{O}(1/m_b^2)$ including two-loop QCD corrections [1027, 1028], yielding

$$R(X_c) = 0.223 \pm 0.004\,, \tag{97}$$

although recent analyses [1029, 1030] have shown that $1/m_b^3$ corrections can decrease $R(X_c)$ by as much as 5%. Combining this with the inclusive measurement $\mathcal{B}(B \to X_c e\nu) = (10.65 \pm 0.16)\%$ [197] implies $\text{Br}(B \to X_c\tau\nu) = (2.38 \pm 0.05)\%$. This is in good agreement with the LEP measurement $\mathcal{B}(b \to X\tau\nu) = (2.41 \pm 0.23)\%$ [310], where X can be any multibody state. However, the present measurements for $\mathcal{B}(B \to D\tau\nu) + \mathcal{B}(B \to D^*\tau\nu) = (2.71 \pm 0.18)\%$ [1028], when further combined with the SM predictions for $\mathcal{B}(B \to D^{**}\tau\nu)$ [1005, 1006], implies $\mathcal{B}(B \to X_c\tau\nu) > (2.8 \pm 0.2)\%$, already well in excess of the SM prediction for the semitauonic inclusive process. An indirect $R(X_c)$ anomaly then arises independent from the details of the form factor parameterizations involved in $R(D^{(*)})$. Given these tensions, and since measurement of the inclusive process would involve both different theory uncertainties and different systematics compared to the exclusive modes, direct measurement of $B \to X_c\tau\nu$ is of high interest in further understanding the $b \to c\tau\nu$ anomalies.

7.2.3 *Models of NP for $b \to c\tau\nu$*

A possible NP origin of the deviations in $R(D^{(*)})$ requires a large contribution with respect to the SM. Defining $\hat{R}(X) = R(X)/R(X)|_{\text{SM}}$, we have with present data $\hat{R}(D) = 1.36 \pm 0.15$ and $\hat{R}(D^*) = 1.19 \pm 0.06$. This points to $\gtrsim 10\%$ NP contribution to the amplitude when the SM and NP contributions interfere, and $\gtrsim 40\%$ if they do not. The scale of NP for the $R(D^{(*)})$ anomaly is then

$$\Lambda_{\text{NP}} = \frac{1}{\sqrt{|V_{cb}|}} \frac{1}{\sqrt{|\Delta C_i|}} \frac{v}{\sqrt{2}} \sim \frac{1\text{ TeV}}{\sqrt{|\Delta C_i|}}\,, \tag{98}$$

and the contributions are expected to enter at tree level. Possible mediators, assuming they couple only to SM fields, were classified in [1028]. If the present central values $R(D^{(*)})$ are sustained, this anomaly will be established by the time of the measurements at HL/HE-LHC, cf. Fig. 42 left. The focus will hence shift to model differentiation in $b \to c\tau\nu$ and the analysis of the lepton- and quark-flavor structure of the NP contributions. A completely general NP analysis will require theoretical care. For instance, form-factor determinations from $b \to c\ell\nu$ decays could also be sensitive to NP contributions, subject to the constraint that extractions of $|V_{cb}|$ from these decays can be made consistent with all other global data on CKM unitarity. Consequently, experimentally determined form-factor parameters may require a simultaneous fit to the deviations or additional determinations of form-factor ratios, which, however, are expected to be available at the required precision by the start of HL/HE-LHC. See Sec. 11 for corresponding prospects from lattice QCD.

The tree-level mediators that can explain the $R(D)$-$R(D^*)$ anomaly are a W' [925, 926, 943, 946] generating C_{V_L}, a charged color-neutral scalar [999, 1031–1037] generating $C_{S_{L,R}}$ in Eq. (94), and leptoquarks [341,377,828,950,952,954,958,959,962,963,968,1038–1048] generating various couplings, mostly C_{V_L} or $C_{S_L} \sim C_T$. For comparisons between these models, see for instance [1000, 1028, 1049–1053]. Allowing for additional light particles opens up the possibility to address the anomalies with contributions involving right-handed neutrinos [1047, 1054–1060], since the neutrino is not detected.

In order to differentiate between the different combinations of NP operators that these models produce at low energies, information beyond $R(D^{(*)})$ is needed [1030, 1061]. Presently, the available additional observables in $b \to c\tau\nu$ transitions are: *(i)* differential distributions in q^2 [379, 380] already excluding some fine-tuned scenarios despite their large uncertainties; *(ii)* the first measurements of the τ polarization asymmetry and the longitudinal fraction in $B \to D^*\tau\nu$ [995, 996]; *(iii)* the measurement

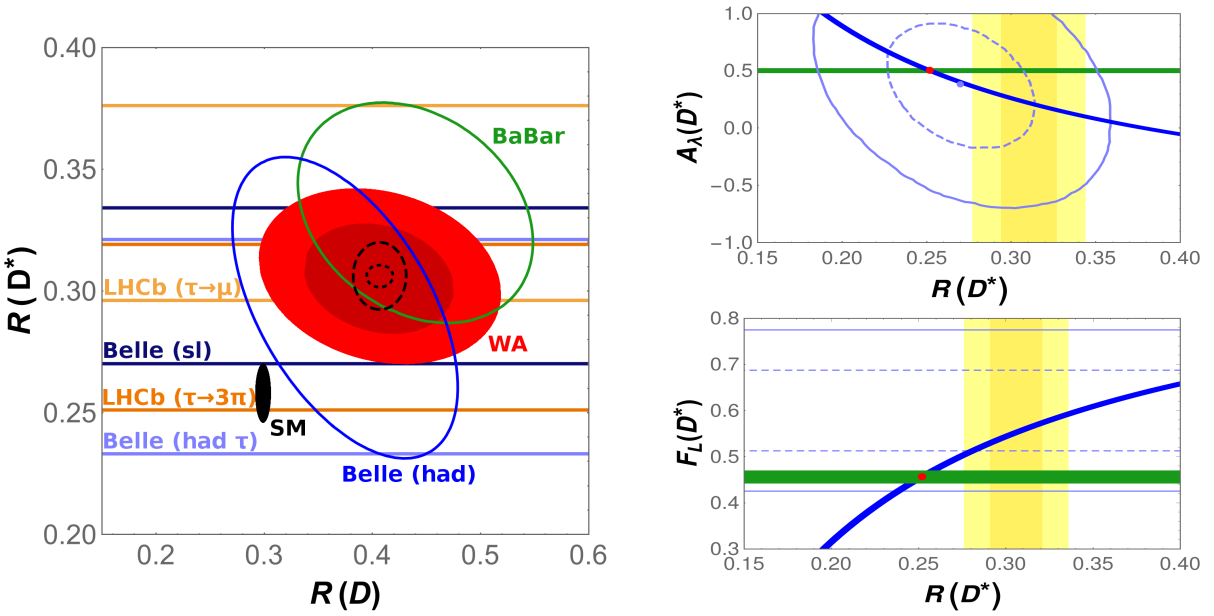

Fig. 42: Left: Present status of the $R(D)$-$R(D^*)$ anomaly, showing the individual measurements (68% CL contours), the world average (68% and 95% CL filled ellipses), the SM prediction (95% CL filled ellipse) as well as the projections for LHCb measurements by 2025 (dashed contour), and Upgrade II (dotted contour, both at 68% CL, assuming the present central value). Right: Correlations between $R(D^*)$ and the τ-polarization asymmetry $A_\lambda(D^*)[= -P_\tau(D^*)]$ (upper panel) and the longitudinal fraction $F_L(D^*)$ (lower panel) for NP scenarios with only a left-handed vector coupling (green) or only scalar couplings (blue), together with the first measurements [995, 996] (light blue) and the experimental average for $R(D^*)$ (yellow bands), excluding [995] in the upper panel. Updated and adapted from Ref. [1031].

of $R(J/\psi)$ [18], which is up to 2σ above the SM prediction, as well as that of any NP model (see the previous subsection); *(iv)* the measurement of the inclusive rate $b \to X\tau\nu$ at LEP [310, 1062], yielding $\hat{R}(X_c) = 1.01 \pm 0.10$, in slight tension with the measurements for $R(D^{(*)})$ [1027–1029, 1031]; *(v)* the (indirect) bound on $B_c \to \tau\nu$ from the B_c lifetime [1046, 1063, 1064], providing a strong constraint on models with only scalar couplings and disfavoring them as a solution for $R(D^*)$ for values close to the present central value.

Additional indirect constraints apply within UV-complete NP models: high-p_T searches for signatures related to potential mediators of these transitions often provide strong constraints via, e.g., $b\bar{b} \to \tau\tau$ [369], $b\bar{c} \to \tau\nu$ [378] or $h \to \tau\tau$ [1065], while radiative corrections can result in constraints from lepton universality in τ decays [970], lepton-flavor violating decays [970], charged-lepton magnetic moments [1065] and electric dipole moments [1066]. Current data on $\Upsilon(1S) \to \tau\tau$ decays also constrain most mediator models, and a future programme of measuring both Υ and ψ decays can have sensitivity to all NP UV completions [1067]. The current bounds on $b \to s\nu\bar{\nu}$, now only $\mathcal{O}(1)$ above the SM [1068, 1069], can also put severe constraints on particular NP models [1070, 1071]. Finally, it is interesting to note that contributions to $b \to s\ell\ell$ and $b \to s\gamma$ are also generically produced at loop level [908].

At the HL/HE-LHC qualitative progress in identifying potential NP in $b \to c\tau\nu$ can be understood chiefly in terms of two classes of observables:

- Precision results for $R(X)$: $R(D^{(*)})$ can establish NP and give basic model differentiation. $R(\Lambda_c^{(*)})$ is a measurement with independent systematics that improves model discrimination since it is sensitive to a different combination of NP parameters. The same applies to inclusive $R(X_c)$, to be

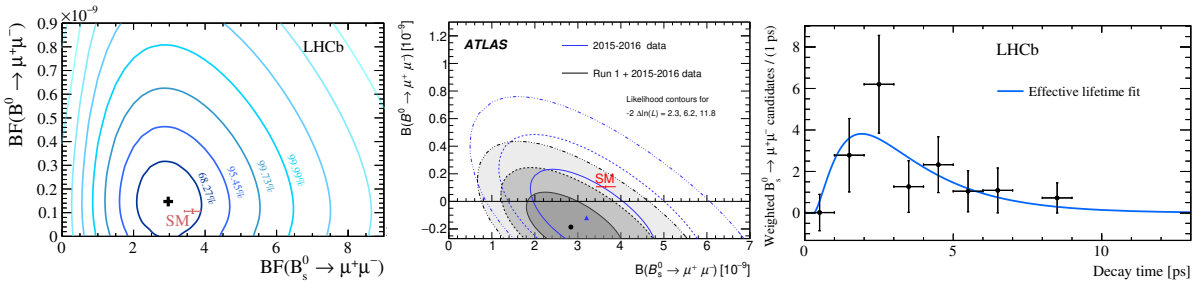

Fig. 43: A two-dimensional representation of the LHCb (left) and ATLAS (middle) branching fraction measurements for $B^0 \to \mu^+\mu^-$ and $B^0_s \to \mu^+\mu^-$. The central values are indicated with the marker. The profile likelihood contours for 1,2,3...Gaussian σ are shown as blue contours (left) and grey shaded areas (middle). The red cross labelled SM reports the Standard Model predictions. Right: background-subtracted $B^0_s \to \mu^+\mu^-$ decay-time distribution with the LHCb fit result superimposed.

measured by Belle II. Other modes, like $R(D_s^{(*)})$ or $R(J/\psi)$, will add to these and provide cross-checks with independent systematic uncertainties.

- Differential-rate measurements in $B \to X\tau\nu$: Differential measurements in q^2 as well as in the helicity angles and the τ-polarization are powerful discriminators between the SM and NP, as well as between different NP models [974, 998, 999, 1031, 1050, 1072–1084]. For instance, the low-recoil region in $B \to D\tau\nu$ is very sensitive to scalar contributions, tensor contributions change the polarization in the high-recoil region in $B \to D^*$ in a unique manner, and left-handed vector contributions leave normalized quantities unchanged while affecting the total rates sizably. Examples for the discriminating power of such measurements are given in Fig. 42 (right), where correlations in NP models are shown together with the first measurements of two proposed quantities by Belle [995, 996]. First studies regarding the reach of LHCb for such observables are presented in Sec. 7.3.7. Already semi-integrated quantities like the forward-backward asymmetry or the observables shown in Fig. 42 can be very powerful in distinguishing different NP scenarios.

At high $p_{\rm T}$, $bc\tau\nu$ operators can also be directly probed by the $pp \to \tau X$+MET (missing transverse energy) signature at the LHC, inclusively [378], or with a b-tag in the final state, with model discrimination possible at the beyond the 3σ level in at the HL-LHC [817]. This channel would allow one to probe all the NP scenarios addressing the $R(D^{(*)})$ anomalies in the HL-LHC phase (see Sec. 10). Analysis of NP effects in $b \to c\tau\nu$ will be made more powerful and self-consistent by the development of dedicated NP reweighting tools such as `Hammer` [1085]. These tools will permit experimental collaborations to efficiently reweight their very large simulated datasets to arbitrary NP models and thus fit for WCs as part of experimental analyses. Observation of NP in $b \to c\tau\nu$ would warrant precise measurements at HL-/HE-LHC of related modes, $b \to c(e,\mu)\nu$, $b \to u\tau\nu$ and $t \to b\tau\nu$ transitions.

7.3 Experimental perspectives

7.3.1 Measurements of $B_q \to ll$ from LHCb/ATLAS/CMS

Following the observation of $B^0_s \to \mu^+\mu^-$ by the CMS and LHCb collaborations [1086], the most stringent constraints on $B^0_s \to \mu^+\mu^-$ and $B^0 \to \mu^+\mu^-$ have been set by the LHCb [15] and ATLAS [825, 1087] collaborations, cf., Fig. 43. Both sets of measurements are compatible with the SM predictions.

HL-LHC will offer a compelling opportunity to extend the ATLAS and CMS $B^0_s \to \mu^+\mu^-$ and $B^0 \to \mu^+\mu^-$ studies to the expected integrated high luminosity. Flexible trigger systems and inner tracker improvements will allow both experiments to maintain efficient low-$p_{\rm T}$ dimuon triggers and achieve good mass resolution, which are the key ingredients for the $B_{s,d} \to \mu^+\mu^-$ analysis. Fig. 44 demonstrates the ATLAS and CMS $B \to \mu^+\mu^-$ invariant mass reconstruction capabilities in the HL-

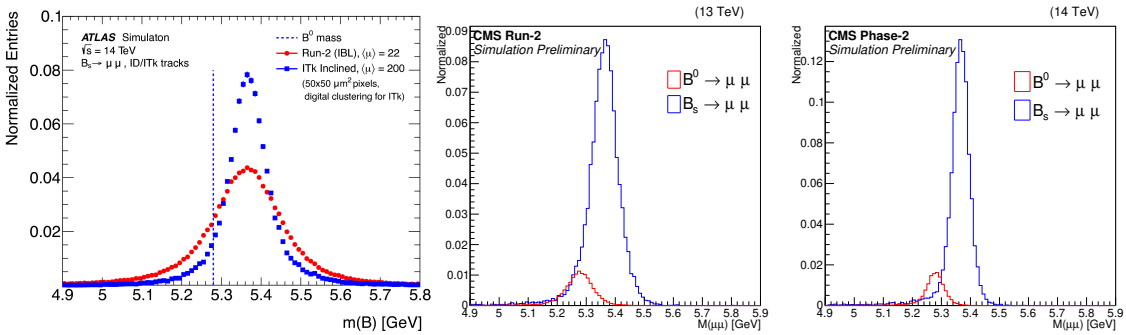

Fig. 44: Left: comparison of the ATLAS invariant mass spectra for simulated $B_s^0 \to \mu^+\mu^-$ events with the current (Run-2) and upgraded (ITk) detectors. A vertical line at the B_d mass value is drawn to visualize the B_s-B_d signals separation. Middle and right plots: CMS B_s^0 and B^0 invariant mass distributions in the Run-2 and Phase-2 scenario respectively. The B_s^0 distribution is normalized to unity and the B^0 distribution is normalized according to the SM expectation. CMS plots are taken from [1088].

LHC era. The pseudorapidity $|\eta_f|$ of the most forward muon (of the candidate) is used to visualize the CMS results and compare the performance of Phase-2 against Run-2. In Fig. 44 the signal mass distributions for $|\eta_f| < 1.4$ are overlaid. The CMS improved separation between $B^0 \to \mu^+\mu^-$ and $B_s^0 \to \mu^+\mu^-$ in Phase-2 is evident; this will help to separate the B^0 signal from the tails of the B_s^0 signal,which now becomes a background for the B^0 measurement.

The LHCb detector is already well optimised for this decay, and planned improvements to the tracking and muon detector shielding in LHCb's upgrades will ensure that the muon reconstruction and identification performance does not degrade with increasing pileup. Both ATLAS and CMS make HL-LHC extrapolations with a PU scenario of 200 interactions per bunch-crossing, which was found not to have strong impact on the analysis performance. While the uncertainty on $\mathcal{B}(B^0 \to \mu^+\mu^-)$ remains statistically limited for HL-LHC projections (300 fb^{-1}/3 ab^{-1}), the projected uncertainty on $\mathcal{B}(B_s^0 \to \mu^+\mu^-)$ depends on the assumptions made for the systematic uncertainties. The current systematic uncertainty is dominated by sources external to the analysis, such as the relative uncertainty associated with the b-quark fragmentation probability ratio, f_s/f_d [1089], followed by the branching fractions of the normalisation modes and less significant systematics arising from internal analysis effects (e.g., 2% each from particle identification and track reconstruction in the case of LHCb, individual efficiencies in the case of ATLAS and CMS).

Systematic uncertainties are treated slightly differently in the projections of the three experiments. ATLAS conservatively assumes in the HL-LHC projections that the f_s/f_d and the normalization modes branching fraction uncertainties will be at the same level as previously used, i.e., 5.8% and 3%, while CMS and LHCb project them to be 3.5% and 1.4%, respectively, based on reasonable assumptions about additional Belle II inputs and improvements in the knowledge of form-factor ratios and branching fraction measurements. A more complete discussion of sensitivity projections and systematics therein from ATLAS and CMS are presented in Refs [1090] and [1088]. For LHCb, the remaining experimental systematic uncertainties are already at the $\sim$ 3 percent level, and because they rely on data-driven corrections from calibration samples they can be expected to be reduced to the $\sim$ 1.4 percent level in Upgrade II. The resulting HL-LHC projected statistical and systematic uncertainties for the three experiments are summarized in table 28; for the comparisons of the ATLAS, CMS and LHCb reaches (such as the one carried out in Fig. 47) , the reference scenarios considered are respectively the "3 ab^{-1} Intermediate", "3 ab^{-1}" and "300 fb^{-1}".

At the end of the Upgrade II data taking period, LHCb assumes to achieve an overall uncertainty

Table 28: Projected ATLAS, CMS and LHCb uncertainty on $\mathcal{B}(B_s^0 \to \mu^+\mu^-)$ and $\mathcal{B}(B^0 \to \mu^+\mu^-)$.The HL-LHC scenario corresponds to an integrated luminosity of 300 fb^{-1} for LHCb and 3 ab^{-1} for ATLAS and CMS. For each extrapolation the total (statistical+systematic) uncertainties are reported.

		$\mathcal{B}(B_s^0 \to \mu^+\mu^-)$	$\mathcal{B}(B^0 \to \mu^+\mu^-)$
Experiment	Scenario	stat + syst %	stat + syst %
LHCb	23 fb^{-1}	8.2	33
LHCb	300 fb^{-1}	4.4	9.4
CMS	300 fb^{-1}	12	46
CMS	3 ab^{-1}	7	16
ATLAS	Run 2	22.7	135
ATLAS	3 ab^{-1} Conservative	15.1	51
ATLAS	3 ab^{-1} Intermediate	12.9	29
ATLAS	3 ab^{-1} High-yield	12.6	26

on $\mathcal{B}(B_s^0 \to \mu^+\mu^-)$ of about 4.4%, which would imply an uncertainty on $\mathcal{B}(B_s^0 \to \mu^+\mu^-)$ to be approximately 0.30×10^{-9} with 23 fb^{-1} and 0.16×10^{-9} with 300 fb^{-1}. The LHCb reach on the ratio of branching fractions $\mathcal{B}(B^0 \to \mu^+\mu^-)/\mathcal{B}(B_s^0 \to \mu^+\mu^-)$ is expected to remain limited by statistics and decrease from 90% for the current measurement to $\sim 34\%$ with 23 fb^{-1} and $\sim 10\%$ with 300 fb^{-1}.

The CMS projections are obtained by extrapolating the Run-2 analysis performances to the HL-LHC scenario. Trigger efficiencies comparable to those of Run-2, with manageable rates, are expected to be attained [1091] and are here assumed. The effect of the increased pileup on the signal selection efficiency was also found to be manageable. The inner tracker of the CMS HL-LHC detector is estimated to provide a 40-50% improvement relative to Run-2 on the dimuon mass resolution. This results in an improved separation of the B_s^0 and B^0 signals, lowering the signal cross-feed contamination that is specially crucial for the B^0 observation, and a reduction of the level of the semileptonic background in the signal region (see Fig. 44). With the full Phase-2 integrated luminosity of 3000 fb^1, CMS expects to measure the $B_s^0 \to \mu^+\mu^-$ branching fraction at the level of 7%. precision, and observe the $B^0 \to \mu^+\mu^-$ decay with a significance in excess of 5σ. Fig. 45 shows the invariant mass fit projections for the $B_{s,d} \to \mu^+\mu^-$ analyses for an integrated luminosity of 3000 fb^{-1}.

The ATLAS projections [1090] are extrapolated from the ATLAS Run 1 analysis [1092]. Assumptions include the training of a multivariate classifier capable of similar background rejection and signal purities and an analysis selection with comparable pile-up immunity as Run 1. The study takes into account the scaling of B production cross-section and integrated luminosity relative to Run 1, and explores different triggering scenarios corresponding to different dimuon transverse momentum thresholds, $(p_T^{\mu_1}, p_T^{\mu_2})$: $(6\,\text{GeV}, 6\,\text{GeV})$, $(6\,\text{GeV}, 10\,\text{GeV})$ and $(10\,\text{GeV}, 10\,\text{GeV})$. For each of these scenarios the sensitivity is categorized on the basis of the signal statistics expected relative to the Run 1 analysis (x15, x60 and x75 respectively, in 3 ab^{-1} of HL-LHC ATLAS data), yielding the projected 68.3%, 95.5% and 99.7% likelihood contours in Fig. 46.

Fig. 47 compares the projected experimental sensitivities of ATLAS, CMS, and LHCb with the BR predictions from a particular class of BSM models [1094]. All estimates use the quoted SM predictions

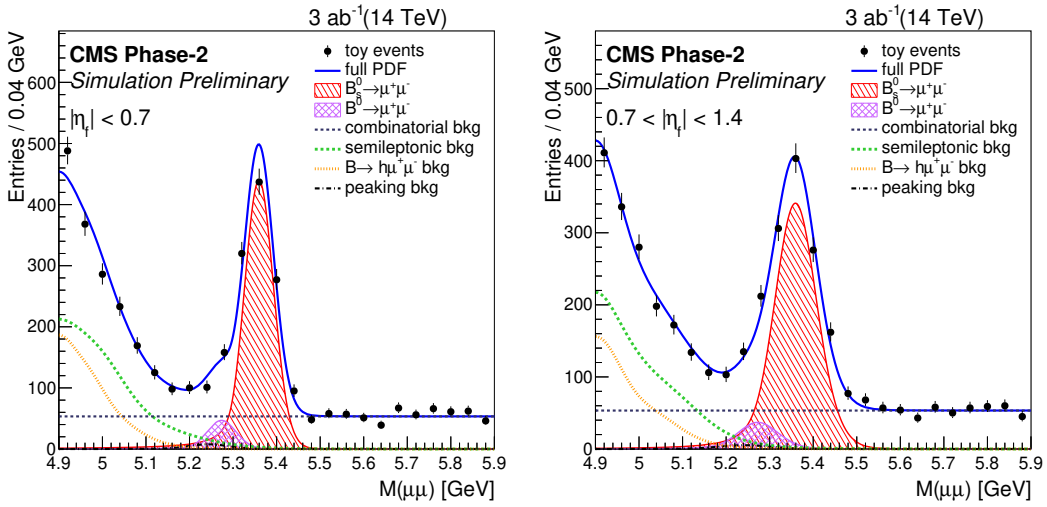

Fig. 45: Projected dimuon invariant mass distributions with overlaid fit results for the $B_{d,s} \to \mu^+\mu^-$ analyses by CMS, with an integrated luminosity of 3000 fb^{-1}. Events where the most forward muon lies in the barrel (left) and forward (right) regions of the detector display different mass resolutions and are categorized accordingly in the analysis. The SM relative B_s^0 and B^0 contributions are here assumed. (Plots are taken from [1088]).

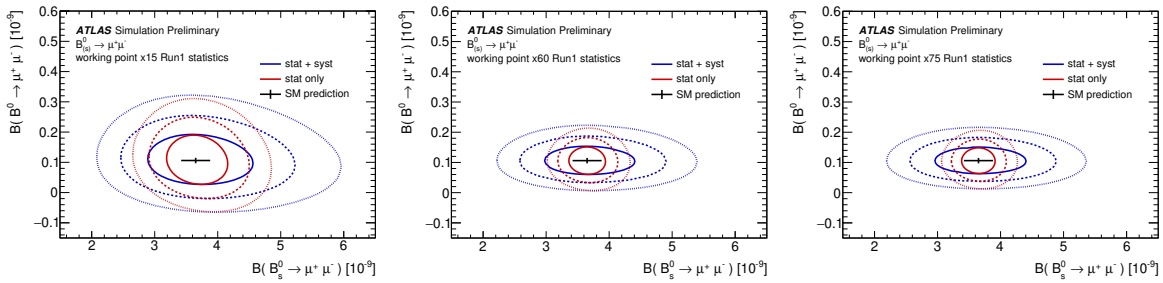

Fig. 46: ATLAS projected 68.3% (solid), 95.5% (dashed) and 99.7% (dotted) confidence level profiled likelihood ratio contours for the "conservative" (top), "intermediate" (middle) and "high-yield" HL-LHC extrapolations. Red contours do not include the systematic uncertainties, which are then included in the blue ellipsoids. The black point shows the SM theoretical prediction and its uncertainty [1093].

as central values for the branching fractions. The estimated experimental sensitivity at HL-LHC is close to the uncertainty of the current SM prediction from theory, which is dominated by the uncertainty on the B_s^0 decay constant, f_{B_s}, determined from lattice QCD calculations, and the CKM matrix elements. Both are expected to improve in precision in the future. The power of the HL-LHC data set to discriminate not only between the SM and BSM models, but also within the parameter space of those BSM models, is clear.

With the HL-LHC data set, precise measurements of additional observables are possible, namely the effective lifetime, $\tau^{\text{eff}}_{\mu\mu}$, and the time-dependent CP asymmetry of $B_s^0 \to \mu^+\mu^-$ decays. Both quantities are sensitive to possible new contributions from the scalar and pseudo-scalar sector in a way complementary to the branching ratio measurement [320]. The effective lifetime is related to the mean B_s^0 lifetime τ_{B_s} through the relation

$$\tau^{\text{eff}}_{\mu\mu} = \frac{\tau_{B_s}}{1-y_s^2}\frac{1+2A^{\mu\mu}_{\Delta\Gamma}y_s+y_s^2}{1+A^{\mu\mu}_{\Delta\Gamma}y_s}\,, \tag{99}$$

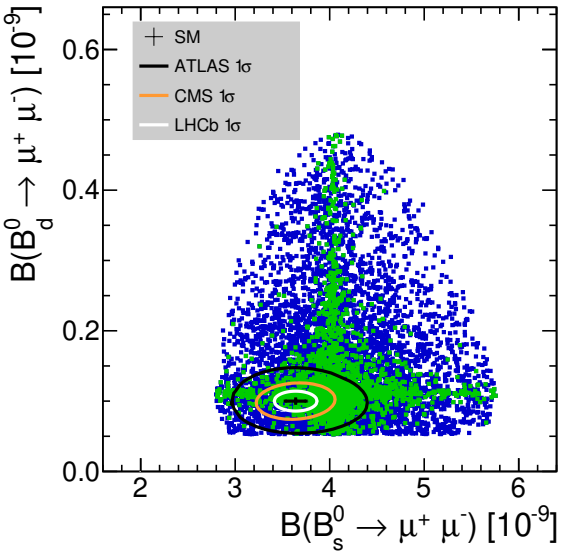

Fig. 47: $B_s^0 \to \mu^+\mu^-$ and $B^0 \to \mu^+\mu^-$ branching ratios as computed using new sources of flavour-changing neutral currents, as discussed in Ref. [1094]. The green points are the subset consistent with other measurements. The black cross point is the SM prediction, while the coloured contours show the expected 1-sigma HL-LHC sensitivites of ATLAS, CMS, and LHCb.

where $y_s = \tau_{B_s}\Delta\Gamma_s/2$, and $\Delta\Gamma_s = \Gamma_{B^0_{sL}} - \Gamma_{B^0_{sH}}$. In the SM, $A^{\mu\mu}_{\Delta\Gamma} = 1$, with only the heavy mass eigenstate decaying to $\mu^+\mu^-$. In BSM scenarios it can take any value between -1 and 1. LHCb has performed the first measurement of the $B_s^0 \to \mu^+\mu^-$ effective lifetime using a dataset of 4.4 fb^{-1}, resulting in $\tau^{\rm eff}_{\mu\mu} = 2.04 \pm 0.44 \pm 0.05$ ps [15] (Fig. 43, right). The relative uncertainty on $\tau^{\rm eff}_{\mu\mu}$ is expected to decrease to approximately 8% with 23 fb^{-1} and 2% with 300 fb^{-1}, being statistically limited.

The CMS sensitivity for a measurement of the $B_s^0 \to \mu^+\mu^-$ effective lifetime is estimated using an ensemble of pseudo-experiments generated with parameters reflecting the projected Phase-2 conditions. The signal lifetime distribution for each pseudo-experiment is obtained using the sPlot technique [1095] to separate out the background, and then fitted with a model consisting of an exponential function, convolved with a Gaussian function that describes the expected decay time resolution, and multiplied by an efficiency function that accounts for reconstruction effects. The outcome of such a pseudo-experiment is shown in Fig. 48. The effective lifetime is expected to be measured with a statistical precision of 3% at 3000 fb^{-1}.

While the current experimental uncertainty is larger than for $\tau_{B^0_{sH}} - \tau_{B^0_{sL}}$, a $2-3\%$ uncertainty on $\tau^{\rm eff}_{\mu\mu}$ would allow to set stringent constraints on $A^{\mu\mu}_{\Delta\Gamma}$ and in particular would allow to break the degeneracy between any possible contribution from new scalar and pseudoscalar mediators.

Assuming a tagging power of about 3.7% [10], a dataset of 300 fb^{-1} allows LHCb to reconstruct a pure sample of more than 100 flavour-tagged $B_s^0 \to \mu^+\mu^-$ decays (effective yield) and measure their time-dependent CP asymmetry. From the relation

$$\frac{\Gamma(B_s^0(t) \to \mu^+\mu^-) - \Gamma(\bar{B}_s^0 \to \mu^+\mu^-)}{\Gamma(B_s^0(t) \to \mu^+\mu^-) + \Gamma(\bar{B}_s^0 \to \mu^+\mu^-)} = \frac{S_{\mu\mu}\sin(\Delta m_s t)}{\cosh(y_s t/\tau_{B_s}) + A^{\mu\mu}_{\Delta\Gamma}\sinh(y_s t/\tau_{B_s})}\,, \tag{100}$$

where t is the signal proper time and Δm_s is the mass difference of the heavy and light B_s^0 mass eigenstates, $S_{\mu\mu}$ can be measured with an uncertainty of about 0.2. The signal yield expected in a 23 fb^{-1} dataset, on the other hand, is too low to allow a meaningful constraint to be set on $S_{\mu\mu}$. A nonzero value for $S_{\mu\mu}$ would automatically indicate evidence of CP-violating phases beyond the SM.

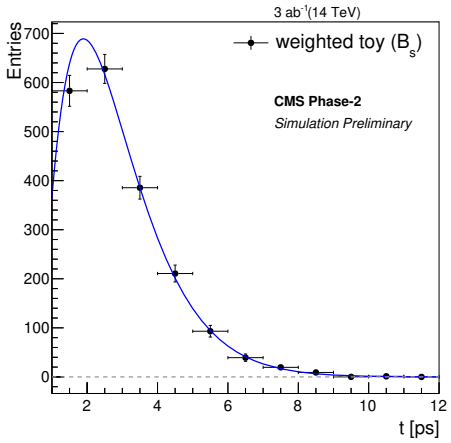

Fig. 48: Projection of a background-subtracted proper decay time distribution, with fit result overlaid, with the CMS experiment and 3000 fb^{-1}. The estimated uncertainty in the $B_s^0 \to \mu^+\mu^-$ effective lifetime is obtained by fitting an ensemble of corresponding pseudo-experiments. (The plot is taken from [1088]).

Being sensitive to a wider set of effective operators (O_7, O_9 and O_{10}) [1096], the $B_s^0 \to \mu^+\mu^-\gamma$ decay offers an interesting counterpart to $B_s^0 \to \mu^+\mu^-$. The theoretical branching fraction is expected to be one order of magnitude larger than the $B_s^0 \to \mu^+\mu^-$ one [1097], owing to the removal of the helicity suppression, when integrated over the full q^2 spectrum. However, the presence of the photon makes the direct reconstruction challenging at LHCb. No limit exist today on the $B_s^0 \to \mu^+\mu^-\gamma$ channel, while the $B^0 \to \mu^+\mu^-\gamma$ is limited at 1×10^{-7} at 90% CL by the BaBar experiment [1098].

Given the experimental difficulty, two complementary techniques are employed for the study of the $B_s^0 \to \mu^+\mu^-\gamma$ decay at LHCb. The first is a full reconstruction which is more sensitive at low and mid q^2, where the photon energy is higher, and the second, recently proposed in Ref. [834], without photon reconstruction but only sensitive at high q^2.

The only non-negligible partially reconstructed background is the not yet measured $B_d \to \mu^+\mu^-\pi^0$, whose branching fraction is theoretically estimated to be of the same order of magnitude as the signal. The main difficulty of the measurement is therefore the combinatorial background, because the uncertainty on the photon momentum enlarges the signal width and blurs its kinematics. Based on current reconstruction efficiencies, the expected sensitivity at the end of Run 3 (Upgrade II) is $\sim 9\sigma$ ($\sim 22\sigma$). The use of $B_s \to J/\psi\eta$ and $B_d \to K\pi\gamma$ as normalisation channels reduces the systematic uncertainties due to the selection.

The partially reconstructed method consists of studying the $B_s^0 \to \mu^+\mu^-\gamma$ decay as a shoulder on the left of the $B_s^0 \to \mu^+\mu^-$ peak in the dimuon mass distribution. The SM contribution as background has been considered negligible so far. Conversely, large branching fractions could be easily excluded [834] when considering this as an additional component. The SM branching fraction for this region would be around 2×10^{-10}, implying a first observation would be possible with Run 3 and certainly with Run 4 data, while extremely tight limits could already be determined with Run 2.

7.3.2 Measurements of $b \to s\ell\ell$ from LHCb/ATLAS/CMS

7.3.2.1 Yield and systematics evolution

With the large data set that will be collected at the end of Run 5, it will be possible to make a precise determination of the angular observables in narrow bins of q^2 or using a q^2-unbinned approach [804,806];

LHCb foresees to achieve around 440 000 fully reconstructed $B^0 \to K^{*0}\mu^+\mu^-$ decays, CMS around 700 000 excluding the q^2 range overlapping with the resonant decays [1099].

The current ATLAS, CMS and LHCb measurements are statistically limited. For LHCb the major systematics are those which affect the calculation of the angular acceptance. Most of the systematic uncertainties are expected to reduce significantly with more integrated luminosity due to larger control samples. Both the LHCb statistical and systematic uncertainties are therefore scaled with integrated luminosity when obtaining the projections. In this context it is interesting to note that Upgrade II will provide signal yields that are of the order of the current tree-level control modes $B^0 \to J/\psi K^{*0}$ and $B_s^0 \to J/\psi\,\phi$. In the most recent measurement of ϕ_s from $B_s^0 \to J/\psi\,\phi$, the systematic uncertainties on the decay amplitudes due to modeling of the angular acceptance were already at the 0.001-0.002 level. Therefore, even without considering further improvements from the larger control samples available in Upgrade II, these uncertainties will not systematically limit the Upgrade II analysis.

The CMS sensitivity for the measurement of the P_5' parameter at HL-LHC is extrapolated [1099] from the CMS Run-1 results [1100] under some assumptions: effects of improvements in the analysis strategy (e.g., different selection criteria or fits) are not considered and the trigger thresholds and efficiency are assumed to remain the same. The latter is likely to be a conservative assumption since the availability of tracking information at the first level trigger may result in a higher efficiency than in Run-1. The extrapolation method also assumes that the signal-to-background is the same; indeed, the main source of background is from other b-hadron decays, whose cross-section scales the same as the signal. Samples of simulated events are used to evaluate three relevant aspects of the analysis, namely mass resolution, CP mistagged rate, and the effect of pileup, to justify the extrapolation method; no degradation in the projected analysis performance was found. For each q^2 bin, the expected $B^0 \to K^{*0}\mu^+\mu^-$ signal yields are obtained from a sample of simulated signal events generated with the Phase-2 conditions, including an average of 200 pileup, and scaled to the integrated luminosity of 3000 fb $^{-1}$.

The estimated statistical uncertainty on the P_5' parameter at 3000 fb^{-1} is obtained by scaling the statistical uncertainty measured in Run-1 by the square root of the ratio between the yields observed in Run-1 and the Phase-2 simulation. The evolution of the systematic uncertainties is also extrapolated from the Run-1 analysis. Improved understanding of theory and the experimental apparatus is expected to reflect in a factor of 2 reduction in many uncertainties in the Phase-2 scenario. The uncertainties which depend on the available amount of data are scaled the same as the statistical uncertainties. The uncertainty related to the limited number of simulation events is neglected, under the assumption that sufficiently large simulation samples will be available by the time the HL-LHC becomes operational.

The ATLAS study extrapolates the signal and background yields based on the Run 1 analysis data observations [1101], accounting for 3000 fb^{-1} of integrated luminosity and a $\times 1.7$ increase in the b production cross-section. Monte-Carlo simulations are employed to estimate the experimental precision achievable, including the improved 4-prong invariant mass resolution projected with the ATLAS upgraded tracking system [1102]. Particular care is taken in applying likely trigger selections, emulating trigger thresholds and accounting for the q^2-dependency of the trigger efficiency. Three different sets of di-muon trigger threshold scenarios are considered: two 6 GeV muons, the combinaton of 6 GeV and a 10 GeV muon, or two muons of 10 GeV. Although not dominant in the result, systematic uncertainties are carefully extrapolated as well: signal and background fit model accuracies are expected to improve in proportion to the available data statistics, detector acceptance and mistagging accuracy are driven by MC statistics and thus assumed to produce negligible effects, the inclusion of S-wave contributions to the data fit is extrapolated to improve the effect of this systematic by a factor 5, and detector alignment and B-field systematic uncertainties are expected to improve approximately by a factor 4 with larger calibration samples and the use of new techniques [1103].

The precision of the future $b \to s\ell\ell$ branching fraction measurements from the LHC experiments will be limited also by the knowledge of the $B \to J/\psi X$ decay modes that are used to normalise the

Table 29: Wilson coefficients in benchmark NP scenarios. The first scenario is inspired by the present discrepancies in the rare decays, including the angular distributions of the decay $B^0 \to K^{*0}\mu^+\mu^-$ and the measurements of the branching fraction ratios R_K and R_{K^*}. The second scenario is inspired by the possibility of explaining the rare decays discrepancies and those measured in the observables $R(D^{(*)})$. The third and fourth scenarios assume small nonzero right-handed couplings.

scenario	$C_9^{\rm NP}$	$C_{10}^{\rm NP}$	C_9'	C_{10}'
I	-1.4	0	0	0
II	-0.7	0.7	0	0
III	0	0	0.3	0.3
IV	0	0	0.3	-0.3

observed signals. The knowledge of these branching fractions will be improved by the Belle II collaboration but will inevitably limit the precision of the absolute branching fractions of rare $b \to s\ell^+\ell^-$ processes. The comparison between the predicted and measured branching fractions will in any case be limited by the theoretical knowledge of the form factors.

7.3.2.2 Sensitivity projections

In order to estimate the sensitivity to BSM effects in $b \to s\ell\ell$ decays, a number of benchmark NP scenarios are considered, see Table 29. Scenarios I and II are inspired by the current discrepancies. The first scenario is the one that best explains the present $b \to s\mu\mu$ decay data. The second is the best explaining the rare semileptonic measurements within a purely left-handed scenario. This requirement is theoretically well motivated and arises in models designed to simultaneously explain the discrepancies seen in both tree-level semitauonic and loop-level semileptonic decays. The third and fourth scenarios assume that the current discrepancies are not confirmed but there is instead a small contribution from right-handed currents that would not be visible with the current level of experimental precision. These scenarios will serve to illustrate the power of the large LHCb Upgrade II data set to distinguish between different NP models. This power relies critically on the ability to exploit multiple related decay channels.

Unlike the systematics limited branching fractions, a more precise comparison between theory and experiment can be achieved by studying isospin and CP asymmetries, which will be experimentally probed at percent-level precision with the LHCb Upgrade II data set. This will also enable new decay modes to be studied, for example higher spin K^* states and modes with larger numbers of decay products. It is also possible to reduce theoretical and experimental uncertainties by comparing regions in angular phase-space of $b \to s\ell\ell$ decays. The angular distribution of $B \to V\ell^+\ell^-$ decays, where V is a vector meson, can be expressed in terms of eight q^2-dependent angular coefficients that depend on the Wilson coefficients and the form factors. Measurements of angular observables in $B^0 \to K^{*0}\mu^+\mu^-$ decays show a discrepancy with respect to the SM predictions [813, 814, 899, 1100, 1101, 1104–1118]. This discrepancy is largest in the so-called optimized observable P_5' [899]. The decay $B_s^0 \to \phi\mu^+\mu^-$ can also be described by the same angular formalism as the $B^0 \to K^{*0}\mu^+\mu^-$ decay. However, in this case the B_s^0 and $\overline{B}_s^0$ mesons decay to a common final state and it is not possible to determine the full set of observables without tagging the initial flavour of the B_s^0.

The expected precision of an unbinned LHCb-only determination of P_5' in the SM and in Scenarios I and II is illustrated in Fig. 49, where we have followed the theoretical approaches in Refs. [804, 806] for the predictions. Upgrade II will enable these scenarios to be clearly separated from the SM and from each other. By combining information from all of the angular observables in the decay, it will also be possible for LHCb to distinguish models with much smaller NP contributions. Fig. 50 shows the expected $3\,\sigma$ sensitivity to NP in the Wilson coefficients $C_{9,10}'$ assuming the central values for the SM,

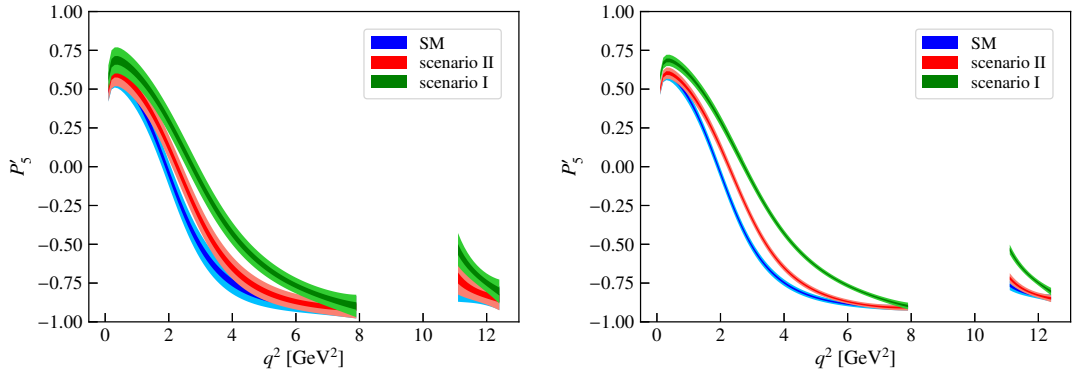

Fig. 49: Total experimental sensitivity, including systematics, at LHCb to the P_5' angular observable in the SM, Scenarios I and II for the Run 3 (left) and the Upgrade II (right) data sets. The sensitivity is computed assuming that the charm-loop contribution is determined from the data.

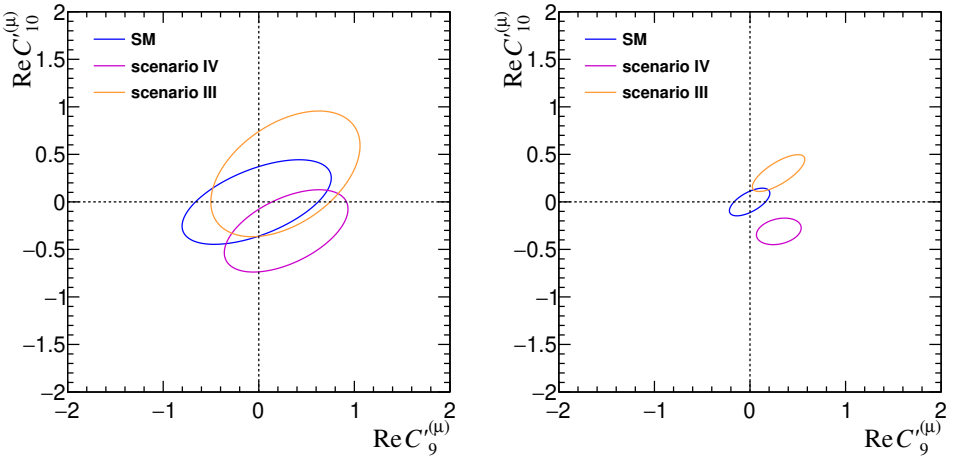

Fig. 50: Expected sensitivity to the Wilson coefficients C_9' and C_{10}' from the future LHCb analysis of the $B^0 \to K^{*0}\mu^+\mu^-$ decay. The ellipses correspond to 3 σ contours for the SM, Scenario III and Scenario IV for the Run 3 (left) and the Upgrade II (right) data sets.

Scenario III and Scenario IV. These scenarios are also clearly distinguishable with the precision that will be available with the Upgrade II data set.

The CMS projected statistical uncertainties and total uncertainties for the measurement of P_5' versus q^2 for an integrated luminosity of 3000 fb^{-1} are shown in Fig. 51, along with the Run 1 results.

The P_5' total uncertainties in the q^2 bins are estimated to improve up to a factor of 15 in the 3000 fb^{-1} scenario [1099], compared to those quoted in the Run-1 analysis. The extrapolation to 300 fb^{-1} integrated luminosity is also estimated by CMS [1099] and provides an improvement of up to a factor of 7 with respect to the Run-1 analysis. These results are among the inputs of the global fit to the HL-LHC experimental projections shown in Fig. 40, which indicates the potential sensitivity to the SM and NP scenarios in the C_9- C_{10} Wilson-coefficient plane.

The foreseen Phase-2 total integrated luminosity offers the opportunity to perform the angular analysis in narrower q^2 bins, in order to measure the P_5' shape as a function of q^2 with finer granularity. The q^2 region below the J/ψ mass(-squared), which is more sensitive to possible new physics effects, is considered. Each Run-1 q^2 bin is split into smaller and equal-size bins to achieve a statistical uncertainty of the order of the total systematic uncertainty in the same bin. With respect to the Phase-2 systematic

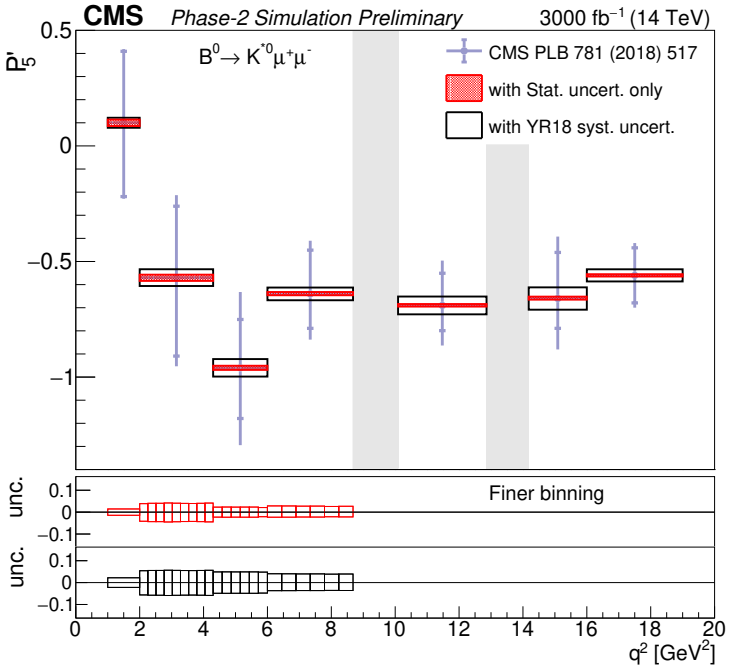

Fig. 51: Projected statistical (hatched regions) and total (open box) uncertainties on the CMS P_5' parameter versus q^2 in the Phase-2 scenario at 3000 fb^{-1}. The CMS Run-1 measurement of P_5' is also shown by circles with inner vertical bars representing the statistical uncertainties and outer vertical bars representing the total uncertainties. The vertical shaded regions correspond to the J/Ψ and ψ' resonances. The two lower pads represent the statistical (upper pad) and total (lower pad) uncertainties with the finer q^2 binning. (The plot is taken from [1099]).

uncertainties with wider bins, the systematic uncertainties that were scaled the same as the statistical uncertainties are adjusted to account for less data in each finer bin while the other uncertainties are unchanged. The corresponding statistical and total uncertainties on P_5' are shown in the lower two pads of Fig. 51.

The analysis in narrow q^2 bins provides a better determination of the P_5' parameter shape which will allow for testing theoretical predictions. The CMS available projection is for the single P_5' angular parameter; with the foreseen HL-LHC statistics, CMS will have the capability to perform a full angular analysis of the $B^0 \to K^{*0}\mu^+\mu^-$ decay mode.

The ATLAS [1119] projected statistical and systematic uncertainties are provided in the same q^2 bins employed in the Run 1 analysis, and for the same set of angular parameters already published. Table 30 reports the combined statistical and systematic uncertainty expectations for the different trigger scenarios considered, with the projected uncertainties for all the angular parameters compared to current theoretical predictions in figure 52. Reference [1119] includes full detail on the breakdown of statistical and systematic contributions. The precision in measuring e.g. the P_5' parameter is expected to improve by a factor between 5 and 9 relative to the Run 1 result, depending on the trigger scenario considered.

Furthermore, with large data sets expected at the HL-LHC it will be possible for the LHC experiments to probe $B \to V\ell^+\ell^-$ SM contributions, under the premise that a genuine NP contribution is expected to have no q^2 dependence, while, e.g., a charm loop contribution is expected to grow when approaching the pole of the charmonia resonances. A measurement using Breit-Wigner functions to parametrise the resonances, and their interference with the short-distance contributions to the decay, was

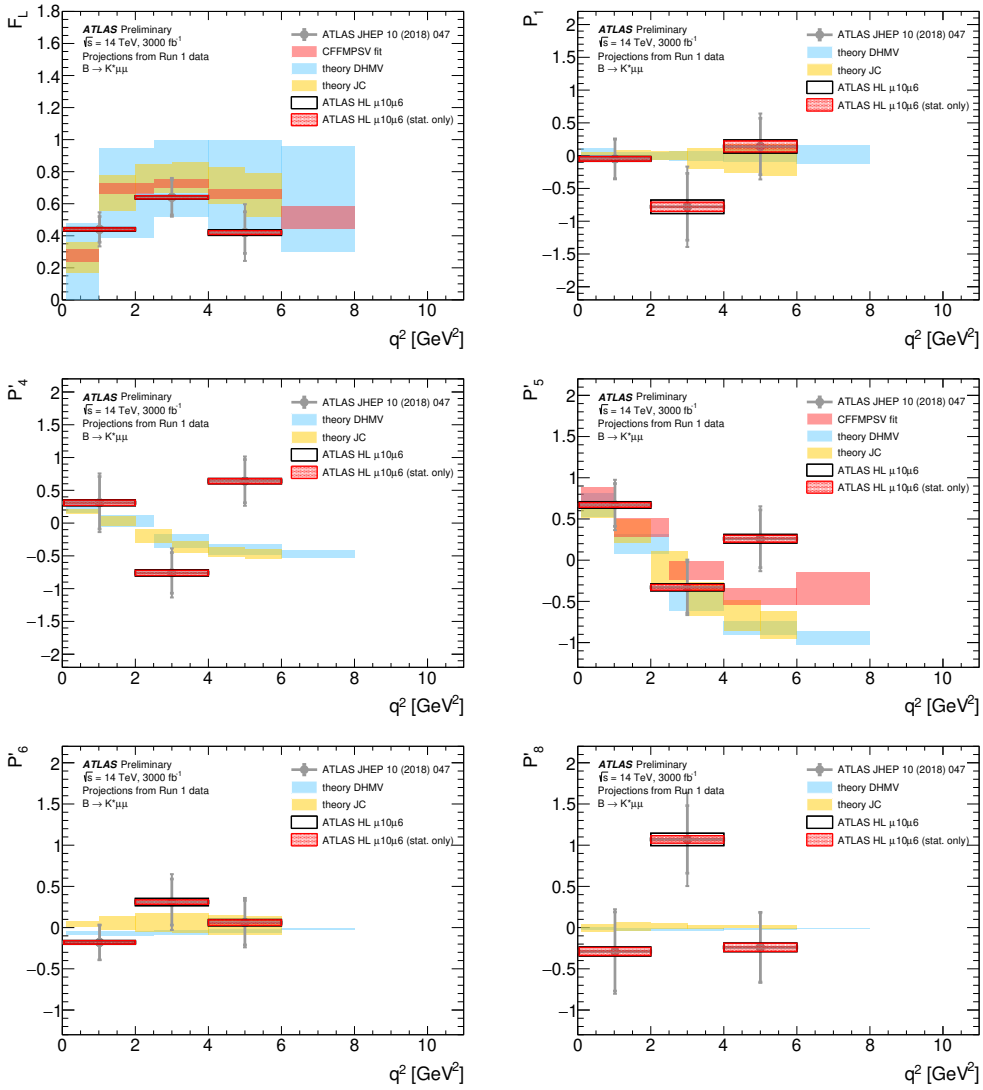

Fig. 52: Projected ATLAS HL-LHC measurement precision in the $F_{\rm L}$, P_1, P_4', P_5', P_6' and P_8' parameters for the intermediate μ10μ6 trigger scenario compared to the ATLAS Run 1 measurement. Alongside theory predictions (CFFMPSV [1120], DHMV [1121], JC [843]) are also shown. Both the projected statistical and the total (statistical and systematic) uncertainties are shown. While the HL-LHC toy-MC were generated with the DHMV central values of the $F_{\rm L}$ and $P_i^{(\prime)}$ parameters, in these plots the central values are moved to the ATLAS Run 1 measurement for better visualization of the improvement in the precision.

proposed in Ref. [805]. A similar technique has already been applied by LHCb to the Run-1 data for the $B^+ \to K^+\mu^+\mu^-$ decay [1122]. An alternative approach using additional phenomenological inputs has also been proposed [1123]. Such a combination of phenomenological and experimental methods may improve our knowledge of the charm-loop contribution and form factors, which would allow C_9^μ and C_{10}^μ to be determined with great precision in $b \to s\mu\mu$ transitions.

7.3.3 Measurements of b → dll

Thanks to LHCb's particle identification capabilities, the Upgrade II data set will provide a unique opportunity to make precise measurements of $b \to d\ell\ell$ processes. Using the Run 1 and 2 data sets, LHCb data

have been used to observe the decays $B^+ \to \pi^+\mu^+\mu^-$ [1124, 1125] and $\Lambda_b^0 \to p\pi^-\mu^+\mu^-$ [1126], and to find evidence for the decays $B^0 \to \pi^+\pi^-\mu^+\mu^-$ (in a $\pi^+\pi^-$ mass region that is expected to be dominated by $B^0 \to \rho^0\mu^+\mu^-$) and $B_s^0 \to \overline{K}^{*0}\mu^+\mu^-$ [1127] with branching fractions at the $\mathcal{O}(10^{-8})$ level. The existing data samples comprise $\mathcal{O}(10)$ decays in these decay modes. The upgrade will provide samples of thousands, or tens of thousands of such decays. The ability to measure the properties of these processes depends heavily on the PID performance of the LHCb subdetectors. In the case of the $B_s^0 \to \overline{K}^{*0}\mu^+\mu^-$ decay, excellent mass resolution is also critical to separate B_s^0 and B^0 decays.

The ratio of branching fractions between the CKM-suppressed $b \to d\ell\ell$ transitions and their CKM-favoured $b \to s\ell^+\ell^-$ counterparts, together with theoretical input on the ratio of the relevant form factors, enables the ratio of CKM elements $|V_{td}|/|V_{ts}|$ to be determined. The precision on $|V_{td}|/|V_{ts}|$ from such decays is dominated at present by the statistical uncertainty on the experimental measurements of $B^+ \to \pi^+\mu^+\mu^-$, and is much less precise than the determination from mixing measurements. The theoretical uncertainty at high-q^2 is at the level of 4% and is expected to improve with further progress on the form factors from lattice QCD [1128]. Around 17 000 $B^+ \to \pi^+\mu^+\mu^-$ decays are expected in the full 300 fb^{-1} dataset, allowing an experimental precision better than 2%.

The current set of measurements of $b \to s\ell\ell$ processes have demonstrated the importance of angular measurements in the precision determination of Wilson coefficients. With the LHCb Upgrade II dataset, where a sample of 4300 $B_s^0 \to \overline{K}^{*0}\mu^+\mu^-$ decays is expected, it will be possible to make a full angular analysis of a $b \to d\ell^+\ell^-$ transition. The $B_s^0 \to \overline{K}^{*0}\mu^+\mu^-$ decay is both self-tagging and has a final state involving only charged particles. The LHCb Upgrade II data set will allow the angular observables in this decay to be measured with better precision than the existing measurements of the $B^0 \to K^{*0}\mu^+\mu^-$ angular distribution.

The LHCb Upgrade II dataset will also give substantial numbers of $B^{0,+} \to \rho^{0,+}\mu^+\mu^-$ and $\Lambda_b^0 \to N\mu^+\mu^-$ decays. Although the $B^0 \to \rho^0\mu^+\mu^-$ decay does not give the flavour of the initial B meson, untagged measurements will give sensitivity to a subset of the interesting angular observables. Analysis of the

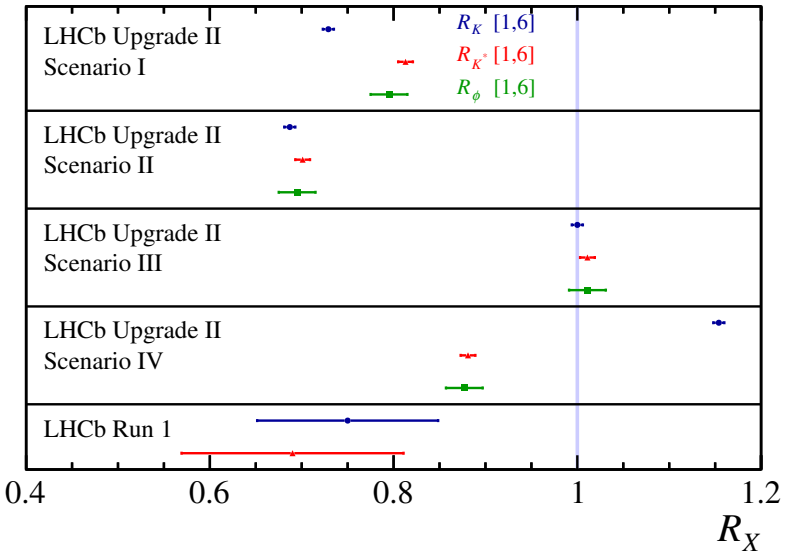

Fig. 53: Projected sensitivity for the R_K, R_{K^*} and R_ϕ measurements in different NP scenarios with the Upgrade II data set. The existing Run 1 measurements of R_K and R_{K^*} are shown for comparison.

$\Lambda_b^0 \to N^* \mu^+ \mu^-$ decay will require statistical separation of overlapping $p\pi^-$ resonances with different J^P by performing an amplitude analysis of the final-state particles.

The combination of information from $\mathcal{B}(B^0 \to \mu^+\mu^-)$, the differential branching fraction of the $B^+ \to \pi^+\mu^+\mu^-$ decay, and angular measurements, notably of $B_s^0 \to \overline{K}^{*0}\mu^+\mu^-$, will indicate whether NP effects are present in $b \to d$ transitions at the level of 20% of the SM amplitude with more than 5σ significance.

7.3.4 LFU tests in $b \to (s,d)\ell\ell$

The Run 1 LHCb data have been used to perform the most precise measurements of R_K and R_{K^*} to-date [5,6] (see Fig. 53). These measurements are compatible with the SM at the level of 2.1–2.6 standard deviations. Assuming the current detector performance, approximately 46 000 $B^+ \to K^+e^+e^-$ and 20 000 $B^0 \to K^{*0}e^+e^-$ candidates are expected in the range $1.1 < q^2 < 6.0\,\text{GeV}^2/c^4$ in the Upgrade II data set. The ultimate precision on R_K and R_{K^*} will be better than 1%. The importance of the Upgrade II data set in distinguishing between different NP scenarios is highlighted in Fig. 53. With this data set all four NP scenarios could be distinguished at more than $5\,\sigma$ significance.

The Upgrade II data set will also enable the measurement of other R_X ratios e.g., R_ϕ, R_{pK} and the ratios in CKM suppressed decays. For example, with $300\,\text{fb}^{-1}$, it will be possible to determine $R_\pi = \mathcal{B}(B^+ \to \pi^+\mu^+\mu^-)/\mathcal{B}(B^+ \to \pi^+e^+e^-)$ with a few percent statistical precision. A summary of the expected performance for a number of different R_X ratios is indicated in Table 31.

In addition to improvements in the R_X measurements, the enlarged Upgrade II data set will give access to new observables. For example, the data will allow precise comparisons of the angular distribution of dielectron and dimuon final-states. Differences between angular observables in $B \to X\mu^+\mu^-$ and $B \to Xe^+e^-$ decays are theoretically pristine [1129, 1130] and are sensitive to different combinations of Wilson coefficients compared to the R_X measurements. Fig. 54 shows that an upgraded LHCb detector will enable such decays to be used to discriminate between different NP models, for example separating between Scenarios I and II [1131]. Excellent NP sensitivity can be achieved irrespective of the assumptions made about the hadronic contributions to the decays.

In the existing LHCb detector, electron modes have an approximately factor five lower efficiency

Table 31: Estimated yields of $b \to se^+e^-$ and $b \to de^+e^-$ processes and the statistical uncertainty on R_X in the range $1.1 < q^2 < 6.0\,\text{GeV}^2/c^4$ extrapolated from the Run 1 data. A linear dependence of the $b\bar{b}$ production cross section on the pp centre-of-mass energy and unchanged Run 1 detector performance are assumed. Where modes have yet to be observed, a scaled estimate from the corresponding muon mode is used.

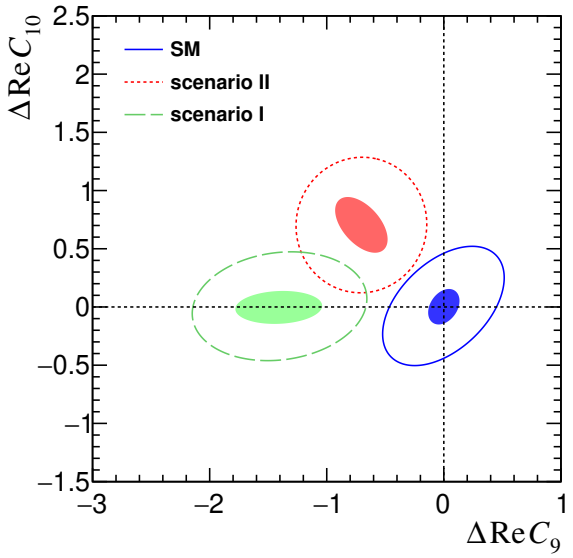

Fig. 54: Constraints on the difference in the C_9 and C_{10} Wilson coefficients from angular analyses of the electron and muon modes with the Run 3 and Upgrade II data sets. The 3σ regions for the Run 3 data sample are shown for the SM (solid blue), a vector-axial-vector new physics contribution (red dotted) and for a purely vector new physics contribution (green dashed). The shaded regions denote the corresponding constraints for the Upgrade II data set.

than the corresponding muon modes, owing to the tendency for the electrons to lose a significant fraction of their energy through bremsstrahlung in the detector. This loss impacts on the ability to reconstruct, trigger and select the electron modes. The precision with which observables can be extracted therefore depends primarily on the electron modes and not the muon modes. In order for R_X measurements to

benefit from the large Upgrade II data samples, it will be necessary to reduce systematic uncertainties to the percent level. These uncertainties are controlled by taking a double ratio between R_X and the decays $B \to J/\psi X$, where the J/ψ decays to $\mu^+\mu^-$ and e^+e^-. This approach is expected to work well, even with very large data sets.

Other sources of systematic uncertainty can be mitigated through design choices for the upgraded detector. The recovery of bremsstrahlung photons is inhibited by the ability to find the relevant photons in the ECAL (over significant backgrounds) and by the energy resolution. A reduced amount of material before the magnet would reduce the amount of bremsstrahlung and hence would increase the electron reconstruction efficiency and improve the electron momentum resolution. Higher transverse granularity would aid signal selection and help reduce the backgrounds. With a large number of primary pp collisions, the combinatorial background will increase and will need to be controlled with the use of timing information. However, the Run 1 data set indicates that it may be possible to tolerate a significant (i.e., larger than a factor two) increase in combinatorial backgrounds without destroying the signal selection ability.

7.3.5 *Time dependent angular analyses in $b \to (s,d)ll$*

Time dependent analyses of rare decays into CP-eigenstates can deliver orthogonal experimental information to time-integrated observables. So far, no time-dependent measurement of the $B^0_s \to \phi\mu^+\mu^-$ decay has been performed due to the limited signal yield of 432 ± 24 in the Run 1 data sample [900]. However, the larger data samples available in Upgrade II will enable time-dependent studies. The framework describing $\overline{B}$ and $B \to V\ell^+\ell^-$ transitions to a common final-state is discussed in Ref. [1132], where several observables are discussed that can be accessed with and without flavour tagging. Two observables called s_8 and s_9, which are only accessible through a time-dependent flavour-tagged analysis, are of particular interest. These observables are proportional to the mixing term $\sin(\Delta m_s t)$ and provide information that is not available through flavour specific decays. Assuming a time resolution of around $45\,\text{fs}$ and an effective tagging power of 5% results in an effective signal yield of 2000 decays for the Upgrade II data set.

As a first step towards a full time-dependent analysis, the effective lifetime of the decay $B^0_s \to \phi\mu^+\mu$ can be studied. The untagged time-dependent decay rate is given by

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}t} \propto e^{-\Gamma_s}\left[\cosh\left(\frac{\Delta\Gamma_s t}{2}\right) + A^{\Delta\Gamma}\sinh\left(\frac{\Delta\Gamma_s t}{2}\right)\right]. \tag{101}$$

The observable $A^{\Delta\Gamma}$ can be related to the angular observables F_L and S_3 via $A^{\Delta\Gamma} = 2S_3 - F_\mathrm{L}$. Due to the significant lifetime difference $\Delta\Gamma_s$ in the B^0_s system, even an untagged analysis can probe right-handed currents. For the combined low- and high-q^2 regions, preliminary studies suggest a statistical sensitivity to $A^{\Delta\Gamma}$ of 0.05 can be achieved with a $300\,\text{fb}^{-1}$ data set.

With the Upgrade II data set it will also be possible to perform a time-dependent angular analysis of the $b \to d$ process $B^0 \to \rho^0\mu^+\mu^-$. This process differs from $B^0_s \to \phi\mu^+\mu^-$ in two important regards: it is CKM suppressed and therefore has a smaller SM branching fraction; and $\Delta\Gamma_d \approx 0$, removing sensitivity to $A^{\Delta\Gamma}$. The uncertainties on the angular observables are expected to be of the order of 0.1 for this case.

The time-dependent angular analyses will still be statistically limited even with $300\,\text{fb}^{-1}$. It will be important to maintain good decay-time resolution and the performance of the particle identification will be crucial to control backgrounds, as well as to improve flavour tagging performance.

7.3.6 *Measurements of $b \to s\gamma$*

The time dependent CP asymmetry of $B \to f_{CP}\gamma$ arises from the interference between decay amplitudes with and without $B^0_{(s)} - \overline{B}^0_{(s)}$ mixing and is predicted to be small in the SM [881, 1133, 1134]. As a

consequence, a large asymmetry due to interference between the B mixing and decay diagrams can only be present if the two photon helicities contribute to both B and $\overline{B}$ decays. From the time dependent decay rate

$$\Gamma(B^0_{(s)}(\overline{B}^0_{(s)}) \to f_{CP}\gamma)(t) \sim e^{-\Gamma_s t}\Big[\cosh\left(\frac{\Delta\Gamma_{(s)}}{2}\right) - \mathcal{A}^{\Delta}\sinh\left(\frac{\Delta\Gamma_{(s)}}{2}\right) \pm \\ \pm \mathcal{C}_{CP}\cos\left(\Delta m_{(s)}t\right) \mp \mathcal{S}_{CP}\sin\left(\Delta m_{(s)}t\right)\Big], \tag{102}$$

where A^{Δ}, $\mathcal{C}_{CP}$ and $\mathcal{S}_{CP}$ depend on the photon polarisation [888]. Two strategies can be devised: one studying the decay rate independently of the flavour of the B meson, which allows A^{Δ} to be accessed, and one tagging the flavour of the B meson, which accesses $\mathcal{S}_{CP}$ and $\mathcal{C}_{CP}$. The first strategy has been exploited at LHCb to study the 4000 $B^0_s \to \phi\gamma$ candidates collected in Run 1 to obtain $A^{\Delta} = -0.98^{+0.46}_{-0.52}\,(\text{stat})^{+0.23}_{-0.20}\,(\text{syst})$ [891], compatible at two standard deviations from the prediction of $A^{\Delta}_{\text{SM}} = 0.047^{+0.029}_{-0.025}$.

With $\sim$ 60k signal candidates expected with 50 fb^{-1}, the full analysis, including flavour tagging information, will improve the statistical uncertainty on A^{Δ} to ~ 0.07, and will need a careful control of the systematic uncertainties. The analysis performed with $\sim$ 800k signal decays expected with 300 fb^{-1}, with a statistical uncertainty to ~ 0.02, requires some of the possible improvements in π^0 reconstruction of the Upgrade II detector to be able to use the full statistical power of the data.

In addition to studying the B^0_s system, LHCb can study the time-dependent decay rate of $B^0 \to K^0_S\pi^+\pi^-\gamma$ decays, which permits access of the photon polarisation through the $\mathcal{S}_{CP}$ term. With $\mathcal{O}(1000)$ signal events in Run 1, around 35k and 200k are expected at the end of Run 4 and Upgrade II, respectively (1.75k and 10k when considering the flavour tagging efficiency), opening the doors to a very competitive measurement of $\mathcal{S}_{CP}$ in the B^0 system.

Another way to study the photon polarisation is through the angular correlations among the three-body decay products of a kaonic resonance in $B \to K_{\text{res}}(\to K\pi\pi)\gamma$, which allows the direct measurement of the photon polarisation parameter in the effective radiative weak Hamiltonian [883]. As a first step towards the photon polarisation measurement, LHCb observed nonzero photon polarisation for the first time by studying the photon angular distribution in bins of $K^+\pi^-\pi^+$ invariant mass [1135], but the determination of the value of this polarisation could not be performed due to the lack of knowledge of the hadronic system. To overcome this problem, a method to measure the photon polarisation using a full amplitude analysis of $B \to K\pi\pi\gamma$ decays is currently under development [1136], with an expected statistical sensitivity on the photon polarisation parameter of $\sim 5\%$ in the charged mode with the Run 1 dataset. The extrapolation of the precision to 300 fb^{-1} results in a statistical precision better than 1%, and hence control of the systematic uncertainties will be crucial.

The polarisation of the photon emitted in $b \to s\gamma$ transitions can also be accessed via semileptonic $b \to s\ell\ell$ transitions, for example in the decay $B^0 \to K^{*0}\ell^+\ell^-$. Indeed, as mentioned in previous sections, at very low q^2 these decays are dominated by the electromagnetic dipole operator $\mathcal{O}^{(\prime)}_7$. Namely, the longitudinal polarisation fraction (F_{L}) is expected to be below 20% for $q^2 < 0.2\,\text{GeV}^2/c^4$. In this q^2 region, the angle ϕ between the planes defined by the dilepton system and the $K^{*0} \to K^+\pi^-$ decay is sensitive to the $b \to s\gamma$ photon helicity.

While the $K^{*0}\mu^+\mu^-$ final state is experimentally easier to select and measure at LHCb, the $K^{*0}e^+e^-$ final state allows q^2 values below $4m^2_\mu$ to be probed, where the sensitivity to the photon helicity is maximal. Compared to the radiative channels used for polarisation measurements, the $B^0 \to K^{*0}e^+e^-$ final state is fully charged and gives better mass resolution and therefore better separation from partially reconstructed backgrounds.

The sensitivity of this decay channel at LHCb was demonstrated by an angular analysis performed with Run 1 data [1137]. The angular observables most sensitive to the photon polarisation at low q^2 are $A^{(2)}_{\text{T}}$ and A^{Im}_{T}, as defined in Ref. [1137, 1138]. Indeed, in the limit $q^2 \to 0$, these observables can

be expressed by the following functions of $C_{7\gamma}^{(\prime)}$ (assuming NP contributions to be much smaller than $|C_{7\gamma}^{\rm SM}|$):

$$A_{\rm T}^{(2)}(q^2 \to 0) \simeq 2\frac{\mathcal{R}e(C_7^{\prime *})}{|C_7|} \quad \text{and} \quad A_{\rm T}^{\rm Im}(q^2 \to 0) \simeq 2\frac{\mathcal{I}m(C_7^{\prime *})}{|C_7|}. \tag{103}$$

In order to maximise the sensitivity to the photon polarisation, the angular analysis should be performed as close as possible to the low q^2 endpoint. However, the events at extremely low q^2 have worse ϕ resolution (because the two electrons are almost collinear) and are polluted by $B^0 \to K^{*0}\gamma$ decays with the γ converting in the VELO material. In the Run 1 analysis [1137] the minimum required $m(e^+e^-)$ was set at $20\,\text{MeV}/c^2$, but this should be reduced as the Upgrade II VELO detector will have a significantly lower material budget (multiple scattering is the main effect worsening the ϕ resolution). Similarly, the background from γ conversions will be reduced with a lighter RF-foil or with the complete removal of it in Upgrade II [807].

Using the signal yield as given in Table 31 leads to the following statistical sensitivities to $A_{\rm T}^{(2)}$ and $A_{\rm T}^{\rm Im}$: 12% with $8\,\text{fb}^{-1}$, 7% with $23\,\text{fb}^{-1}$ and 2% with $300\,\text{fb}^{-1}$. The theoretical uncertainty induced when this observable is translated into a photon polarisation measurement is currently at the level of 2% but should improve by the time of the Upgrade II analyses. The current measurements performed with Run 1 data have a systematic uncertainty of order 5% coming mainly from the modelling of the angular acceptance and from the uncertainty on the angular shape of the combinatorial background. The acceptance is independent of ϕ at low q^2 and its modelling can be improved with larger simulation samples and using the proxy channel $B^0 \to K^{*0}J/\psi(\to e^+e^-)$.

Weak radiative decays of b baryons are largely unexplored, with the best limits coming from CDF: $\mathcal{B}(\Lambda_b^0 \to \Lambda\gamma) < 1.3 \times 10^{-3}$ at 90% CL [1139]. They offer a unique sensitivity to the photon polarisation through the study of their angular distributions, and will constitute one of the main topics in the radiative decays programme in the LHCb Upgrade II.

With predicted branching fractions of $O(10^{-5} - 10^{-6})$, the first challenge for LHCb will be their observation, as the production of long-lived particles in their decay, in addition to the photon, means in most cases that the b-baryon secondary vertex cannot be reconstructed. This makes their separation from background considerably more difficult than in the case of regular radiative b decays.

The most abundant of these decays is $\Lambda_b^0 \to \Lambda(\to p\pi^-)\gamma$, which is sensitive to the photon polarisation mainly[7] through the distribution of the angle between the proton and the Λ momentum in the rest frame of the Λ (θ_p),

$$\frac{\mathrm{d}\,\Gamma}{\mathrm{d}\cos\theta_p} \propto 1 - \alpha_\gamma \alpha_{p,1/2} \cos\theta_p, \tag{104}$$

where α_γ is the asymmetry between left- and right-handed amplitudes and $\alpha_{p,1/2} = 0.642 \pm 0.013$ [310] is the $\Lambda \to p\pi^-$ decay parameter. Using specialised trigger lines for this mode $15 - 150$ signal events are expected using the Run 2 dataset. Preliminary studies show that a statistical sensitivity to α_γ of $(20 - 25)\%$ is expected with these data, which would be reduced to $\sim 15\%$ with $23\,\text{fb}^{-1}$ and below 4% with $300\,\text{fb}^{-1}$. In the LHCb Upgrade II, the addition of timing information in the calorimeter will be important to be able to study this combinatorial-background dominated decay; additionally, improved downstream reconstruction would allow the use of downstream Λ decays, which make up more than 2/3 of the total signal.

The $\Xi_b \to \Xi^-(\to \Lambda(\to p\pi^-)\pi^-)\gamma$ decay presents a richer angular distribution, with dependence to the photon polarisation in both the Λ angle (θ_Λ) and proton angle (θ_p),

$$\frac{\mathrm{d}\,\Gamma}{\mathrm{d}\cos\theta_\Lambda \cos\theta_p} \propto 1 - \alpha_\gamma \alpha_\Xi \cos\theta_\Lambda + \alpha_{p,1/2} \cos\theta_p \left(\alpha_\Xi - \alpha_\gamma \cos\theta_\Lambda\right), \tag{105}$$

[7] In the following, we assume that the Λ_b^0 (and any other beauty baryon) polarisation is zero [1140], removing part of the photon polarisation dependence.

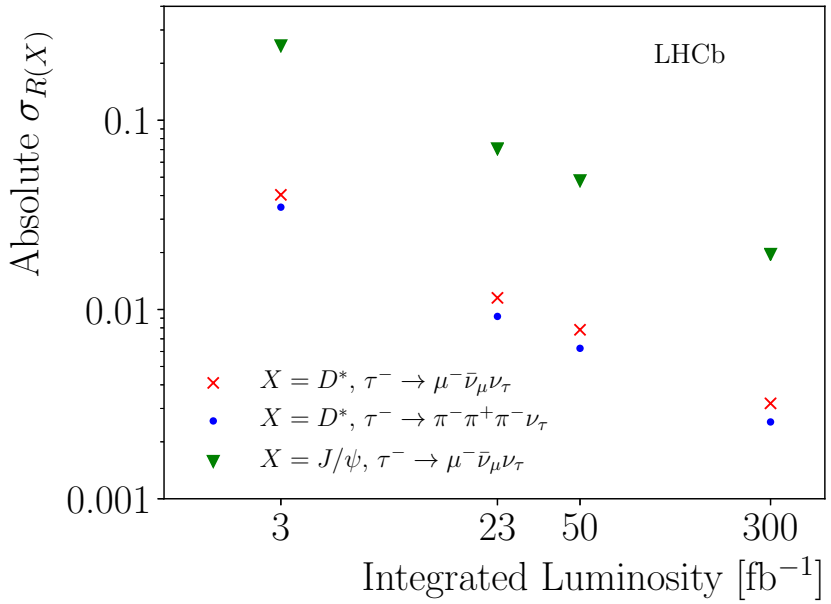

Fig. 55: The projected absolute uncertainties on $\mathcal{R}(D^*)$ and $\mathcal{R}(J/\psi)$ from the current sensitivities (at 3 fb^{-1}) to 23 fb^{-1}, 50 fb^{-1}, and 300 fb^{-1}.

but the lower $\sigma(pp \to \Xi_b)$, combined with a lower reconstruction efficiency due to the presence of one extra track, results in an order of magnitude fewer events than in the Λ_b^0 case, making the increase of statistics from the Upgrade II even more relevant. With a similar sensitivity to the photon polarisation to that of $\Lambda_b^0 \to \Lambda(\to p\pi^-)\gamma$, $\Xi_b \to \Xi^-\gamma$ decays will allow this parameter to be probed with a precision of 40% and 10% with 23 and 300 fb^{-1}, respectively.

7.3.7 *Measurements of $b \to c\ell\nu$ including B_c and b-baryon prospects*

LHCb has made measurements of $R(D^{(*)})$ using both muonic ($\tau^+ \to \mu^+\nu\nu$) and hadronic ($\tau^+ \to \pi^+\pi^-\pi^+\nu$) decays of the tau lepton [16, 17, 997]. Due to the presence of multiple neutrinos these decays are extremely challenging to measure. The measurements rely on isolation techniques to suppress partially reconstructed backgrounds, B meson flight information to constrain the kinematics of the unreconstructed neutrinos, and a multidimensional template fit to determine the signal yield. Fig. 55 shows how the absolute uncertainties on the LHCb muonic and hadronic $\mathcal{R}(D^*)$ measurements are projected to evolve with respect to the current status. The major uncertainties are the statistical uncertainty from the fit, the uncertainties on the background modelling and the limited size of simulated samples. A major effort is already underway to commission fast simulation tools. The background modelling is driven by a strategy of dedicated control samples in the data, and so this uncertainty will continue to improve with larger data samples. From Run 3 onward it is assumed that, taking advantage of the full software HLT, the hadronic analysis can normalise directly to the $B^0 \to D^{*-}\mu^+\nu_\mu$ decay, thus eliminating the uncertainty from external measurements of $\mathcal{B}(B^0 \to D^{*-}\pi^+\pi^-\pi^+)$. It is assumed that all other sources of systematic uncertainty will scale as $\sqrt{\mathcal{L}}$. With these assumptions, an absolute uncertainty on $\mathcal{R}(D^*)$ of 0.003 will be achievable for the muonic and hadronic modes with the 300 fb^{-1} Upgrade II dataset.

On the timescale of Upgrade II, interest will shift toward new observables beyond the branching fraction ratio [1141]. The kinematics of the $B \to D^*\tau\nu$ decays is fully described by the dilepton mass, and three angles which are denoted χ, θ_L and θ_D. LHCb is capable of resolving these three angles, as can be seen in Fig. 56. However, the broad resolutions demand very large samples to extract the underlying physics. The decay distributions within this kinematic space are governed by the underlying spin

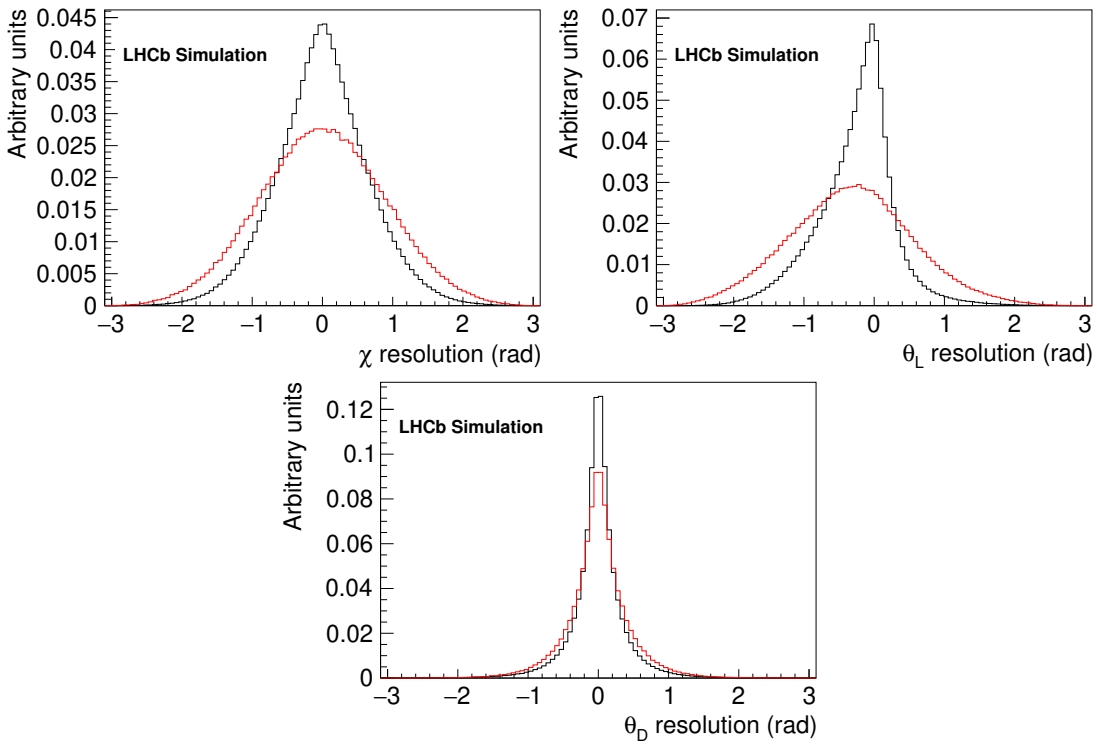

Fig. 56: Angular resolution for simulated $B \to D^* \mu\nu$ (black) and $B \to D^* \tau\nu$ (red) decays, with $\tau^+ \to \mu^+ \nu\nu$. This demonstrates our ability to resolve the full angular distribution, with some level of statistical dilution.

structure, and precise measurements of these distributions will allow the different helicity amplitudes to be disentangled. This can be used both to constrain the Lorentz structure of any potential NP contribution, and to measure the hadronic parameters governing the $B \to D^* \tau\nu$ decay, serving as an essential baseline for SM and non-SM studies. The helicity-suppressed amplitude which presently dominates the theoretical uncertainty on $R(D^{(*)})$ is too strongly suppressed in the $B \to D^{(*)} \mu\nu$ decays to be measurable, however this can be accessed in the $B \to D^{(*)} \tau\nu$ decay directly. If any potential NP contributions are assumed not to contribute via the helicity-suppressed amplitude then the combined measurements of $B \to D^{(*)} \mu\nu$ and $B \to D^{(*)} \tau\nu$ decays will allow for a fully data-driven prediction for $R(D^{(*)})$ under the assumption of lepton universality, eliminating the need for any theory input relating to hadronic form factors. However, these measurements have yet to be demonstrated with existing data. This exciting programme of differential measurements needs to be developed on Run 1 and 2 data before any statement is made about the precise sensitivity, but it offers unparalleled potential to fully characterise both the SM and non-SM contributions to the $b \to c\tau\nu$ transition.

As measurements in $\mathcal{R}(D^*)$ become more statistically precise, it will become increasingly more urgent to provide supplementary measurements in other b-hadron species with different background structure and different sources of systematic uncertainties. For example, the $\overline{B}{}^0_s \to D^+_s \tau^- \overline{\nu}$ and $\overline{B}{}^0_s \to D^{*+}_s \tau^- \overline{\nu}$ decays will allow supplementary measurements at high yields, and do not suffer as badly from cross-feed backgrounds from other mesons, unlike, for example, $\overline{B}{}^0 \to D^{*+} \tau^- \overline{\nu}$, where the B^+ and B^0_s both contribute to the $D^{*+} \mu X$ or $D^{*+} \pi^- \pi^+ \pi^- X$ final states. Furthermore, the comparison of decays with different spins of the b and c hadrons can enhance our sensitivity to different NP scenarios [77,1142]. No published measurements exist for the B^0_s case yet, but based on known relative efficiencies and assuming the statistical power of this mode tracks $\mathcal{R}(D^{(*)})$, we expect less than 6% relative uncertainty after Run 3, and 2.5% with the Upgrade II data, where limiting systematic uncertainties are currently

expected to arise from corrections to simulated pointing and vertex resolutions, from knowledge of particle identification efficiencies, and from knowledge of the backgrounds from random combinations of charm and muons. It is conceivable that new techniques and control samples could further increase the precision of these measurements.

Methods are currently under development for separating the $\overline{B}{}^0_s \to D_s^{*+}\ell^-\overline{\nu}$ and $\overline{B}{}^0_s \to D_s^+\ell^-\overline{\nu}$ modes, and given the relative slow pion ($D^{*+} \to D^0\pi^+$) and soft photon ($D_s^{*+} \to D_s^+\gamma$) efficiencies, the precision in $\overline{B}{}^0_s \to D_s^+\tau\nu$ decays can be expected to exceed that in $\overline{B}{}^0_s \to D_s^{*+}\tau\nu$, the reverse of the situation for $\mathcal{R}(D^{(*)})$. An upgraded ECAL would extend the breadth and sensitivity of $\mathcal{R}(D_s^{*(*)+})$ measurements possible in the Upgrade II scenario above and beyond the possible benefits of improved neutral isolation in $\mathcal{R}(D)$ or $\mathcal{R}(D_s^+)$ measurements.

Of particular interest are the semitauonic decays of b baryons and of B_c^+ mesons. The former provides probes of entirely new Lorentz structures of NP operators which pseudoscalar to pseudoscalar or vector transitions simply do not access. The value of probing this supplementary space of couplings has already been demonstrated by LHCb with its Run 1 measurement of $|V_{ub}|$ via the decay $\Lambda_b^0 \to p\mu^-\overline{\nu}$, which places strong constraints on right-handed currents sometimes invoked to explain the inclusive-exclusive tensions in that quantity. By the end of Run 3, it is expected that the relative uncertainty for $\mathcal{R}(\Lambda_c^+)$ will reach below 4%, and 2.5% by the end of Upgrade II. A further exciting prospect is the study of $b \to u\mu\nu$ decays, which have been beyond experimental reach thus far. For example the decay $B^+ \to p\bar{p}\mu\nu$ offers a clean experimental signature. Our capabilities with this decay could benefit from the enhanced low momentum proton identification with the TORCH subdetector.

Meanwhile, the $B_c^+ \to J/\psi\,\tau^-\overline{\nu}$ decay is an entirely unique state among the flavoured mesons as the bound state of two distinct flavors of heavy quark, and, through its abundant decays to charmonium final states, provides a highly efficient signature for triggering and reconstruction at high instantaneous luminosities. Measurements of $B_c^+ \to J/\psi\,\ell\overline{\nu}$ decays involve a trade-off between the approximately 100 times smaller production cross-section for B_c^+ verses the extremely efficient $J/\psi \to \mu^+\mu^-$ signature in the LHCb trigger. For illustration, in Run 1, LHCb reconstructed and selected 19 000 $B_c^+ \to J/\psi\,\mu^-\overline{\nu}$ decays, compared with 360 000 $\overline{B}{}^0 \to D^{*+}\mu^-\overline{\nu}$. This resulted in a measurement of $\mathcal{R}(J/\psi) = 0.71 \pm 0.17 \pm 0.18$ [18]. As a result of the smaller production cross-section, the muonic measurements have large backgrounds from $h \to \mu$ misidentification from the relatively abundant $B \to J/\psi\,X_h$ decays, where X_h is any collection of hadrons, and so they are very sensitive to the performance of the muon system and PID algorithms in the future. Here it is assumed that it will be possible to achieve similar performance to Run 1 in the upgraded system.

To project the sensitivity for $B_c^+ \to J/\psi\,\tau^-\overline{\nu}$ based on Ref. [18], it is assumed that all the systematic uncertainties can be reduced with the size of the input data except for those that were assumed not to scale with data for the previous predictions. For these, we assume that they can be reduced down until they reach the same absolute size as the corresponding systematic uncertainties in the Run 1 muonic $\mathcal{R}(D^*)$ analysis. In addition, it is assumed that sometime in the 2020s lattice QCD calculations of the form factors for this process will allow the systematic uncertainty due to signal form factors to be reduced by an additional factor of two. This results in a projected absolute uncertainty for the muonic mode of 0.07 at the end of Run 3 and 0.02 by the end of Upgrade II, as can be seen in Fig. 55. Measurements in the hadronic mode can be expected to reach similar sensitivities.

7.3.8 Searches for LFV, LNV, BNV and interplay with tests of LU

The LHCb collaboration has recently published [1143] the world's best limits on the branching fractions of the $B_s^0 \to e^\pm\mu^\mp$ and $B^0 \to e^\pm\mu^\mp$ decays using the first $3\,\text{fb}^{-1}$ collected in 2011 and 2012 at 7 and 8 TeV respectively. The acceptance of the $B_s^0 \to e^\pm\mu^\mp$ decays can be affected by the relative contribution of the two B_s^0 mass eigenstates to the total decay amplitude, due to their large lifetime difference. Therefore, the upper limit on the branching fraction of $B_s^0 \to e^\pm\mu^\mp$ decays is evaluated in two extreme

hypotheses: where the amplitude is completely dominated by the heavy eigenstate or by the light eigenstate. The results are $\mathcal{B}(B_s^0 \to e^\pm\mu^\mp) < 6.3\,(5.4) \times 10^{-9}$ and $\mathcal{B}(B_s^0 \to e^\pm\mu^\mp) < 7.2\,(6.0) \times 10^{-9}$ at 95% (90%) CL, respectively. The limit for the branching fraction of the B^0 mode is $\mathcal{B}(B^0 \to e^\pm\mu^\mp) < 1.3\,(1.0) \times 10^{-9}$ at 95% (90%) CL.

Assuming similar performances in background rejection and signal retention as in the current analysis, at the end of Run 4 the LHCb experiment will be able to probe branching fractions of $B_s^0 \to e^\pm\mu^\mp$ and $B^0 \to e^\pm\mu^\mp$ decays down to 8×10^{-10} and 2×10^{-10}, respectively. The additional statistics accumulated during the Upgrade II data taking period will push down these limits to 3×10^{-10} and 9×10^{-11} respectively, close to the interesting region where NP effects may appear. The Upgrade II improvement in electron reconstruction will be very important in attaining, or exceeding, this goal.

An upper limit on the $B^0 \to \tau^\pm\mu^\mp$ channel has been already set by BaBar: $\mathcal{B}\left(B^0 \to \tau^\pm\mu^\mp\right) < 2.2 \times 10^{-5}$ at 90% CL [1144]. The first search for the $B_s^0 \to \tau^\pm\mu^\mp$ channel is in progress in LHCb and the results are expected soon on data recorded in 2011 and 2012 using the $\tau^\pm \to \pi^\pm\pi^\mp\pi^\pm\nu$ and $\tau^\pm \to \pi^\pm\pi^\mp\pi^\pm\pi^0\nu$ decay modes. Given the presence of a neutrino that escapes detection this kind of analysis is much more complicated than those investigating electron or muon final states. A specific reconstruction technique is used in order to infer the energy of the ν, taking advantage of the known τ vertex position given by the 3π reconstructed vertex. This way, the complete kinematics of the process can be solved up to a two-fold ambiguity. LHCb expects to reach sensitivities of a few times 10^{-5} with the Run 1 and 2 data sets. Extrapolating the current measurements to the Upgrade II LHCb could reach $\mathcal{B}\left(B^0 \to \tau^\pm\mu^\mp\right) < 3 \times 10^{-6}$ at 90% CL. The mass reconstruction technique depends heavily on the uncertainty on the primary and the τ decay vertices, hence improvement in the tracking system in Upgrade II, including a removal or reduction in material of the VELO RF foil, will be very valuable.

In many generic NP models with LFUV, CLFV decays of b-hadrons can be linked with the anomalies recently measured in $b \to s\ell\ell$ decays [5, 6, 899]. If NP indeed allows for CLFV then the branching fractions of $B \to K\ell\ell'$ or $\Lambda_b^0 \to \Lambda\ell\ell'$ will be enhanced with respect to their purely leptonic counterparts, since the helicity suppression is lower. Furthermore, if observed, they would allow the measurement of more observables with respect to the lepton flavour violating decays discussed in the previous sections, thanks to their multi-body final states and, in the case of Λ_b^0, to the non-zero initial spin.

The current limits set by the B-Factories on the branching fractions of $B \to Ke\mu$ and $B \to K\tau\mu$ decays are $< 13 \times 10^{-8}$ [1107] and $< 4.8 \cdot 10^{-5}$ [1145] at 90% confidence level, respectively.

At LHCb, searches for $B^+ \to K^+e^\pm\mu^\mp$, $B^0 \to K^{*0}\tau^\pm\mu^\mp$, $B^+ \to K^+\tau^\pm\mu^\mp$ and $\Lambda_b^0 \to \Lambda e^\pm\mu^\mp$ are ongoing. These searches are complementary, as charged lepton flavour violation couplings among different families are expected to be different. The analyses involving τ leptons reconstruct candidates via the $\tau^- \to \pi^-\pi^-\pi^+\nu_\tau$ channel, which allows the reconstruction of the τ decay vertex.[8] All these decays contain at least one muon, which is used to efficiently trigger on the event. Usually, since these decays involve combinations of leptons that are not allowed in the SM, the backgrounds can be kept well under control, leaving very clean samples only polluted by candidates formed by the random combinations of tracks. This combinatorial effect is higher for the channel with a τ in the final state decaying into three charged pions. The other relevant background comes from chains of semileptonic decays, where two or more neutrinos are emitted and therefore combinations of leptons of different flavours are possible. These decays have typically a low reconstructed invariant mass, due to the energy carried away by the neutrinos, and so they do not significantly pollute the signal region.

The expected upper limits at LHCb using the first $9\,\text{fb}^{-1}$ of data taken are $\mathcal{O}(10^{-9})$ and $\mathcal{O}(10^{-6})$ for the $B^+ \to K^+e^\pm\mu^\mp$ and $B^0 \to K^{*0}\tau^\pm\mu^\mp$ decays respectively, at 90% confidence level. The limit for $B^+ \to K^+\tau^\pm\mu^\mp$ is expected to be similar to $B^0 \to K^{*0}\tau^\pm\mu^\mp$. The sensitivity of these analyses

[8] It should be noted that searches for $B^+ \to K^+\tau^\pm\mu^\mp$ from B_{s2}^* without τ reconstruction can give complementary information.

scales almost linearly with luminosity for $B^+ \to K^+ e^\pm \mu^\mp$, and with the square root of the luminosity for $B^0 \to K^{*0} \tau^\pm \mu^\mp$. In both cases, the expected limits using the Upgrade II data are in the region of interest of the models currently developed for explaining the B anomalies, so they will provide strong constraints on the NP scenarios with CLFV

Experimentally, Lepton-Number Violating (LNV) and Baryon-Number Violating (BNV) measurements are null searches, so sensitivity is assumed to scale linearly with luminosity $\mathcal{L}$ when the background is negligible and as $\sqrt{\mathcal{L}}$ if the background is significant. LHCb has already published searches in certain channels, and others are in progress:

- Searches for LNV in various B-meson decays of the form $B \to X\mu^+\mu^+$, where X is a system of one or more hadrons. The principal motivation is the sensitivity to contributions from Majorana neutrinos [1146], which may be on-shell or off-shell, depending on the decay mode. The published results consist of searches for $B^+ \to K^-\mu^+\mu^+$, $B^+ \to \pi^-\mu^+\mu^+$ and $B^+ \to D^+_{(s)}\mu^-\mu^-$ [1147–1149]. A limit of $\mathcal{B}(B^+ \to \pi^-\mu^+\mu^+) < 4 \times 10^{-9}$ is set at the 95% confidence level, along with more detailed limits as a function of the Majorana neutrino mass. Since the combinatorial background was found to be low but not negligible with the Run 1 data, we estimate that the limit can be improved by a factor of ten with the full Upgrade II dataset.
- Search for BNV in Ξ_b^0 oscillations [438]. Six-fermion, flavour-diagonal operators, involving two fermions from each generation, could give rise to BNV without violating the nucleon stability limit [1150,1151]. Since the Ξ_b^0 (bsd) has one valence quark from each generation, it could couple directly to such an operator and oscillate to $\overline{\Xi}_b^0$. The published search used the Run 1 data and set a lower limit on the oscillation period of 80 ps. Since events are tagged by decays of the $\Xi_b^{\prime-}$ and Ξ_b^{*-} resonances, with the former being particularly clean, and since the analysis also uses the decay-time distribution of events, the sensitivity is expected to scale linearly. Although the decay mode used in the published analysis is hadronic ($\Xi_b^0 \to \Xi_c^+\pi^-$), future work could also benefit from the lower-purity but higher-yield semileptonic mode $\Xi_b^0 \to \Xi_c^+\mu^-\overline{\nu}_\mu$.
- $\Lambda_c^+ \to \overline{p}\mu^+\mu^+$. This channel has previously been investigated at the e^+e^- B-Factories. The current upper limit, obtained by BaBar [1152], is $\mathcal{B}(\Lambda_c^+ \to \overline{p}\mu^+\mu^+) < 9.4 \times 10^{-6}$ at the 90% confidence level. With Run 1 and 2 data alone, it should be possible to reduce this to 1×10^{-6}. Further progress depends on the background level, but an additional factor of 5–10 with the full Upgrade II statistics is likely.
- $\Lambda_c^+ \to \mu^+\mu^-\mu^+$. Experimentally, this is a particularly promising decay mode: the final state with three muons is very clean, and there are no known sources of peaking background. This search could be added for little extra effort to the $\tau^- \to \mu^+\mu^-\mu^-$ search described in the preceding section.

8 The top quark and flavour physics

Among the SM fermions the top quark stands out. It has a large mass and an $\mathcal{O}(1)$ coupling to the Higgs, quite distinct from any other SM fermion. Studying top quark properties may shed light on the resolution of the SM flavour puzzle, or at least as to why one and only one Yukawa coupling is large. The large Higgs-top coupling is also the reason for the weak scale hierarchy problem to be so acute – the quadratic divergent corrections to the Higgs mass are driven almost completely by this coupling. BSM models addressing the hierarchy problem may thus well leave an imprint in the top quark properties and decays. For instance, the FCNC top decays, $t \to c\gamma, cZ, cg$, are null tests of the SM and are used as BSM probes.

Top quark also directly enters the flavour phenomenology. Loops with the top quark are responsible for the largest short-distance contributions to the down-quark FCNCs. The SM predictions are thus controlled by the flavour couplings of the top – with B and K transitions determining the CKM matrix elements V_{tb}, V_{ts}, V_{td} through these virtual effects. Determining V_{tx} directly from high $p_{\rm T}$ transitions, as well as the structure of the Wtb vertices, can then serve as independent consistency checks of the SM.

Top quarks can also be used as a clean source of tagged B mesons. Ref. [1153], for instance, suggested to use top-pair events, where at least one of the tops decays semi-leptonically, to measure CP violation in heavy flavor mixing and decays. This measurement was then performed for the first time at by ATLAS in Ref. [1154].

The LHC is already a top factory and the currently available statistics has allowed ATLAS and CMS to perform a vast campaign of top related measurements. However, the larger number of top quarks at HL-LHC and HE-LHC will open new possibilities for precise measurements of top-quark properties and for significant improvements probing NP, such as the rare FCNC decays.

8.1 Global effective-field-theory interpretation of top-quark FCNCs

Authors (TH): Gauthier Durieux, Teppei Kitahara, Cen Zhang.

8.1.1 Effective operators

Starting from an Effective Field Theory (EFT) with full $SU(3)_C \times SU(2)_L \times U(1)_Y$ gauge symmetry and matter content of the SM, one can show that odd-dimensional operators all violate baryon or lepton numbers [1155]. Imposing the conservation of these quantum numbers, the leading higher dimensional operators of the SM arise at dimension six. We follow the top-quark EFT conventions set by the LHC TOP WG in Ref. [1156]. The LHC TOP WG employs linear combinations of Warsaw-basis operators [375] which appear in interactions with physical fields after electroweak symmetry breaking.

The operators contributing to top-quark FCNC processes fall into several categories. We consider operators involving exactly two quarks, as well as those involving two quarks and two leptons. Operators containing four quarks only start contributing at next-to-leading order in QCD in most of the measurements we consider ($pp \to tj$ is the exception). The corresponding Warsaw-basis operators are [1156]

$$
\begin{aligned}
O_{u\varphi}^{(ij)} &= \bar{q}_i u_j \tilde{\varphi}\,(\varphi^\dagger\varphi), & O_{lq}^{1(ijkl)} &= (\bar{l}_i\gamma^\mu l_j)(\bar{q}_k\gamma^\mu q_l),\\
O_{\varphi q}^{1(ij)} &= (\varphi^\dagger i\overleftrightarrow{D}_\mu\varphi)(\bar{q}_i\gamma^\mu q_j), & O_{lq}^{3(ijkl)} &= (\bar{l}_i\gamma^\mu\tau^I l_j)(\bar{q}_k\gamma^\mu\tau^I q_l),\\
O_{\varphi q}^{3(ij)} &= (\varphi^\dagger i\overleftrightarrow{D}^I_\mu\varphi)(\bar{q}_i\gamma^\mu\tau^I q_j), & O_{lu}^{(ijkl)} &= (\bar{l}_i\gamma^\mu l_j)(\bar{u}_k\gamma^\mu u_l),\\
O_{\varphi u}^{(ij)} &= (\varphi^\dagger i\overleftrightarrow{D}_\mu\varphi)(\bar{u}_i\gamma^\mu u_j), & O_{eq}^{(ijkl)} &= (\bar{e}_i\gamma^\mu e_j)(\bar{q}_k\gamma^\mu q_l),\\
O_{\varphi ud}^{(ij)} &= (\tilde{\varphi}^\dagger iD_\mu\varphi)(\bar{u}_i\gamma^\mu d_j), & O_{eu}^{(ijkl)} &= (\bar{e}_i\gamma^\mu e_j)(\bar{u}_k\gamma^\mu u_l),\\
O_{uW}^{(ij)} &= (\bar{q}_i\sigma^{\mu\nu}\tau^I u_j)\,\tilde{\varphi}W^I_{\mu\nu}, & O_{lequ}^{1(ijkl)} &= (\bar{l}_i e_j)\,\varepsilon\,(\bar{q}_k u_l),\\
O_{dW}^{(ij)} &= (\bar{q}_i\sigma^{\mu\nu}\tau^I d_j)\,\varphi W^I_{\mu\nu}, & O_{lequ}^{3(ijkl)} &= (\bar{l}_i\sigma^{\mu\nu} e_j)\,\varepsilon\,(\bar{q}_k\sigma_{\mu\nu} u_l),\\
O_{uB}^{(ij)} &= (\bar{q}_i\sigma^{\mu\nu} u_j)\quad\tilde{\varphi}B_{\mu\nu}, & O_{ledq}^{(ijkl)} &= (\bar{l}_i e_j)(\bar{d}_k q_l)\\
O_{uG}^{(ij)} &= (\bar{q}_i\sigma^{\mu\nu}T^A u_j)\,\tilde{\varphi}G^A_{\mu\nu}
\end{aligned}
\tag{106}
$$

The operators $O_{\varphi ud}$, O_{dW}, and O_{ledq}, only contribute to charged top-quark currents (not considering SM electroweak corrections) and are therefore not relevant for our purposes. The EFT degrees of freedom appearing in top-quark FCNC processes were defined in Appendices E.1-2 of Ref. [1156]. They are:

$$
\begin{aligned}
c_{t\varphi}^{[I](3a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{u\varphi}^{(3a)}\}, & c_{uA}^{[I](3a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{c_W C_{uB}^{(3a)} + s_W C_{uW}^{(3a)}\}, &(107)\\
c_{t\varphi}^{[I](a3)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{u\varphi}^{(a3)}\}, & c_{uA}^{[I](a3)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{c_W C_{uB}^{(a3)} + s_W C_{uW}^{(a3)}\}, &(108)\\
c_{\varphi q}^{-[I](3+a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{\varphi q}^{1(3a)} - C_{\varphi q}^{3(3a)}\}, & c_{uZ}^{[I](3a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{-s_W C_{uB}^{(3a)} + c_W C_{uW}^{(3a)}\}, &(109)\\
c_{\varphi u}^{[I](3+a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{\varphi u}^{(3a)}\}, & c_{uZ}^{[I](a3)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{-s_W C_{uB}^{(a3)} + c_W C_{uW}^{(a3)}\}, &(110)
\end{aligned}
$$

as well as $c_{uG}^{[I](3a)} \equiv \underset{\text{Re}}{[\text{Im}]}\{C_{uG}^{(3a)}\}$, $c_{uG}^{[I](a3)} \equiv \underset{\text{Re}}{[\text{Im}]}\{C_{uG}^{(a3)}\}$, and

$$
\begin{aligned}
c_{lq}^{-[I](\ell,3+a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{lq}^{-(\ell\ell 3a)}\}, & c_{lequ}^{S[I](\ell,3a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{lequ}^{1(\ell\ell 3a)}\}, &(111)\\
c_{eq}^{[I](\ell,3+a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{eq}^{(\ell\ell 3a)}\}, & c_{lequ}^{S[I](\ell,a3)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{lequ}^{1(\ell\ell a3)}\}, &(112)\\
c_{lu}^{[I](\ell,3+a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{lu}^{(\ell\ell 3a)}\}, & c_{lequ}^{T[I](\ell,3a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{lequ}^{3(\ell\ell 3a)}\}, &(113)\\
c_{eu}^{[I](\ell,3+a)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{eu}^{(\ell\ell 3a)}\}, & c_{lequ}^{T[I](\ell,a3)} &\equiv \underset{\text{Re}}{[\text{Im}]}\{C_{lequ}^{3(\ell\ell a3)}\}. &(114)
\end{aligned}
$$

Compared to the anomalous coupling parametrization, the EFT approach has two features that are worth emphasizing. First, it includes four-fermion operators, which have been unduly neglected in most experimental analyses (apart from Ref. [1158]). Second, the EFT approach captures the correlations between interaction terms that derive from electroweak gauge invariance. For instance, the $\bar{t}\sigma^{\mu\nu}T^A q\; h\; G^A_{\mu\nu}$ and $\bar{t}\sigma^{\mu\nu}T^A q\; G^A_{\mu\nu}$ interactions arise from the same O_{uG} operator and their coefficients are thus related. In Fig. 57, we show examples of four-point interactions contributing to single top-quark FCNC production. Correlations also arise from the fact that left-handed down- and up-type quarks belong to a single gauge-eigenstate doublet. Operator coefficients measurable in B-meson physics are thus related to those relevant to top-quark physics (see Secs. 8.1.5 and 8.2.2).

8.1.2 Theory predictions

Because the LHC is a hadron collider, theory predictions at LO are often not sufficient when an accurate interpretation of observables in terms of theory parameters is needed. Typical NLO QCD corrections in top-decay processes [1159–1164] amount to approximately 10%, while in production processes they can reach between about 30% and 80% [1165–1169]. Theory predictions for top-quark FCNC processes are in general available at NLO accuracy in QCD. Complete results at NLO in QCD for top-quark FCNC

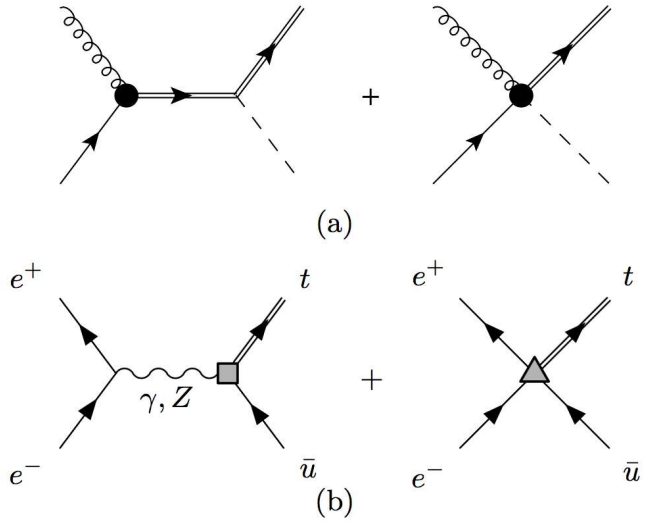

Fig. 57: Effective operators give rise to four-point contact interactions that are overlooked in the approach with anomalous couplings, although they contribute to FCNC processes at the same order in $1/\Lambda^2$ as the three-point ones. Representative diagrams are shown for $ug \to th$ production (or radiative $t \to hug$ decay), and $e^+e^- \to t\,\bar{u}$ (or $t \to u\,e^+e^-$ decay). Figure taken from Ref. [1157].

decays through two-quark and two-quark–two-lepton operators can be found in Ref. [1164]. Single top-quark production associated with a neutral gauge boson, γ, Z, or the scalar boson h have also been studied. Two-quark operators have been implemented in the `FeynRules/MadGraph5_aMC@NLO` simulation chain [372, 1170, 1171], allowing for automated NLO QCD predictions matched to parton shower. Details on this implementation have been presented in Ref. [1172]. Two-quark-two-lepton operators are now also available in `MadGraph5_aMC@NLO` (see Ref. [1173]). Finally, the direct top-quark production with decay process, $pp \to bW^+$, involves additional technical difficulties due to the intermediate top-quark resonance. It is now being studied, and the corresponding NLO generator matched to parton shower will be available in the future [1174].

8.1.3 Existing limits

Table 32 lists the existing limits on FCNC processes. We follow Ref. [1157] and interpret them in a global EFT analysis. Several additional remarks are in order:

- For $t \to q\ell\ell$ we use the predictions at NLO in QCD provided in Ref. [1157] for the $m_{\ell\ell} \in [78, 102]$ GeV range although the most stringent constraints by ATLAS are set using $|m_{\ell\ell} - m_Z| < 15$ GeV. The CMS bounds obtained by combining production and decay process cannot be reinterpreted to include four-fermion operators.
- For single top-quark production through the tqg interaction, we use the best constraints: in the up-quark channel by CMS and in the charm-quark channel by ATLAS. We naively combine them using the numerical value at NLO in QCD for the $t \to jj$ branching fraction provided in Sec. V.B of Ref. [1157].
- For single top-quark production in association with a photon, we note the very interesting fiducial limit provided by Ref. [1175] which allows for an accurate reinterpretation. However, we use the simplified approach of Ref. [1157] based on the limit quoted on the total cross section and use the numerical values computed at NLO in QCD for $pp \to t\gamma + \bar{t}\gamma$ with a 30 GeV cut on the photon $p_{\rm T}$ although a 50 GeV cut was applied in Ref. [1175].
- For $t \to hj$ decay we use the most stringent limits set by ATLAS in the multilepton channel. The

Table 32: Summary of the existing 95% C.L. limits on top-quark FCNC branching fractions obtained at the LHC. A summary plot is available at https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots#table21. Ref. [1175] has set limits in a fiducial volume at the particle level for $pp \to t\gamma$ (not displayed in this table). Numbers in bold are used as inputs to the global EFT analysis.

dependence on all operator coefficients, except $C_{t\phi}$ and C_{tG}, is assumed to be negligible.

- Limits on $e^+e^- \to tj + \bar{t}j$ obtained at LEP II [1184] still dominate constraints on four-fermion operators involving electrons, while $t \to q\ell\ell$ at hadron colliders are the only measurements constraining four-fermion operators featuring a pair of muons. However, the latter limits are not explicitly shown below. We use the limit from the highest LEP II centre-of-mass energy, $\sqrt{s} = 207$ GeV, which is the most sensitive to four-fermion operators, $\sigma(e^+e^- \to tj + \bar{t}j) < 170$ fb.

The global analysis based on existing data gives 95% C.L. limits on the EFT Wilsons coefficients in the notation of Ref. [1156], shown in Fig. 58 (left panel). As explained in Ref. [1157], no statistical combination is attempted, i.e., limits from different measurements are only overlaid. Fig. 59 (left panel) show two-dimensional constraints in the $c^-_{\varphi q,\varphi u}$,$c_{eq,eu}$ plane. This illustrates the complementarity between the LHC and the LEP II measurements; the former gives better constraints on two-fermion operators, the latter on four-fermion operators.

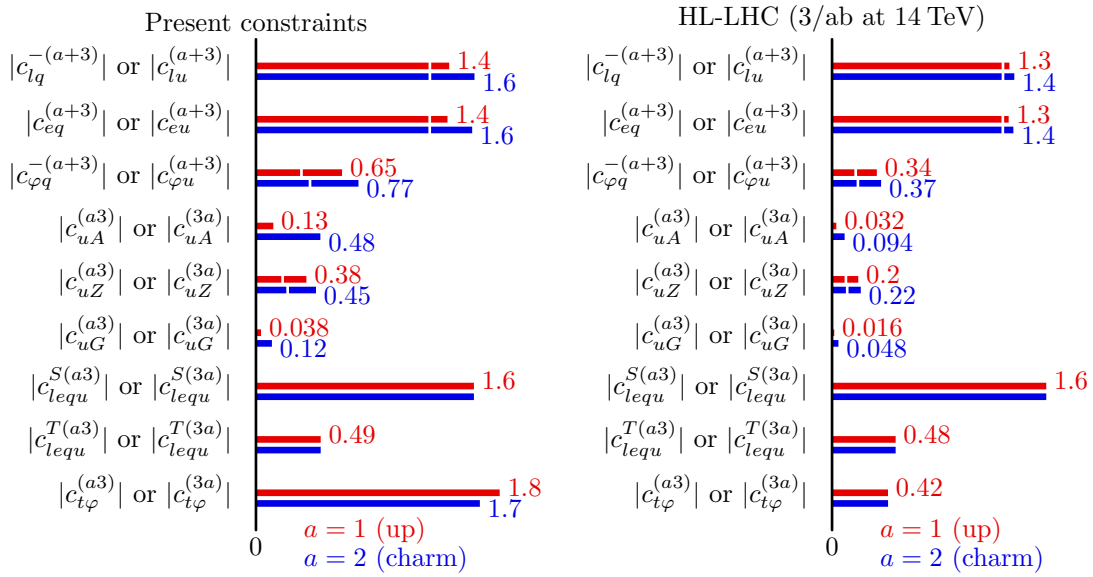

Fig. 58: Current (left) and projected HL-LHC (right) 95% C.L. limits on top-quark FCNC operator coefficients in the conventions of Ref. [1156]. Red and blue bars denote top-up and top-charm FCNCs, respectively. White marks indicate individual limits, obtained under the unrealistic assumption that all the other operator coefficients vanish.

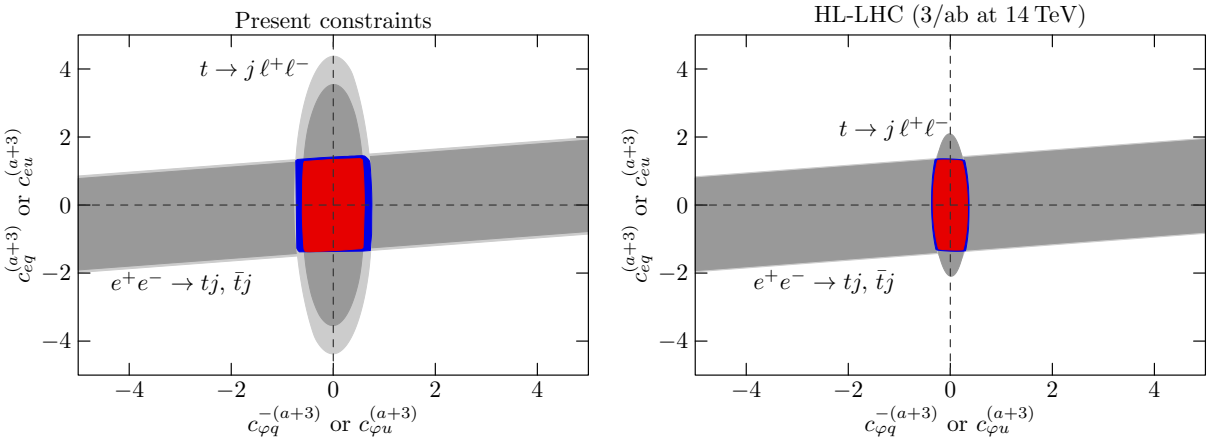

Fig. 59: Current (left) and prospective HL-LHC (right) 95% C.L. limits on top-quark FCNC operator coefficients in a two-dimensional plane formed by two- (x axis) and four-fermion (y axis) operator coefficients. Other parameters are marginalized over, within the constraints obtained when all measurements are included. Red and blue regions are the combined constraints for top-up and top-charm FCNCs. The impact of $t \to j\ell^+\ell^-$ and $e^+e^- \to tj, \bar{t}j$ measurements is displayed separately in dark and light gray colors for top-up and top-charm FCNCs, respectively.

8.1.4 Future limits

We use the prospects presented in Sec. 8.1.6 to estimate the future reach of global constraints for the HL-LHC scenario. As previously, we assume that the limits quoted on the $\mathrm{Br}(t \to qZ)$ branching fraction are derived using the dilepton decays of the Z boson, in a $m_{\ell\ell} \in [78, 102]$ GeV window for the dilepton invariant mass. This determines the sensitivity to four-fermion operators. The limits on the $tq\gamma$ interaction were derived by a combination of production and decay processes [1185]. Since the only prospect provided is on the $\mathcal{B}(t \to q\gamma)$ branching fraction, we approximate it as though it is from the measurement of the decay process only. This assumption affects primarily the dependence of bounds on

tqg interactions.

The results of a global fit based on the HL-LHC prospects are displayed in Fig. 58 (right panel). Comparing with the left panel, constraints on two-fermion operators are typically improved by a factor of a few, while those on four-fermion operators are only marginally improved, mostly indirectly through the improvement of the limits on other operator coefficients. The two dimensional plane of Fig. 59 (right panel) shows that LEP II constraints on $e^+e^- \to tj, \bar{t}j$ production will start having little impact, even on the four-fermion operators, after the HL-LHC phase.

8.1.5 *Complementarity with B-meson and kaon rare processes*

The NP effective operators which include the top quark also contribute to the low-scale effective Hamiltonian for meson decays, and hence, precision measurements of the B-meson and kaon rare processes provide complementary constraints to the NP top-quark operators [1186–1188].

In the framework of SMEFT, the $SU(2)_L$ gauge symmetry between t_L and b_L provides a direct constraint to the NP top-quark operators arising from the tree-level matching onto the B physics Hamiltonian [904, 1187]. For instance, in the flavour basis, the following operators

$$O_{\ell q}^{1(ij32)} = (\bar{\ell}_i \gamma_\mu P_L \ell_j)(\bar{q}_3 \gamma^\mu P_L q_2) = (\bar{\ell}_i \gamma_\mu P_L \ell_j)(\bar{t} \gamma^\mu P_L c) + (\bar{\ell}_i \gamma_\mu P_L \ell_j)(\bar{b} \gamma^\mu P_L s)\,, \tag{115}$$

$$O_{\ell equ}^{1(ij32)} = (\bar{\ell}_i P_R e_j)\varepsilon(\bar{q}_3 P_R c) = -(\bar{\ell}_i{}^+ P_R e_j)(\bar{t} P_R c) + (\bar{\nu}_i P_R e_j)(\bar{b} P_R c)\,, \tag{116}$$

are constrained from $B_s \to \ell^+\ell^-$, $B \to K^{(*)}\bar{\nu}\nu$, $b \to s\ell^+\ell^-$, and $b \to c\ell^-\bar{\nu}$ observables. Each of the constraints significantly depends on the lepton-flavour dependence (*e.g.*, see Ref. [952]).

Also, the NP operators which include single top quark, *e.g.*,

$$O_{\varphi q}^{1(32)} = (\varphi^\dagger i\overleftrightarrow{D}_\mu \varphi)(\bar{t} \gamma^\mu P_L c) + (\varphi^\dagger i\overleftrightarrow{D}_\mu \varphi)(\bar{b} \gamma^\mu P_L s)\,, \tag{117}$$

and two top quarks, *e.g.*,

$$O_{qd}^{1(33kl)} = (\bar{t} \gamma_\mu P_L t)(\bar{d}^k \gamma^\mu P_R d^l) + (\bar{b} \gamma_\mu P_L b)(\bar{d}^k \gamma^\mu P_R d^l) \quad \text{with } k \neq l\,, \tag{118}$$

can contribute to the low-scale effective Hamiltonian through the one-loop matching conditions at the electroweak symmetry breaking scale by integrating out the top quark, W, Z and the SM Higgs boson. These one-loop contributions are enhanced by the top-quark mass. Although such a two top-quark operator does not contribute to the single top-quark production mentioned in this section, once a UV completion is considered, single and two top-quarks operators could be related. The one-loop matching conditions onto $\Delta F = 1$ processes are given in Ref. [904], while the conditions onto $\Delta F = 2$ ones are given in Ref. [1189]. Besides, one-loop matching conditions to $\Delta F = 0$, *e.g.*, $h \to \tau^+\tau^-$ and the leptonic dipole moments, are investigated in Ref. [1065].

8.1.6 *Experimental perspectives*

8.1.6.1 *Signal modeling*

The generation of signal events at ATLAS is done at NLO with `MadGraph5_aMC@NLO` [372, 1190] and the effective field theory framework developed in the TopFCNC model is used [1157, 1172]. In the case of gqt coupling, the MEtop generator is used instead [1191]. At CMS signal events are simulated at LO with `MadGraph5_aMC@NLO` with the effective lagrangian implemented by means of the `FEYNRULES` package, except in the simulation of signal events for gqt and γqt couplings where `CompHEP` [1192] and `PROTOS 2.0` [1193] are used, respectively. In both experiments `Pythia 8` is used to simulate the parton showering and hadronization. The generation of signal events is done under the assumption of only one non-vanishing FCNC coupling at a time.

Table 33: Summary of the projected reach for the 95% C.L. limits on the branching ratio for anomalous flavor changing top couplings.

$\mathcal{B}$ limit at 95%C.L.	3 ab^{-1}, 14 TeV	15ab^{-1}, 27 TeV	Ref.
$t \to gu$	3.8×10^{-6}	5.6×10^{-7}	[1194]
$t \to gc$	32.1×10^{-6}	19.1×10^{-7}	[1194]
$t \to Zq$	$2.4 - 5.8 \times 10^{-5}$		[1195]
$t \to \gamma u$	8.6×10^{-6}		[1196]
$t \to \gamma c$	7.4×10^{-5}		[1196]
$t \to Hq$	10^{-4}		[1195]

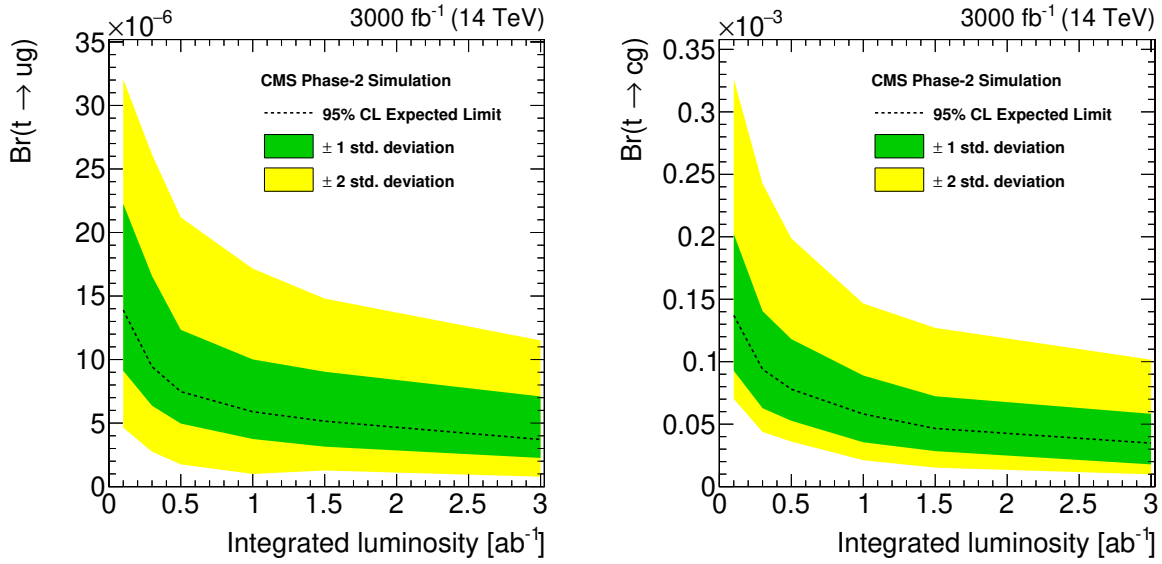

Fig. 60: The expected exclusion limits at 95% C.L. on the branching fractions for the $t \to ug$ (left panel) and $t \to cg$ (right panel) FCNC processes as a function of integrated luminosity.

8.1.6.2 Top-gluon

The gqt FCNC process was studied by ATLAS [1179] and CMS [1180] in single top quark events. The event signature includes the requirement of one isolated lepton and the presence of a significant amount of transverse missing energy (E_T^{miss}). The analysis at CMS requires exactly one b and one non-b jet to be present in the final state with the dominant background arising from the $t\bar{t}$+jets production, while the analysis at ATLAS vetoes any additional jets resulting in the dominant source of background associated with the W+jets production. A neural network-based technique is used to separate signal from background events. The observed (expected) 95% C.L. upper limits in the CMS analysis are $\mathcal{B}(t \to gu) < 2.0\ (2.8) \times 10^{-5}$ and $\mathcal{B}(t \to gc) < 4.1\ (2.8) \times 10^{-4}$, while the resultant limits in case of ATLAS are $\mathcal{B}(t \to gu) < 4.0\ (3.5) \times 10^{-5}$ and $\mathcal{B}(t \to gc) < 2.0\ (1.8) \times 10^{-4}$. The projected limits for 3 ab^{-1} are $\mathcal{B}(t \to gu) < 3.8 \times 10^{-6}$ and $\mathcal{B}(t \to gc) < 32.1 \times 10^{-6}$ [1194].

The dependence of the $\mathcal{B}(t \to ug)$ and $\mathcal{B}(t \to cg)$ exclusion upper limits on integrated luminosity is shown in Fig. 60 with 1 and 2 σ bands corresponding to 68 % and 95 % C.L intervals of distributions of the limits . In addition the two-dimensional contour that reflects the possible simultaneous presence of both FCNC processes. is shown in Fig. 61.

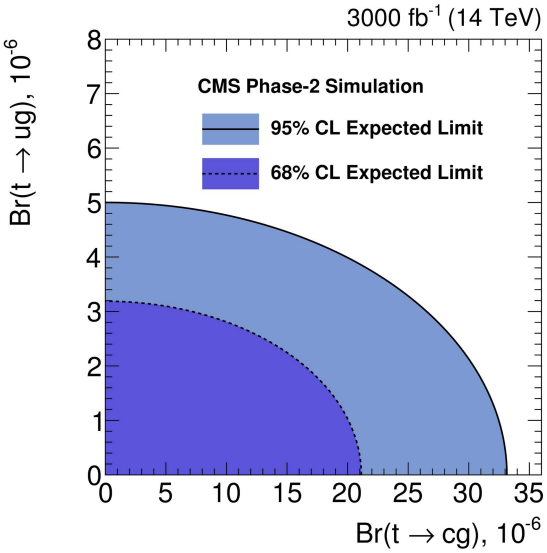

Fig. 61: Two-dimensional expected limits on the $t \to ug$ vs and $t \to cg$ branching fractions at 68% and 95% C.L. for an integrated luminosity of 3000 fb^{-1}

8.1.6.3 Top-Z

ATLAS studied the sensitivity to the tqZ interaction, by performing an analysis [1197] based on simulated samples and following both the strategy of its 13 TeV data analysis on the same subject [1176] and of the general recommendations for this HL-LHC study. The study is performed in the three charged lepton final state of $t\bar{t}$ events, in which one of the top quarks decays to qZ, $(q = u, c)$ and the other one decays to bW ($t\bar{t} \to bWqZ \to b\ell\nu q\ell\ell$). The kinematics of the events are reconstructed through a χ^2 minimisation and dedicated control regions are used to normalize the main backgrounds and constrain systematic uncertainties. The main uncertainties, in both the background and signal estimations, are expected to come from theoretical normalization uncertainties and uncertainties in the modeling of background processes in the simulation. Different scenarios for the systematic uncertainties are considered, ranging from the full estimations obtained with the 13 TeV data analysis, to the ones expected with improvements in theoretical predictions, which should be half of the former ones. A binned likelihood function $L(\mu, \theta)$ is used to do the statistical analysis and extract the signal normalisation. An improvement by a factor of five is expected in relation to the current 13 TeV data analysis results. Obtained branching ratio limits are at the level of 4 to 5 $\times 10^{-5}$ depending on the considered scenarios for the systematic uncertainties.

8.1.6.4 Top-gamma

The $t\gamma q$ anomalous interactions have been probed by CMS at 8 TeV in events with single top quarks produced in association with a photon [1175] and the resulting exclusion limits are $\mathcal{B}(t \to \gamma u) < 1.3\ (1.9) \times 10^{-4}$ and $\mathcal{B}(t \to \gamma c) < 2.0\ (1.7) \times 10^{-3}$.

In this section, the sensitivity of the upgraded CMS detector to $tq\gamma$ FCNC transitions is estimated for integrated luminosities of 300 and 3000 fb^{-1} using single top quark production via $q \to q\gamma$, with q being a u or a charm quark [1196]. This analysis focuses on subsequent SM decays of the top quark in a W boson and bottom quark, with the W boson decays leptonically to a muon or electron and a neutrino. The final state signature is the presence of a single muon or electron, large missing transverse momentum, a b jet, and an isolated high energy photon, with a broad η spectrum. The photon properties themselves provide good separation with respect to the dominant background processes from W+jets, and single top

or top quark pair production in association with photons. For the discrimination of signal and background events, and to set the limits on the FCNC couplings, the events are split into two categories depending on the pseudo-rapidity of the photon (central region with $|\eta_\gamma| < 1.4$ and forward region with $1.6 < |\eta_\gamma| < 2.8$). In the central (forward) region the photon p_{T} (energy) is used as a discriminating distribution: the low p_{T} (energy) is background dominated, while the high p_{T} (energy) region is populated by signal events. The distributions are shown in Fig. 62.

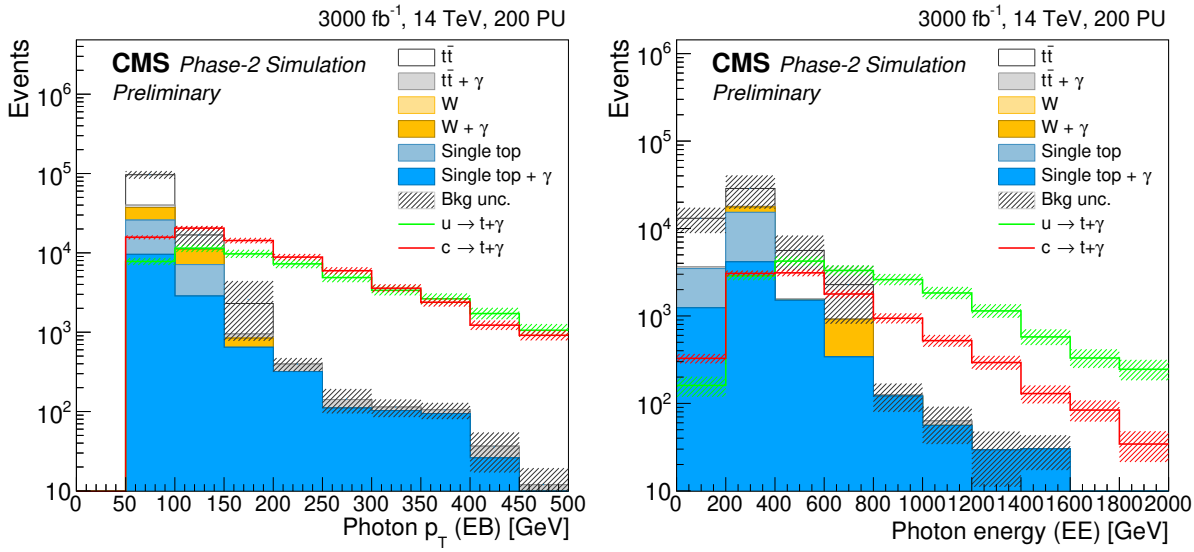

Fig. 62: Transverse momentum of photon candidates for the central η region (left) and energy of photon candidates in the forward region (right).

The limits on the cross section for the single top quark production via $tq\gamma$ are obtained considering systematic uncertainties from variations of the renormalization and factorization scale, b-tagging and jet energy scale corrections and their effects as propagated to missing transverse energy, lepton efficiency and luminosity.

These studies yield the following upper limite on the branching ratios at 95%C.L.: $\mathcal{B}(t \to \gamma u) < 8.6 \times 10^{-6}$, $\mathcal{B}(t \to \gamma c) < 7.4 \times 10^{-5}$.

8.1.6.5 Top-Higgs

The tHq interactions are studied by ATLAS in top quark pair events with $t \to qH, H \to \gamma\gamma$ [1198] and $H \to WW$ [1181] at 13 TeV. The former analysis explores the final state with two isolated photons. For leptonic top quark decays the selection criteria includes the requirement of one isolated lepton, exactly one b jet, and at least one non-b jet. In case of hadronic top quark decays the analysis selects events with no isolated leptons, at least one b jet, and at least three additional non-b jets. The dominant background processes are associated with the production of non-resonant $\gamma\gamma$+jets, $t\bar{t}$+jets and W+$\gamma\gamma$ events. The resultant limits are $\mathcal{B}(t \to Hu) < 2.4\ (1.7) \times 10^{-3}$ and $\mathcal{B}(t \to Hc) < 2.2\ (1.6) \times 10^{-3}$. The search for FCNC in $H \to WW$ includes the analysis of multilepton final states with either two same-sign or three leptons. The dominant backgrounds arising from the ttW, ttZ and non-prompt lepton production are suppressed with a BDT. The obtained limits are $\mathcal{B}(t \to Hu) < 1.9\ (1.5) \times 10^{-3}$ and $\mathcal{B}(t \to Hc) < 1.6\ (1.5) \times 10^{-3}$. The tHq anomalous couplings are probed by CMS in $H \to b\bar{b}$ channel in top quark pair events, as well as in single top associated production with a Higgs boson, at 13 TeV [1183]. The event selection includes the requirement of one isolated lepton, at least two b jets, and at least one additional non-b jet. The dominant $t\bar{t}$ background is suppressed with a BDT discriminant to set the exclusion limits of $\mathcal{B}(t \to Hu) < 4.7\ (3.4) \times 10^{-3}$ and $\mathcal{B}(t \to Hc) < 4.7\ (4.4) \times 10^{-3}$.

Table 34: The current and projected 95% C.L. constraints from direct observables on the real and imaginary parts of the Wilson coefficients that contribute to the Wtb vertex, assuming $\Lambda = 1$ TeV and $c_{\varphi q}^{-} = 0$.

	Coeff.	c_{tW}	c_{bW}	$c_{\varphi tb}$
Current	Re(...)	$[-0.70, 0.82]$	$[-2.2, 2.2]$	$[-8.9, 10.9]$
	Im(...)	$[-1.5, 2.2]$	$[-2.1, 2.2]$	$[-9.9, 9.9]$
3000 fb^{-1}	Re(...)	$[-0.23, 0.58]$	$[-2.2, 2.0]$	$[-9.3, 10.6]$
	Im(...)	$[-1.2, 1.3]$	$[-2.2, 2.1]$	$[-9.9, 9.9]$

Preliminary projections suggest $\mathcal{B}(t \to Hq) < \mathcal{O}(10^{-4})$ [1195, 1199].

8.2 Anomalous Wtb vertices and CP-violation effects from T-odd kinematic distributions

Authors (TH): Frederic Deliot, Wouter Dekens.

Beyond the SM, contributions to the Wtb vertex have been widely studied in the literature [1187, 1188, 1200–1214]. Assuming that new physics is much heavier than the electroweak scale, the BSM corrections to the Wtb vertex can be described using an EFT. The first contributions appear at dimension six and, in the conventions of [1156], take the following form

$$\mathcal{L}_{tb} = -\bar{t}\left[\frac{g}{\sqrt{2}}\gamma^{\mu}\left(V_{tb}\left(1+\tfrac{v^2}{2}c_{\varphi q}^{-}\right)P_L + \tfrac{v^2}{2}C_{\varphi tb}P_R\right)W_{\mu}^{+} - v\sigma^{\mu\nu}W_{\mu\nu}^{+}\left(C_{bW}P_R + C_{tW}^{*}P_L\right)\right]b + \text{h.c.}\,, \tag{119}$$

where $C_i = (c_i + ic_i^{[I]})/\Lambda^2$. In writing (119) we follow Ref. [1200] and enforce $C_{\varphi q}^{1(33)} + C_{\varphi q}^{3(33)} = 0$ to avoid tree-level FCNC decays of the Z (one also obtains a strong constraint from $Z \to bb$ decays [1208]), such that only the real combination $c_{\varphi q}^{-} = C_{\varphi q}^{1(33)} - C_{\varphi q}^{3(33)}$ appears.

The Wilson coefficients in Eq. (119) are in terms of the often-used anomalous couplings [1202, 1215] given by

$$V_L = V_{tb}^{*}\left(1+\tfrac{v^2}{2}c_{\varphi q}^{-}\right), \qquad V_R = \tfrac{v^2}{2}C_{\varphi tb}^{*}, \qquad g_L = -\sqrt{2}v^2C_{bW}^{*}, \qquad g_R = -\sqrt{2}v^2C_{tW}. \tag{120}$$

Note that within SMEFT gauge invariance links the above vertices to additional interactions. The full form of the relevant SMEFT operators is given in Sec. 8.1.

The above interactions give tree-level contributions to single-top production and to the observables in $t \to W^{+}b$ decay, in particular, to the W-boson helicity fractions. Apart from these processes that are "directly" sensitive to the Wtb vertices, there are "indirect" observables that receive contributions from the same operators through loop diagrams. Examples are $h \to \bar{b}b$, $B \to X_s\gamma$, and searches for electric dipole moments (EDMs). Below we discuss briefly both the direct and indirect limits on the operators in Eq. (119), as well as the projections for the HL-LHC (see also Working-Group 1 Section on this topic).

8.2.1 Direct probes

The Wtb interactions can be probed directly in single-top production and through the W boson helicity fractions in top decays. In the case of polarized top quarks it is possible to construct additional T-odd observables that are sensitive to CP-violating phases in the Wtb couplings. Here we discuss briefly these observables and the resulting (projected) constraints.

Single top production The single-top production cross section has been measured in the t and s channels at the LHC at $\sqrt{s} = 7$, 8, and 13 TeV [1216–1221]. In principle, these cross sections receive contributions from all Wtb couplings. The measurements can be compared with the SM prediction [1222] at NNLO in QCD, while BSM contributions have been evaluated at NLO [1223–1226]. In

Table 35: Indicative constraints on the SMEFT operators contributing to the Wtb vertex from indirect observables. A single Wilson coefficient is taken to be nonzero at a time, and we set $\Lambda = 1$ TeV.

Coeff.	$h \to \bar{b}b$	EWPT	$B \to X_s\gamma$	EDMs
$c_{\varphi q}^-$	–	–	$[-2.0, 2.2]$	–
$c_{\varphi tb}$	$[-0.3, 4.3]$	–	$[-4.6, 4.9] \cdot 10^{-2}$	–
c_{tW}	–	$[-1.1, 0.7]$	$[-0.22, 0.89]$	–
c_{bW}	–	–	$[-13, 3.5] \cdot 10^{-3}$	–
$c_{\varphi tb}^{[I]}$	$[-7.3, 7.3]$	–	$[-0.20, 0.20]$	$[-0.019, 0.019]$
$c_{tW}^{[I]}$	–	–	$[-2.4, 4.5]$	$[-1.0, 1.0] \cdot 10^{-3}$
$c_{bW}^{[I]}$	–	–	$[-4.3, 2.3] \cdot 10^{-2}$	$[-5.5, 5.5] \cdot 10^{-4}$

SMEFT the single-top cross sections can receive contributions from other operators, in particular, from several four-quark operators, see, e.g., Refs. [1210,1211]. Thus, in order to perform an exhaustive global analysis one would have to include these effects as well.

Top quark decays The helicity fractions of the W boson in top decays are mostly sensitive to c_{tW}, c_{bW}, and $c_{\varphi tb}$, and have been measured both at the Tevatron and the LHC [1227–1232]. In addition, the phase δ^- between the amplitudes of longitudinally and transversely polarized W bosons, recoiling against a left-handed b quark, carries information on the imaginary part of C_{tW} [1230, 1233]. The SM predictions for the helicity fractions are known to NNLO in QCD [1234], while the BSM contributions have been computed to NLO [1164, 1201].

As mentioned above, in the case of polarized top-quark decays, it becomes possible to construct additional observables that are sensitive to both the real and imaginary parts of the Wtb couplings. In particular, both the asymmetries constructed in Ref. [1235,1236] and the triple-differential measurements of Ref. [1237] are sensitive to $c_{tW}^{[I]}$ (see also Ref. [1206]). As a result, the limits on $c_{tW}^{[I]}$ already improve noticeably when including current experimental measurements of these angular asymmetries [1214].

After taking into account the current experimental results on single-top production, the helicity fractions, and angular asymmetries one obtains the current (projected) limits in the left (right) panel of Table 34 [1214, 1238]. For an analysis focused on single-top production see Ref. [1239]. These limits were obtained by assuming that $c_{\varphi q}^- = 0$. [9] Comparing the two panels one sees that the current and projected limits on the c_{bW} and $c_{\varphi tb}$ couplings are very similar, while the projected limits on the real and imaginary parts of c_{tW} are roughly a factor of 2 stronger than the current constraints.

Top decays can also be used to probe physics beyond that of the top sector. For example, Ref. [1240] recently suggested that the process $t \to bW \to b\bar{b}c$ can be used to measure V_{cb} at the m_W scale, instead of $V_{cb}(m_b)$ which is probed in B decays.

8.2.2 Indirect probes

The anomalous Wtb interactions contribute to other processes through loop diagrams. Although this can give rise to stringent constraints, their interpretation requires some care. As indirect observables receive contributions from additional operators apart from the Wtb couplings, cancellations between different Wilson coefficients are possible. We will assume this is not the case and derive limits for the case that a single dimension-six operator is generated at the BSM scale.

[9] This coupling is harder to constrain as it is degenerate with a shift in V_{tb}, see Eq. (119). This degeneracy can be broken by using CKM unitarity tests, or by considering additional interactions, such as the Wts, Wtd, and Ztt vertices, that are linked to $c_{\varphi q}^-$ by gauge invariance. A more naive constraint, obtained by setting $V_{tb} = 1$, leads to $|c_{\varphi q}^-| \lesssim 1$ [1225].

Electric dipole moments. Electric dipole moments are probes of CP violation and, therefore, receive contributions from the imaginary parts of the Wtb couplings. The most stringent experimental limits have been obtained on the EDMs of the neutron, mercury, and the ThO molecule, the latter of which can be interpreted as a limit on the electron EDM for our purposes. To obtain the contributions to EDMs one first has to evolve the Wtb operators to low energies, $\mu \sim 2$ GeV. QCD becomes non-perturbative below this scale, and one has to match to Chiral perturbation theory, which describes the CP-odd interactions in terms of hadrons, photons, and electrons. These interactions can then be used to calculate the EDMs of nucleons, atoms, and molecules.

Among the operators in Eq. (119), the $c_{\varphi tb}^{[I]}$ and $c_{bW}^{[I]}$ couplings are mainly constrained by the neutron EDM, while $c_{tW}^{[I]}$ contributes to the electron EDM. The $c_{\varphi tb}^{[I]}$ and $c_{bW}^{[I]}$ first generate the bottom-quark chromo EDM, $O_{dG}^{(33)}$ (in the notation of [1200]), through one-loop diagrams [1225, 1241, 1242], which subsequently induces the Weinberg operator, $O_{\tilde{G}}$, after integrating out the bottom quark [1243–1246]. The hadronic matrix element of the Weinberg operator contributing to the neutron EDM is poorly known. Combining naive-dimensional-analysis and sum-rule estimates [1244, 1247, 1248], one has $|d_n| = 6|e\,(50\,\mathrm{MeV})\,C_{\tilde{G}}(1\,\mathrm{GeV})|$, with an $\mathcal{O}(100\%)$ uncertainty.

The contributions to the electron EDM also arise from a two-step process: $c_{tW}^{[I]}$ first induces CP-odd operators of the form $X_{\mu\nu}\tilde{X}^{\mu\nu}\varphi^\dagger\varphi$, with $X_{\mu\nu}$ a $SU(2)_L$ or $U(1)_Y$ field strength, as well as semileptonic interactions of the form, $(\bar{e}_L\sigma_{\mu\nu}\,e_R)\,(\bar{t}_L\sigma^{\mu\nu}t_R)$, through the renormalization group equations [1224, 1249, 1250]. These additional operators then induce the electron EDM at one loop. Using the above contributions and the current experimental limits [1251–1253], we obtain the constraints in Table 35. The limits from the neutron EDM are expected to improve by 1 to 2 orders of magnitude in the next generation of experiments [1254], while proposals exist to improve the electron EDM limits by several orders of magnitude [1255–1257].

Rare B decays. Unlike EDMs, measurements of $B \to X_s\gamma$ are sensitive to both the real and imaginary parts of the couplings. Although all four of the Wtb vertices give rise to flavour-changing $b \to s$ transitions through one-loop diagrams [904, 1188, 1200], the largest effects are due to $C_{\varphi tb}$ and C_{bW}. Both of these couplings induce contributions proportional to m_t instead of m_b that appears in SM (as well as for $c_{\varphi q}^-$ and C_{tW}), leading to a relative enhancement of m_t/m_b. Here we consider the constraints from measurements of the $B \to X_s\gamma$ branching ratio and the CP asymmetry [197], for which we use the theoretical expressions of [1258] and [1259], respectively. This leads to the constraints in Table 35, which are expected to improve by a factor of a few in the future. In particular, the uncertainty on the branching ratio is expected to decrease by a factor of 2 to 3 at Belle II, while the improvement is projected to be a factor of 5 for the CP asymmetry [196].

Electroweak precision tests. The Wtb operators also modify the self energies of the SM gauge bosons through one-loop diagrams, which are often parametrized by the S, T, and U parameters [1260–1262]. Taking into account the RGE contributions, only c_{tW} induces the S parameter by mixing with the $O_{\varphi WB}$ operator (c_{bW} contributions are proportional to m_b), which leads to the limits in Table 35. Here we assumed only a single dimension-six operator is present at $\mu = \Lambda$, but one can include the couplings of the operators that induce S and T at tree level, $O_{\varphi WB}$ and O_{HD}, and marginalize over them. This can be done because electroweak precision observables carry more information than is captured by the S, T, and U parameters alone. This approach is discussed Ref. [1208, 1263] and leads to weaker limits, $c_{tW} \in [-1.6, 0.8]$, $c_{bW} \in [-2, 24]$, $c_{\varphi q}^- \in [-0.7, 4.7]$ for $\Lambda = 1$ TeV.

Higgs decays. Finally, the Wtb interactions contribute to the process $h \to \bar{b}b$ by inducing corrections to the SM bottom-quark Yukawa coupling [1225]. In particular, the $C_{\varphi tb}$ coupling generates a contribution to the Yukawa coupling that scales as $y_b \sim y_t v^2 C_{\varphi tb}/(4\pi)^2$. Thus, although this contribution only appears at one loop, the suppression is offset by the appearance of the top-quark Yukawa instead of that of the bottom quark. Using the combined ATLAS and CMS analysis [1264] of the Higgs

decays to $\gamma\gamma$, WW, ZZ, $\tau\tau$, $\mu\mu$, and $\bar{b}b$ signal strengths we obtain the limits in Table 35.

8.3 Determinations of V_{tx}

Authors (TH): Mariel Estevez, Darius Faroughy, Jernej Kamenik.

The LHC as a top-quark factory has the ability to directly probe the V_{tx} matrix elements. In particular, measuring the fractions of b-tagged jets in leptonic top decays $t \to Wj$ allows one to set a limit on the ratio

$$\mathcal{R} = \frac{\mathrm{Br}(t \to bW)}{\sum_{x=d,s,b} \mathrm{Br}(t \to Wx)} > 0.995 \tag{121}$$

at 95% CL [1265]. This result, when combined with measurements of t-channel single-top production [1217], provides a direct determination of $|V_{tb}| = 1.07 \pm 0.09$ in the limit $|V_{tb}| \gg |V_{ts}|, |V_{td}|$. Given that these measurements are already dominated by systematic effects, in particular the knowledge of the b-tagging efficiencies and theoretical uncertainties in single-top production, significant improvement in precision of V_{tb} measurement at the HL-LHC or HE-LHC would arguably require novel strategies.

8.3.1 Measuring $|V_{td}|$ at HL-LHC and HE-LHC

A possible experimental strategy to probe the $|V_{td}|$ matrix element directly at the HL(HE)-LHC is using single top production associated with a W boson, $pp \to tW$. The idea is to exploit the production cross-section enhancement, as well as boosts of the top quarks coming from initial state valence d-partons. The d-quark is a valence constituent of the proton and there is an imbalance with the $\bar{d}$-quark that motivates to explore charge asymmetries as possible V_{td}-sensitive observables. The main backgrounds, contrary to t-channel single top production, are charge symmetric or have very small charge asymmetries. The $dg \to tW$ associated production process is interesting because of its sizeable charge asymmetry in proton collisions and also because its kinematics predicts a characteristic angular distribution. We expect a relatively large incoming momentum on average from the valence d-quark. Consequently, a forward W^- is preferred in the lab frame, which is supposed to produce a forward ℓ^- in signal events. The main two backgrounds to the $\ell^+\ell^- bE_T^{\mathrm{miss}}$ final state are the dileptonic $t\bar{t}$ production (missing one of the b-jets from top decays) and $gb \to tW$ associated production, proportional to $|V_{tb}|^2$. Both backgrounds have very small charge asymmetries. In order to increase the sensitivity and enhance the signal cuts can be imposed that reduce the cross-sections of the backgrounds, see Ref. [1266] for details. The most important difference between signal and background comes from the $\eta(\ell^-)$ distribution, where the signal clearly prefers forward negatively charged leptons. The asymmetry

$$A(\eta, p_T) = \frac{N^+ - N^-}{N^+ + N^-}, \tag{122}$$

where $N^\pm = N\left(\Delta|\eta(\ell)| \gtrless 0 \,\&\, \Delta p_T(\ell) \gtrless 0\right)$, is a $|V_{td}|$ sensitive observable. Each process contributes with $N_i^+ - N_i^- = \sigma_i \cdot \mathcal{A}_i \cdot \epsilon_i \cdot A_i(\eta, p_T)$, where the factors on the right hand side are the cross-section, acceptance, selection efficiency and asymmetry, respectively. To quantify the versatility of the proposed charge asymmetry we study the prospective experimental reach in $r \equiv |V_{td}/V_{td}^{\mathrm{SM}}|$ by computing the difference of $A(\eta, p_T)$ to its SM expectation in units of the uncertainty. Based on existing experimental studies of charge asymmetries in top production [1267] we include an estimate for the systematic uncertainty of $\Delta_{sys} = 0.2\%$, and define the significance as

$$\text{significance} = \left|A(\eta, p_T) - A(\eta, p_T)^{\mathrm{SM}}\right| \Big/ \sqrt{(N^+ + N^-)^{-1} + \Delta^2_{\mathrm{syst}}}. \tag{123}$$

Fig. 63 shows the contours of expected experimental significance for $A(\eta, p_T)$ (and r) as functions of luminosity, for 13 TeV and 27 TeV LHC. As a rough guidance we also show with dashed lines the significance for the case that the dominant $t\bar{t}$ background were further reduced by a factor of 2, e.g., by

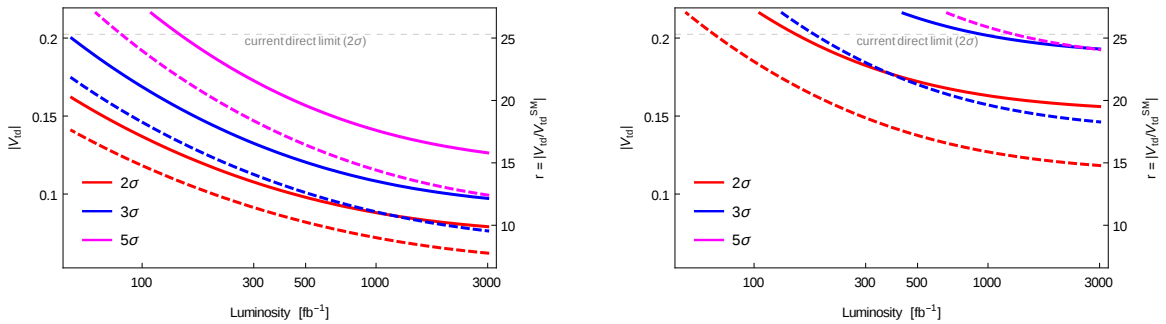

Fig. 63: Contour lines for the projected 2σ, 3σ and 5σ upper bounds on $|V_{td}|$ (and $r \equiv |V_{td}/V_{td}^{\rm SM}|$) as functions of the LHC luminosity at 13 TeV (left) and 27 TeV (right). Dashed lines follow if the dominant $t\bar{t}$ background is reduced by half, see text for details.

using multivariate discrimination techniques as already done in existing single top analyses [1268–1270]. Values of $r < 10$ could be directly accessible at the LHC@13TeV, improving the existing best direct constraint [1265] by roughly a factor of three. The current direct bound on $|V_{td}|$ can be surpassed with the Run 2 dataset, while with $3000\,\text{fb}^{-1}$ it could be possible to probe $|V_{td}| \sim |V_{ts}^{\rm SM}| \simeq 0.04$.

The dominant $t\bar{t}$ background is mostly generated via gluon fusion, which is charge symmetric. There are subleading contributions from processes like $u\bar{u} \to t\bar{t}$ which are charge asymmetric, but only enter at higher orders in QCD. This is the main reason the dominant $t\bar{t}$ background has a strongly suppressed charge asymmetry. At higher collision energies, the probability of finding energetic enough gluons in the proton increases faster than that of valence quarks. Consequently, the fraction of $t\bar{t}$ events from the quark-antiquark initial state is reduced [1267]. This leads to a shrinking charge asymmetry with growing collision energy. Unfortunately, the same happens to the signal, this time because at higher energies the asymmetry between d and $\bar{d}$ partons inside the proton is reduced. The net effect is a severely diminished significance at 27 TeV compared to 13 TeV for comparable luminosities.

8.3.2 Measuring Cabibbo-suppressed decays of the top quark at HL-LHC and HE-LHC

With the large $t\bar{t}$ statistics at the LHC, one might attempt a direct measurement of Cabibbo-suppressed decays of the top quark, $t \to (s,d)\,W^{\pm}$, in leptonic $t\bar{t}$ events. Since there is no practical way to distinguish between strange and down quark jets at the detector level (without dedictated PID systems), one measures

$$\rho \equiv \sqrt{\big(\mathcal{B}(t \to sW) + \mathcal{B}(t \to dW)\big)/\mathcal{B}(t \to bW)}\,. \tag{124}$$

This gives a direct information on $(|V_{ts}|^2 + |V_{td}|^2)^{1/2}$, but not on V_{ts} and V_{td} separately. In the SM, $\rho \approx |V_{ts}| \approx 0.04$.

To perform the measurement it is necessary to discriminate between heavy-flavoured jets, e.g., b-jets from the $t \to bW$ background, gluons from ISR/FSR contamination, and the signal – the light-quark jets (q-jets) from the Cabibbo-suppressed top decays. This can be achieved through a q-tagger based on existing techniques used for b-tagging and quark/gluon jet discrimination [1271]. There are several known useful observables which can be used in a q-tagger. In the following we use: (i) the multiplicity $N_{\rm SV}$ of secondary vertices (SV) in the jet within a fiducial volume of the tracker, (ii) the fraction of longitudinal momentum of the jet carried by the hardest prompt charged track $z_{\rm max} \equiv \max\big[\vec{p}_x \cdot \vec{p}_{\rm jet}/|\vec{p}_{\rm jet}|^2\big]_{x\in{\rm jet}}$, and (iii) the 2-point energy correlation function $U_1^{\beta} = \sum_{i,j\in{\rm jet}} z_T^i z_T^j\,(R_{ij})^{\beta}$, $z_T^i \equiv p_T^i/p_T^{\rm jet}$, where $R_{ij}^2 = (\eta_i-\eta_j)^2 + (\phi_i-\phi_j)^2$ and β is a free real parameter for which quark/gluon discrimination is optimized at $\beta = 0.2$ [1272, 1273], see Ref. [1274] for more details.

For the projections we use the reference working point shown in Table 36. We bin preselected events into one of the six tagged dijet categories $\{jj, jb, jq, qb, qq, bb\}$ where q, b and j represent q -jets,

Table 36: Tagging and mis-tagging efficiencies for the q-tagging working point used in the V_{tq} analysis.

(t) type	Cuts	ϵ_q^t	ϵ_b^t	ϵ_c^t	ϵ_g^t
q-tagger	$N_{SV} = 0$ & $z_{max} > 0.3$	0.18	0.0031	0.038	0.049
b-tagger	$N_{SV} > 3$	0.0091	0.64	0.09	0.016

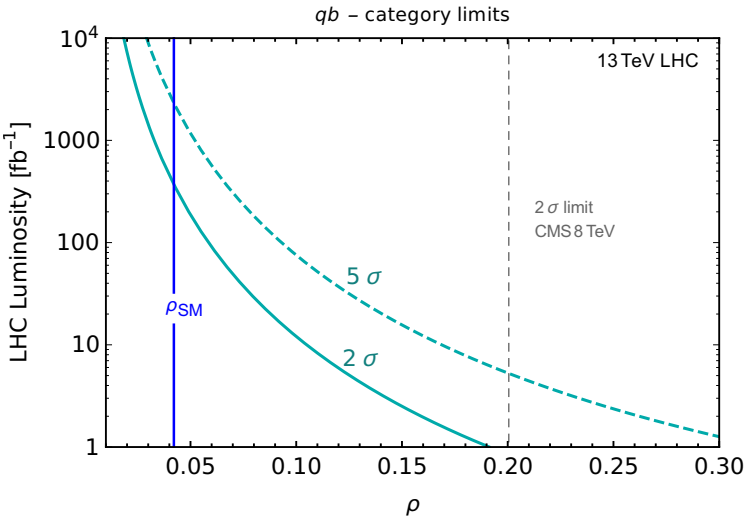

Fig. 64: Illustration of statistical limits on the ratio $\rho \simeq \left(|V_{ts}|^2 + |V_{td}|^2\right)^{1/2}/|V_{tb}|$ from an analysis of Cabbibo-suppressed top decays in leptonic $t\bar{t}$ events at 13TeV LHC. See text for details.

b-jets and non-tagged jets (a jet failing both taggers), respectively. Fig. 64 shows the resulting upper limits on ρ taking into account only statistical uncertainties in the qb category for the signal significance $S/\sqrt{B}$ at 2σ (solid boundary) and 5σ (dashed boundary) as a function of the LHC luminosity, compared to the current best limit by CMS shown by the gray dashed curve. The results suggest that the HL-LHC could find evidence of Cabbibo-suppressed top decays and determine V_{ts} CKM element directly, though the precise precision depends crucially on how well systematic uncertainties can be controlled. The uncertainties in q- and b-tagging efficiencies could be controlled using Zj production. Then a fit of the categorized dijet data $\{jj, jb, jq, qb, qq, bb\}$ in inclusive dilepton events to a probabilistic model taking into account the tagging efficiencies could be performed, similar to that performed in [1265,1275] for the extraction of V_{tb}. Especially relevant for the HE-LHC would be to measure $t \to (s,d)W$ from boosted semi-leptonic $t\bar{t}$ events. Events with one top-tagged fat jet, one narrow jet and one lepton (both daughter candidates of the leptonic top) can be categorized by the flavour content of the narrow jet. A preliminary analysis [1274] suggests comparable sensitivity to the leptonic $t\bar{t}$ dataset already at the 13TeV LHC.

9 The Higgs boson and flavour physics

Authors (TH): F. Bishara, R. Harnik, A. Martin, M. Schlafer, Y. Soreq, E. Stamou, F. Yu.

In the SM the Higgs couplings to the fermions are the origin of the flavour structure. In the SM the Yukawa couplings, y_f, are CP conserving and proportional to the fermion masses, m_f, with a common proportionality factor,

$$y_f^{\rm SM} = \sqrt{2} m_f / v \,, \tag{125}$$

while the tree-level flavour changing couplings are zero. Currently, only the third generation Yukawa couplings have been measured and found to be in agreement with the SM predictions, see Refs. [1276–1282]. For the Higgs couplings to the first two generations, only upper bounds exist at present [1283–1287].

To parametrize the deviations from the SM, it is useful to introduce a generalized κ framework (the summation is over fermion type $f = u, d, \ell$ and generations $i, j = 1, 2, 3$)

$$\mathcal{L}_{\rm eff} = -\kappa_{f_i} \frac{m_{f_i}}{v} h \bar{f}_i f_i + i \tilde{\kappa}_{f_i} \frac{m_{f_i}}{v} h \bar{f}_i \gamma_5 f_i - \left[\left(\kappa_{f_i f_j} + i \tilde{\kappa}_{f_i f_j} \right) h \bar{f}^i_L f^j_R + \text{h.c.} \right]_{i \neq j} . \tag{126}$$

Experimentally, we want to test a number of SM predictions: *(i)* proportionality, $y_f \propto m_f$; *(ii)* the factor of proportionality, $\kappa_{f_i} = 1$; *(iii)* diagonality (no off-diagonal flavour violation), $\kappa_{f_i f_j} = 0$; *(iv)* reality (no CP violation), $\tilde{\kappa}_{f_i} = \tilde{\kappa}_{f_i f_j} = 0$ [1288]. Different Higgs Yukawa couplings are probed both directly and indirectly. Direct methods are: for top Yukawa the $t\bar{t}h$ production [1276–1278]); for bottom and charm, $pp \to Vh, h \to b\bar{b}, c\bar{c}$ [1281–1283]; for leptons $pp \to h \to \ell^+\ell^-$ [1279, 1280, 1284]; for light quarks the exclusive $h \to V\gamma$ decays [1289–1292]. The kinematical distributions [1293, 1294] and global fits to all the Higgs data also provide bounds on different Yukawa couplings.

The Higgs production and decay signal strengths from the CMS collaboration [1295], and from ATLAS for $h \to c\bar{c}$ [1283] from a global fit, which includes the direct observation of $t\bar{t}h$ production, gives for the signal strengths $\mu_{tth} = 1.18^{+0.30}_{-0.27}, \mu_{bb} = 1.12^{+0.29}_{-0.29}, \mu_{cc} < 105, \mu_{\tau\tau} = 1.20^{+0.26}_{-0.24}, \mu_{\mu\mu} = 0.68^{+1.25}_{-1.24}$. In terms of modifications of the flavour-diagonal CP-conserving Yukawas, the best fit values are, see also [1264, 1295],

$$\kappa_t = 1.11^{+0.12}_{-0.10}, \qquad \kappa_b = -1.10^{+0.33}_{-0.23}, \qquad \kappa_\tau = 1.01^{+0.16}_{-0.20}, \qquad \kappa_\mu = 0.79^{+0.58}_{-0.79}. \tag{127}$$

The u, d, s, and charm Yukawa couplings can be constrained from a global fit to the Higgs data and the precision electroweak measurements at LEP. Floating all the couplings in the fit gives [1285, 1287],

$$\kappa_u < 3.4 \cdot 10^3, \qquad \kappa_d < 1.7 \cdot 10^3, \qquad \kappa_s < 42, \qquad \kappa_c \lesssim 6.2. \tag{128}$$

The upper bound on $\mathcal{B}(h \to e^+e^-)$ gives for the electron Yukawa $|\kappa_e| < 611$ [1286, 1296]. The upper bounds on $\kappa_{c,s,d,u}$ roughly correspond to the size of the SM bottom Yukawa coupling and are thus much bigger than the corresponding SM Yukawa couplings. The upper bounds can be saturated only if one allows for large cancellations between the contribution to fermion masses from the Higgs vev and an equally large contribution from NP, but with an opposite sign. In models of NP motivated by the hierarchy problem, the effects of NP are generically well below these bounds.

In the rest of this section we first briefly discuss the expected deviations in a set of NP models, and give the prospects for HL-/HE-LHC (see also [1289, 1297–1301]). An expanded version of the discussion is available in write-up of WG2, Sec. 7.

9.1 New Physics benchmarks for modified Higgs couplings

The expected sizes of effective Yukawa couplings, κ_f, $\tilde{\kappa}_f$ and $\kappa_{ff'}, \tilde{\kappa} f f'$, in popular models of weak scale NP models, some of them motivated by the hierarchy problem are shown in Tables 37 and 38,

Model	κ_t	$\kappa_{c(u)}/\kappa_t$	$\tilde{\kappa}_t/\kappa_t$	$\tilde{\kappa}_{c(u)}/\kappa_t$
SM	1	1	0	0
MFV	$1+\frac{\mathrm{Re}(a_u v^2+2b_u m_t^2)}{\Lambda^2}$	$1-\frac{2\,\mathrm{Re}(b_u)m_t^2}{\Lambda^2}$	$\frac{\mathrm{Im}(a_u v^2+2b_u m_t^2)}{\Lambda^2}$	$\frac{\mathrm{Im}(a_u v^2)}{\Lambda^2}$
NFC	$V_{hu}\,v/v_u$	1	0	0
F2HDM	$\cos\alpha/\sin\beta$	$-\tan\alpha/\tan\beta$	$\mathcal{O}\left(\frac{m_c}{m_t}\frac{\cos(\beta-\alpha)}{\cos\alpha\cos\beta}\right)$	$\mathcal{O}\left(\frac{m^2_{c(u)}}{m_t^2}\frac{\cos(\beta-\alpha)}{\cos\alpha\cos\beta}\right)$
MSSM	$\cos\alpha/\sin\beta$	1	0	0
FN	$1+\mathcal{O}\left(\frac{v^2}{\Lambda^2}\right)$	$1+\mathcal{O}\left(\frac{v^2}{\Lambda^2}\right)$	$\mathcal{O}\left(\frac{v^2}{\Lambda^2}\right)$	$\mathcal{O}\left(\frac{v^2}{\Lambda^2}\right)$
GL2	$\cos\alpha/\sin\beta$	$\simeq 3(7)$	0	0
RS	$1-\mathcal{O}\left(\frac{v^2}{m_{KK}^2}\bar{Y}^2\right)$	$1+\mathcal{O}\left(\frac{v^2}{m_{KK}^2}\bar{Y}^2\right)$	$\mathcal{O}\left(\frac{v^2}{m_{KK}^2}\bar{Y}^2\right)$	$\mathcal{O}\left(\frac{v^2}{m_{KK}^2}\bar{Y}^2\right)$
pNGB	$1+\mathcal{O}\left(\frac{v^2}{f^2}\right)+\mathcal{O}\left(y_*^2\lambda^2\frac{v^2}{M_*^2}\right)$	$1+\mathcal{O}\left(y_*^2\lambda^2\frac{v^2}{M_*^2}\right)$	$\mathcal{O}\left(y_*^2\lambda^2\frac{v^2}{M_*^2}\right)$	$\mathcal{O}\left(y_*^2\lambda^2\frac{v^2}{M_*^2}\right)$

Table 37: Predictions for the flavour-diagonal up-type Yukawa couplings in a sample of NP models (see text for details).

Model	$\kappa_{ct(tc)}/\kappa_t$	$\kappa_{ut(tu)}/\kappa_t$	$\kappa_{uc(cu)}/\kappa_t$
MFV	$\frac{\mathrm{Re}\left(c_u m_b^2 V_{cb}^{(*)}\right)}{\Lambda^2}\frac{\sqrt{2}m_{t(c)}}{v}$	$\frac{\mathrm{Re}\left(c_u m_b^2 V_{ub}^{(*)}\right)}{\Lambda^2}\frac{\sqrt{2}m_{t(u)}}{v}$	$\frac{\mathrm{Re}\left(c_u m_b^2 V_{ub(cb)}V^*_{cb(ub)}\right)}{\Lambda^2}\frac{\sqrt{2}m_{c(u)}}{v}$
F2HDM	$\mathcal{O}\left(\frac{m_c}{m_t}\frac{\cos(\beta-\alpha)}{\cos\alpha\cos\beta}\right)$	$\mathcal{O}\left(\frac{m_u}{m_t}\frac{\cos(\beta-\alpha)}{\cos\alpha\cos\beta}\right)$	$\mathcal{O}\left(\frac{m_c m_u}{m_t^2}\frac{\cos(\beta-\alpha)}{\cos\alpha\cos\beta}\right)$

pNGB	$\mathcal{O}(y_*^2\frac{m_t}{v}\frac{\lambda_{L(R),2}\lambda_{L(R),3}m_W^2}{M_*^2})$	$\mathcal{O}(y_*^2\frac{m_t}{v}\frac{\lambda_{L(R),1}\lambda_{L(R),3}m_W^2}{M_*^2})$	$\mathcal{O}(y_*^2\frac{m_c}{v}\frac{\lambda_{L(R),1}\lambda_{L(R),2}m_W^2}{M_*^2})$

Table 38: Same as Table 37 but for flavour-violating up-type Yukawa couplings. In the SM, NFC and the tree-level MSSM the Higgs Yukawa couplings are flavour diagonal. The CP-violating $\tilde{\kappa}_{ff'}$ are obtained by replacing the real part, Re, with the imaginary part, Im. All the other models predict a zero contribution to these flavour changing couplings.

adapted from [1302–1306]. The predictions are shown for the Standard Model, multi-Higgs-doublet models (MHDM) with natural flavour conservation (NFC) [1307,1308], a "flavourful" two-Higgs-doublet model beyond NFC (F2HDM) [1309–1312] the MSSM at tree level, a single Higgs doublet with a Froggat-Nielsen mechanism (FN) [1313], the Giudice-Lebedev model of quark masses modified to 2HDM (GL2) [1314], NP models with minimal flavour violation (MFV) [1315], Randall-Sundrum models (RS) [1316], and models with a composite Higgs where Higgs is a pseudo-Nambu-Goldstone boson (pNGB) [1317–1320]. Tables 37 and 38 only show predictions for up-quark sector, while the results for down-quark and lepton sectors can be found in (see also Sec. 7 of WG2 write-up).

In Tables 37 and 38, $v = 246$ GeV is the electroweak vev, while Λ is the typical NP scale. For instance, if SM is corrected by dimension six operators with Minimal Flavour Violation (MFV), then the up-quark couplings receive a contribution $Y'_u \bar{Q}_L H^c u_R/\Lambda^2$, so that the Yukawa coupling is $y_u = Y_u + 3Y'_u v^2/(2\Lambda^2)$, with $Y'_u = a_u Y_u + b_u Y_u Y_u^\dagger Y_u + c_u Y_d Y_d^\dagger Y_u + \cdots$, where $Y_{u,d}$ are the SM

Yukawas. The v^2/Λ^2 contributions correct both the diagonal Yukawa couplings, and lead to off-diagonal, flavour violating, couplings.

Not all NP models lead to flavour-violating Yukawa couplings. For instance, in multi-Higgs-doublet models with natural flavour conservation by assumption only one doublet, H_u, couples to the up-type quarks, only one Higgs doublet, H_d, couples to the down-type quarks, and only one doublet, H_ℓ couples to leptons (it is possible that any of these coincide, as in the SM where $H = H_u = H_d = H_\ell$) [1307, 1308]. This only modifies diagonal Yukawa couplings, while off-diagonal remain to be zero, as in the SM. Similar result applies to the MSSM tree-level Higgs potential where $h_{u,d}$ mix into the Higgs mass-eigenstates h and H as $h_u = \cos\alpha h + \sin\alpha H$, $h_d = -\sin\alpha h + \cos\alpha H$, where h is the observed SM-like Higgs, and the vevs are $v_u = \sin\beta\, v$, $v_d = \cos\beta$. Flavourful two-Higgs-doublet model [1309], on the other hand, introduces mass suppressed off-diagonal and CP violating contributions, a direct consequence of the fact that one Higgs doublet couples only to top, bottom and tau, and a second Higgs doublet couples to the remaining fermions (see also [1321–1324]). Off-diagonal and CP violating Yukawa couplings are typical of any model of flavour with new degrees of freedom that are light enough, such as if the Higgs mixes with the flavon from the Froggatt-Nielsen (FN) mechanism [1313], or if FN mechanism gives the structure of both dimension 4 and dimension 6 operators in SMEFT. Another example is the model of quark masses introduced by Giudice and Lebedev [1314], where the quark masses, apart from the top mass, are small, because they arise from higher dimensional operators.

In Randall-Sundrum warped extra-dimensional models, that address simultaneously the hierarchy problem and the hierarchy of the SM fermion masses [1316, 1325–1328], the corrections to the Yukawa couplings are suppressed by the masses of Kaluza-Klein (KK) modes, m_{KK}. If Higgs is a pseudo-Goldstone boson arising from the spontaneous breaking of a global symmetry in a strongly coupled sector, coupling to the composite sector with a typical coupling y_* [1317–1320] (for a review, see [1329]), the corrections to the Yukawa couplings are suppressed by the mass of composite resonance with a typical mass $M_* \sim \Lambda$.

In conclusion, we see that the NP effects in Higgs couplings to the SM fermions are either suppressed by $1/\Lambda^2$, where Λ is the NP scale, or are proportional to the mixing angles with the extra scalars. This means that in the decoupling limit, $\Lambda \to \infty$ and/or small mixing angles, all the NP effects vanish. In the decoupling limit the Higgs couplings coincide with the SM predictions, $\kappa_f = 1$, while $\tilde{\kappa}_f = 0, \kappa_{ff'} = 0, \tilde{\kappa}_{ff'} = 0$.

9.2 Probing charm and light quark Yukawa couplings

The inclusive method of probing the charm-quark Yukawa is in many ways complementary to searches for exclusive decays (see discussion of Sec. 9.2.3) or searches for deviations in Higgs distributions (see Sec. 9.2.4). For example, in the inclusive approach an underlying assumption is that the Higgs coupling to WW and ZZ —entering Higgs production— is SM-like, while the interpretation of Higgs distributions assumes no additional new physics contribution that affects them in a significant way. An important difference between the inclusive and the exclusive approach is that the latter relies on interference with the SM $H \to \gamma\gamma$ amplitude while the former does not. Therefore, in principle the exclusive approach may be sensitive to the sign and CP properties of the coupling to which the inclusive approach is insensitive to. At the same time, measurements of exclusive decays of the Higgs are challenging due to the small probability of fragmenting into the specific final state and large QCD backgrounds, which is why the inclusive approach appears to be the most promising one to probe deviations in the magnitude of the Higgs to charm coupling.

The summary of the projections that are discussed in the following sections, is given in Fig. 66. Shown are the expected HL-LHC constraints from exclusive decays (blue), from Higgs kinematic distributions (purple) and from inclusive c-tagging measurements (yellow), as well as the constraints from the combined $h \to \gamma\gamma$ and $h \to ZZ$ line shapes (dashed lines), from the total width using off-shell methods (green), and from the global fits to Higgs data (red). For the global fit one assumes $\mathcal{B}(h \to \text{BSM}) < 5\%$,

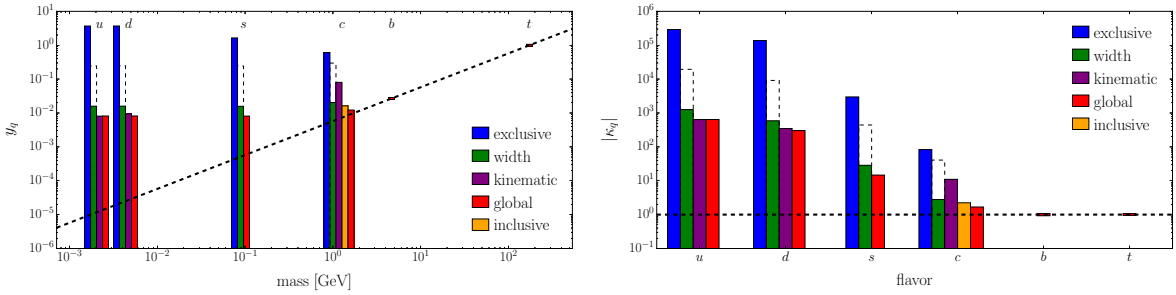

Fig. 65: Summary of the HL-LHC projections for measurements of Higgs Yukawa couplings to quarks discussed in the main text: from exclusive decays (blue), from Higgs kinematic distributions (purple) and from inclusive constraints (yellow), from off-shell bounds on total decay width (green), from the $h \to \gamma\gamma$ and ZZ line shapes (dashed), and from global fits (red).

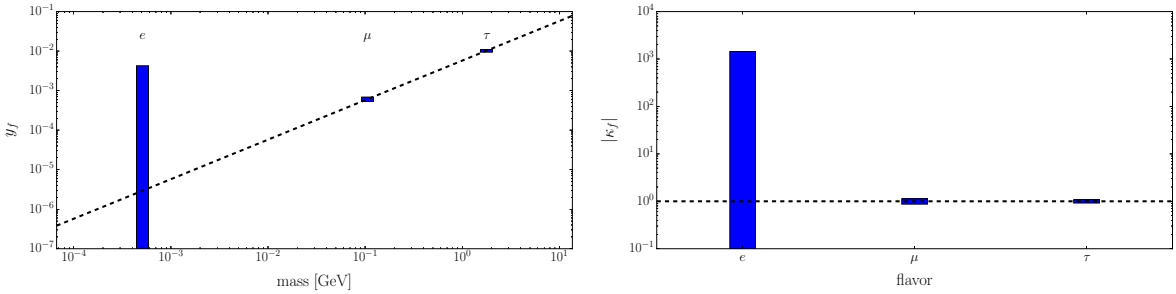

Fig. 66: Summary of the HL-LHC projections for measurements of Higgs Yukawa couplings to leptons from searches for $h \to \ell^+\ell^-$ decays.

while the constraints from the total width assume that one will be able to constrain $\Gamma < 1.2\Gamma_{\rm SM}$ (green bars), and that the resolution for the $\gamma\gamma/ZZ$ line shape will be 200MeV at the HL-LHC. Note that the off-shell constraints are model dependent.

9.2.1 Inclusive charm quark tagging

The most straight-forward way of inclusively probing charm quark Yukawa is to expand the $h \to b\bar{b}$ search with a search for $pp \to (Z/W \to \ell\ell/\nu)(h \to c\bar{c})$ [1285]. Another possibility is to search for $pp \to hc$ production [1298]. The search for $h \to c\bar{c}$ from $pp \to Zh$ at $\sqrt{s} = 13$ TeV was recently performed on a 36.1 fb^{-1} sample by ATLAS [1283]. The c-tagging algorithms are similar to b-tagging ones, with the most relevant quantities the displaced vertices due to a finite lifetime of c-hadrons. Prior to its use in Higgs physics, c-tagging was used early on in Run I of the LHC by ATLAS and CMS in searches for supersymmetry [1330, 1331]. Its usefulness in relations to Higgs physics was first discussed in Ref. [1332] and subsequently used in Ref. [1285] to recast ATLAS and CMS Run I analyses for $h \to b\bar{b}$ to provide the first direct LHC constraint on charm Yukawa.

The efficiency of jet flavour tagging algorithms in associating a jet to a specific quark is correlated with the confidence to reject other hypotheses, e.g., production from light-quarks. Given the rather similar lifetimes of b and c hadrons, there is always a non-negligible contamination of the c-jet sample with b jets [1285]. The ATLAS analysis [1283] used a working point with an efficiency of approximately 41% to tag c-jets and rejection factors of roughly 4 and 20 for b- and light-quark-jets, respectively. An inclusive $h \to c\bar{c}$ analysis must thus either assume a SM value for the bottom Yukawa (as in Ref. [1283]), or break the degeneracy between y_b and y_c, e.g., by using more than one tagging working point with different ratios of c-tagging to b-tagging efficiencies [1285, 1297].

The prospects for measuring $pp \to Zh(\to c\bar{c})$ at the HL-LHC were obtained in Ref. [1333], by

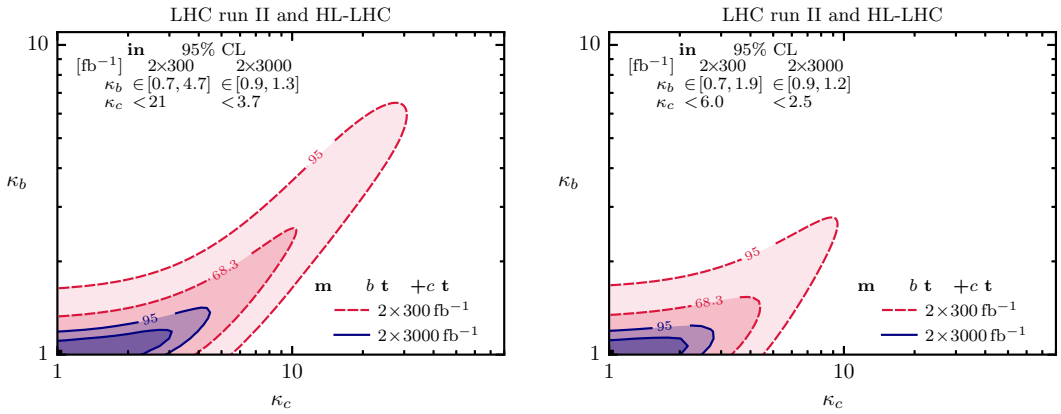

Fig. 67: Projections for measuring charm Yukawa modifications from an inclusive $H \to c\bar{c}$ search at $\sqrt{s} = 14\,\text{TeV}$ using two different c-taggers (left and right panel) [1297]. In red the 95% CL region employing an integrated luminosity of 2×300 fb^{-1} and in blue the region employing 2×3000 fb^{-1}.

rescaling the Run 2 analysis [1283] to an integrated luminosity of 3000 fb^{-1}. Possibilities to reduce the systematic uncertainties were discussed as well. Assuming $\kappa_b = 1$, an upper bound on the signal strength of $\mu_{Zh(c\bar{c})} < 6.3$ at 95% CL can be set. In Ref. [1297] instead, the prospects for measuring $h \to b\bar{b}$ at $\sqrt{s} = 14\,\text{TeV}$ [1334] were recast to obtain the projection for an inclusive $h \to c\bar{c}$ measurement. Both κ_c and κ_b are treated as free variables. Fig. 67 shows results for two flavour tagging working points: a c-tagging efficiency of 30% (c-tag II, left panel) or 50% (c-tag III, right panel), while in both cases the b(light)-jet rejection is 5(200). The κ_b direction is profiled away, giving the HL-LHC sensitivity of $\kappa_c \simeq 21(6)$ at 95% CL with c-tag II (c-tag III) and $2 \times 3000\,\text{fb}^{-1}$ at $\sqrt{s} = 14\,\text{TeV}$, indicated by the blue regions in Fig. 67.

Even though the LHCb experiment operates at lower luminosity compared to ATLAS and CMS, it has unique capabilities for discrimination between b- and c-jets thanks to its excellent vertex reconstruction system [1335]. With the secondary vertex tagging (SV-tagging) LHCb achieved an identification efficiency of 60% on b-jets, of 25% on c-jets and a light jets (light quarks or gluons) mis-identification probability of less than 0.2%. Further discrimination between light and heavy jets and between b- and c-jets is achieved by exploiting the secondary vertex kinematic properties, using Boosted Decision Tree techniques (BDTs). For instance, an additional cut on the BDT that separates b- from c-jets removes 90% of $h \to b\bar{b}$ while retaining 62% of $h \to c\bar{c}$ events [1336].

The LHCb acceptance covers $\sim 5\%$ of the associated production of $W/Z + h$ at 13 TeV. Fig. 68 (left) shows the coverage of LHCb for the $b\bar{b}$ pair produced in the decay of the Higgs boson in association with a vector boson. When the two b-jets are within the acceptance, the lepton from W/Z tends to be in acceptance as well ($\sim$ 60% of the time). Due to the forward geometry, Lorentz-boosted Higgs bosons are likely to be properly reconstructed.

LHCb set upper limits on the $V + h(\to b\bar{b})$ and $V + h(\to c\bar{c})$ production [1336] with data from LHC Run 1. Without any improvements in the analysis or detector, the extrapolation of this to 300fb^{-1} at 14 TeV leads to a sensitivity of $\mu_{Zh(cc)} \lesssim 50$. Detector improvements are expected in future upgrades, in particular in impact parameter resolution which directly affects the c-tagging performance. If the detector improvement is taken into account, the c-jet tagging efficiency with the SV-tagging is expected to improve as shown in Fig. 68 (right). Further improvement is expected from the electron reconstruction due to upgraded versions of the electromagnetic calorimeter. Electrons are used in the identification of the vector bosons associated with the Higgs. With these improvements, the expected limit can be pushed down to $\mu_{Zh(cc)} \lesssim 5 - 10$ which corresponds to a limit of 2-3 times the Standard Model prediction on

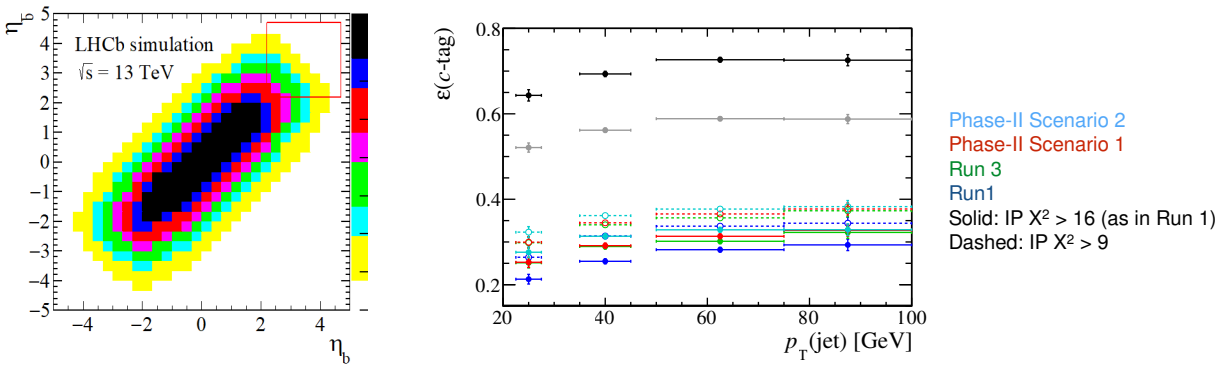

Fig. 68: Left: 2D histogram showing the coverage of the LHCb acceptance for the $b\bar{b}$ pair produced by the Higgs decay in associated production with a W or a Z boson. Right: LHCb c-jet SV-tagging efficiency for different scenarios in the HL-LHC conditions.

the charm Yukawa coupling. This extrapolation does not include improvements in analysis techniques: for instance Deep Learning methods can be applied to exploit correlations in jets substructure properties to reduce the backgrounds.

9.2.2 Strange quark tagging

The main idea behind the strange tagger described in Ref. [1337] is that strange quarks—more than other partons—hadronize to prompt kaons which carry a large fraction of the jet momentum. Although the current focus at LHC is mainly on charm and bottom tagging, recognizing strange jets has been attempted before at DELPHI [1338] and SLD [1339], albeit in Z decays.

Fig. 69 shows results for a strange tagger based on an analysis of event samples of Higgs and W events generated with PYTHIA 8.219 [373, 1340]. In each of the two hemispheres of the resonance decay, the charged pions and kaons stemming from the resonance are selected with an assumed efficiency of 95%. Similarly, K_S are identified with an efficiency of 85% if they decay via $K_S \to \pi^+\pi^-$ within 80 cm of the interaction point, which allows one to reconstruct the decaying neutral kaon. Among the two lists of kaon candidates—one per hemisphere—one kaon in each list is chosen for further analysis such that the scalar sum of their momenta is maximized while rejecting charged same-sign pairs. The events are separated into the categories charged-charged (CC), charged-neutral (CN) and neutral-neutral (NN) with relative abundances of about CC:CN:NN$\approx 9:6:1$.

All selected candidates are required to carry a large momentum $p_{||}$ along the hemisphere axis. This cut reduces the background from gluon jets as gluons radiate more than quarks and therefore tend to spread their energy among more final state particles. In addition, charged kaons need to be produced promptly, in order to reject heavy flavour jets. The latter requirement is implemented by a cut on the impact parameter d_0 after the truth value has been smeared by the detector resolution.

The efficiencies obtained in the CC and CN channel for a cut of $d_0 < 14$ μm are shown in Fig. 69. While there is clearly still ample room for improvement, this simple tagger already shows a good suppression of the bottom, charm and gluon background by orders of magnitude. Due to missing particle identification at ATLAS and CMS, the efficiencies for first-generation jets and strange jets are degenerate in the CC channel. However, in the CN channel, due to the required K_S, a suppression of pions is achieved that breaks this degeneracy. This is particularly interesting in light of the HL-LHC, where a large background from first generation jets is expected.

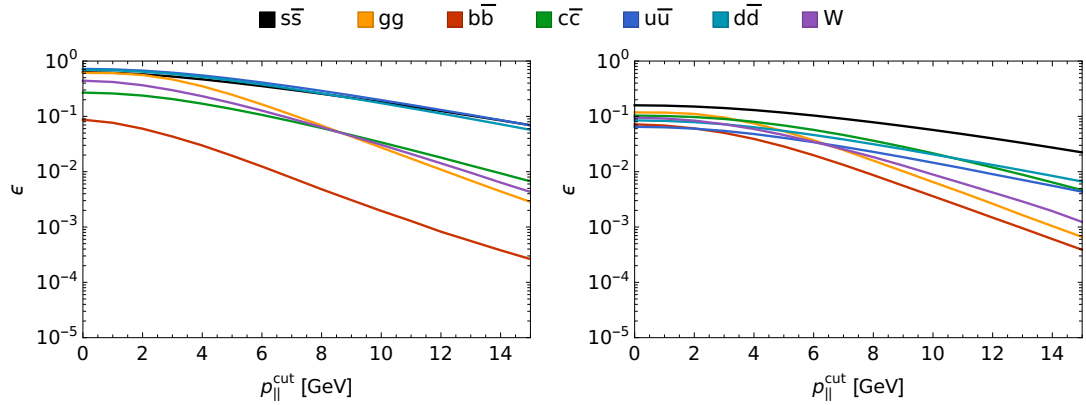

Fig. 69: Efficiencies as function of the cut on $p_{||}$ and for d_0 <14 μm to reconstruct the different Higgs decay channels and W decays as $s\bar{s}$ event by the described tagger. The left plot shows the CC channel, the right the CN channel.

mode	$\mathcal{B}_{h\to V\gamma}<$	$\mathcal{R}_{V\gamma,ZZ^*}<$	Yukawa range
$J/\psi\,\gamma$	$1.5\cdot10^{-3}$ [1289, 1290]	9.3	$-295\kappa_Z+16\kappa_{\gamma\gamma}^{\rm eff}<\kappa_c<295\kappa_Z+16\kappa_{\gamma\gamma}^{\rm eff}$
$\phi\,\gamma$	$4.8\cdot10^{-4}$ [1292, 1341]	3.2	$-140\kappa_Z+10\kappa_{\gamma\gamma}^{\rm eff}<\bar{\kappa}_s<140\kappa_Z+10\kappa_{\gamma\gamma}^{\rm eff}$
$\rho\,\gamma$	$8.8\cdot10^{-4}$ [1292]	5.8	$-285\kappa_Z+42\kappa_{\gamma\gamma}^{\rm eff}<2\bar{\kappa}_u+\bar{\kappa}_d<285\kappa_Z+42\kappa_{\gamma\gamma}^{\rm eff}$

Table 39: The current 95% C.L. upper bounds, assuming SM Higgs production, on different exclusive $h\to V\gamma$ decays, and the interpretation in terms of the Higgs Yukawa couplings. Note that $\bar{\kappa}_q=y_q/y_b^{\rm SM}$.

9.2.3 Exclusive Higgs decays

Exclusive Higgs decays to a vector meson, V, and a photon, $h\to V\gamma$, can directly probe bottom, charm [1300,1301], strange, down and up [1287] quark Yukawas. On the experimental side, both ATLAS and CMS reported first upper bounds on $h\to\Upsilon\gamma$, $J/\psi\gamma$ [1289,1290], $h\to\phi\gamma$ and $h\to\rho\gamma$ [1292,1341], sensitive to diagonal Yukawa couplings. The $h\to V\gamma$ decays receive two contributions, from $h\to\gamma\gamma^*$ decay followed by a $\gamma^*\to V$ fragmentation, and from a numerically smaller amplitude that involves the direct coupling of quarks to the Higgs [1287, 1300, 1301, 1342]. The sensitivity to the quark Yukawa couplings thus comes mostly from the interference of the two amplitudes.

Normalizing to the $h\to ZZ^*\to4\ell$ channel the total Higgs width cancels [1285, 1299],

$$\mathcal{R}_{V\gamma,ZZ^*}\equiv\frac{\mu_{V\gamma}}{\mu_{ZZ^*}}\frac{\mathcal{B}_{h\to V\gamma}^{\rm SM}}{\mathcal{B}_{h\to ZZ^*}^{\rm SM}}\simeq\frac{\Gamma_{h\to V\gamma}}{\Gamma_{h\to ZZ^*}}, \tag{129}$$

where $\mathcal{B}_{h\to ZZ^*}^{\rm SM}$ is the SM branching ratio for $h\to ZZ^*\to4\ell$. In the last equality we also assumed perfect cancellation of the production mechanisms (this is entirely correct, if $h\to\gamma\gamma$ is used as normalization channel, but at present this leads to slightly worse bounds on light quark Yukawas). Using predictions from Ref. [1299] gives the currently allowed ranges for light quark Yukawa couplings, collected in Table 39 (here κ_Z and $\kappa_{\gamma\gamma}^{\rm eff}$ parametrize deviations of $h\to ZZ,\gamma\gamma$ amplitudes relative to their SM values).

For prospects to probe light quark Yukawa at HL-/HE-LHC we follow Ref. [1297]. Rescaling with luminosity and the increased production cross sections both the signal and backgrounds, while ignoring any changes to the analysis that may change the ratios of the two, gives the projected sensitivities listed in Table 40. The estimates in Table 40 are in agreement with the ATLAS projection for $h\to J/\psi\gamma$ [1343], which quotes $\mathcal{R}_{J/\psi\gamma,ZZ^*}<0.34^{+0.14}_{-0.1}$. We see that only large enhancements, with Yukawa coupling of

mode	collider energy	$\mathcal{R}_{V\gamma,ZZ^*} <$	Yukawa range ($\kappa_V = \kappa_{\gamma\gamma}^{\rm eff} = 1$)
$J/\psi\,\gamma$	14 TeV	$0.47\sqrt{L_3}$	$16 - 67L_3^{1/4} < \kappa_c < 16 + 67L_3^{1/4}$
	27 TeV	$0.28\sqrt{L_3}$	$16 - 52L_3^{1/4} < \kappa_c < 16 + 52L_3^{1/4}$
$\phi\,\gamma$	14 TeV	$0.33\sqrt{L_3}$	$11 - 46L_3^{1/4} < \bar{\kappa}_s < 11 + 46L_3^{1/4}$
	27 TeV	$0.20\sqrt{L_3}$	$11 - 35L_3^{1/4} < \bar{\kappa}_s < 11 + 35L_3^{1/4}$
$\rho\,\gamma$	14 TeV	$0.60\sqrt{L_3}$	$44 - 93L_3^{1/4} < 2\bar{\kappa}_u + \bar{\kappa}_d < 44 + 93L_3^{1/4}$
	27 TeV	$0.36\sqrt{L_3}$	$44 - 72L_3^{1/4} < 2\bar{\kappa}_u + \bar{\kappa}_d < 44 + 72L_3^{1/4}$

Table 40: The projections of bounds on Yukawa couplings for HL-/HE-LHC as functions of integrated luminosity, $L_3 \equiv (3/\text{ab})/\mathcal{L}$. Note that $\bar{\kappa}_q = y_q/y_b^{\rm SM}$.

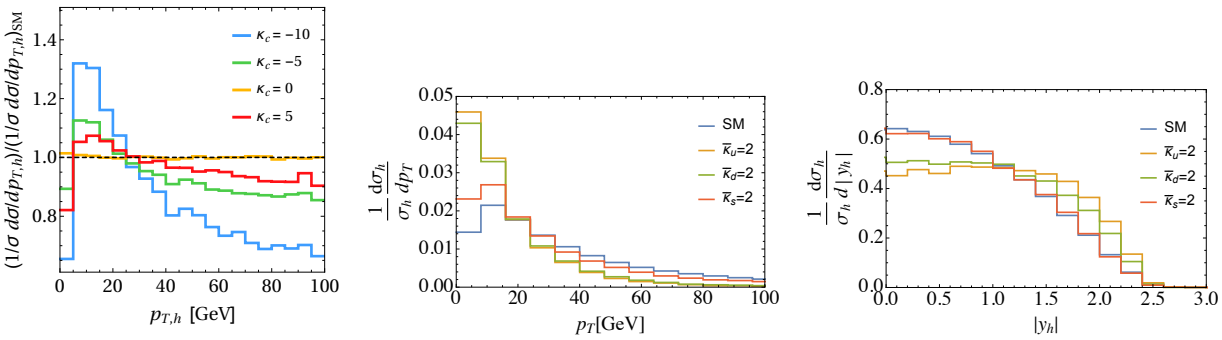

Fig. 70: Normalized Higgs $p_{\rm T}$ and rapidity distributions for modified charm (left) and u, d and s Yukawas (middle and right). Taken from [1294] and [1293].

light quarks well above the values of bottom Yukawa will be probed. To be phenomenologically viable, these would require large cancellations in the contributions to the light quark masses (and a mechanism to avoid indirect bounds from global fits to the Higgs data).

Higgs exclusive decays can in principle also probe off-diagonal couplings by measuring modes such as $h \to B_s^*\gamma$ [1287]. However, the Higgs flavour violating couplings are strongly constrained by meson mixing [1344, 1345], so that the expected rates are too small to be observed. For a detailed discussion of $h \to MZ, MW$ channels see [1346].

9.2.4 Yukawa constraints from Higgs distributions

9.2.4.1 Higgs $p_{\rm T}$ and rapidity distributions

In general, the Higgs $p_{\rm T}$ distribution probes whether NP particles are running in the $gg \to h + (g)$ loops [1347–1358]. However, the soft part of the $p_{\rm T}$ spectrum is also an indirect probe of light quark Yukawas [1293, 1294]. If Higgs, unlike in the SM, is produced from the $u\bar{u}$ or $d\bar{d}$ fusion, then *(i)* the Sudakov peak is shifted to $p_T \sim 5\,$GeV from $\sim 10\,$GeV in the SM [1293, 1359], and *(ii)* the rapidity distributions are more forward, i.e., shifted toward larger η [1293], see Fig. 70. Enhanced s or c Yukawa couplings also lead to softer Higgs $p_{\rm T}$ spectrum. The dominant effect for charm quark is due to one loop contributions to $gg \to hj$ process that are enhanced by double logarithms [1360], while for strange quark it is due to $s\bar{s}$ fusion production of the Higgs [1293]. Fig. 70 shows the corresponding normalized distributions, for which many theoretical and experimental uncertainties cancel.

The 8 TeV ATLAS results on Higgs $p_{\rm T}$ distributions [1361] were converted to the following 95 %

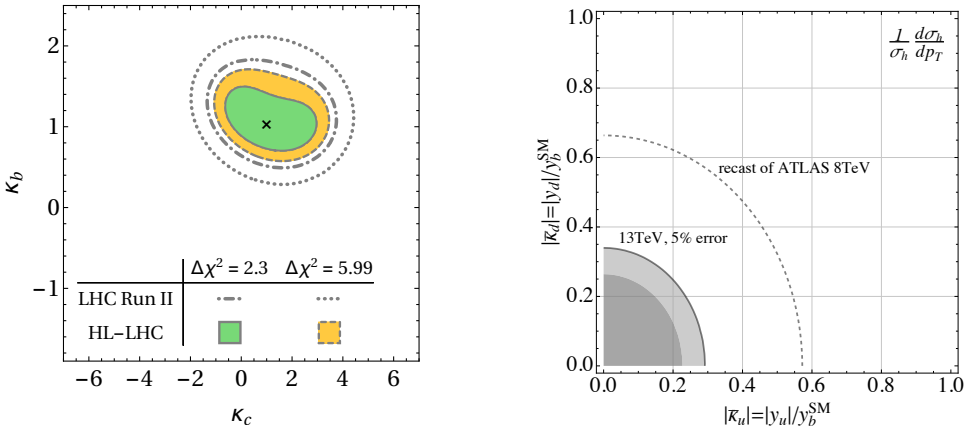

Fig. 71: The sensitivity of Higgs $p_{\rm T}$ distributions to the light quark Yukawa couplings at 13 TeV LHC Run2 and HL-LHC: to charm and bottom [1294] (left) and to up and down [1293] (right, assuming total 5% systematic+statistical uncertainty).

CL bounds in Ref. [1293]

$$\bar{\kappa}_u = y_u/y_b^{\rm SM} < 0.46\,, \qquad \bar{\kappa}_d = y_d/y_b^{\rm SM} < 0.54\,, \tag{130}$$

stronger than the corresponding bounds from fits to the inclusive Higgs production cross sections. The sensitivities expected at HL-LHC are shown in Fig. 71 (right), assuming a 5% total uncertainty in each $p_{\rm T}$ bin. CMS interpreted the 35.9 fb^{-1} measurement of 13 TeV Higgs $p_{\rm T}$ spectrum in terms of 95 % CL bounds on c and b Yukawa couplings [1362]

$$-4.9(-33) < \kappa_c < 4.8(38), \qquad -1.1(-8.5) < \kappa_b < 1.1(18), \tag{131}$$

assuming the branching fractions depend only on κ_c or κ_b (in addition the total decay width is allowed to float freely). These bounds on the c and b Yukawa are weaker than the bounds from the global fit of the 8 TeV Higgs data along with the electroweak precision data allowing all Higgs coupling to float [1285] and from the direct measurement of $h \to b\bar{b}$ by using b-tagging. The projected HL-LHC sensitivity for $\kappa_{c,b}$ from higgs p_T distributions, while assuming SM branching ratios, is shown in Fig. 71 (left). For the case that tha bounds depends only on the κ_c and κ_b, the bound on the c Yukawa is stronger than the bound from the global fit of the 8 TeVHiggs data along with the electroweak precision data, allowing all Higgs couplings to float [1285]. However, it relies on strong assumptions that the Higgs couplings (besides c or b) are SM like, and it is mostly sensitive to the cross section and not to the angular shape as the latter bound.

Fig. 72 shows expected one sigma κ_c, κ_b contours from 3000fb^{-1} global fits, obtained by extrapolating the measured constraints in Ref. [1363]. The fit uses expected differential distributions, obtained by extrapolating the $\sqrt{s} = 13$ TeV $p_{\rm T}$ distributions in the $h \to \gamma\gamma$ [1364] and $h \to ZZ^{(*)} \to 4\ell$ [1365] ($\ell = e$ or μ) decay channels, as well as a search for $h \to b\bar{b}$ at large $p_{\rm T}$ [1366], which enhances the sensitivity to κ_t. The simultaneous extended maximum likelihood fit to the diphoton mass, four-lepton mass, and soft-drop mass, $m_{\rm SD}$, [1367, 1368] spectra in all the analysis categories of the $h \to \gamma\gamma$, $h \to ZZ$, and $h \to b\bar{b}$ channels, gives the results in Fig. 72 (left) when only κ_c and κ_b are varied, while all the other couplings are set to the SM value, and in Fig. 72 (right), if in addition the Higgs total decay width is allowed to float. In the fit for Fig. 72 (left) the largest sensitivity to κ_c, κ_b comes from the total cross sections times branching ratios, while for Fig. 72 (right) it is due to normalized differential distributions $(1/\sigma)(d\sigma/dp_T)$. In Fig. 72 the systematic uncertainties are conservatively kept at current level (dubbed Scenario 1). There is only a minor change in the projected constraints on κ_c, κ_b in case of reduced systematic uncertainties (Scenario 2) compared to Scenario 1.

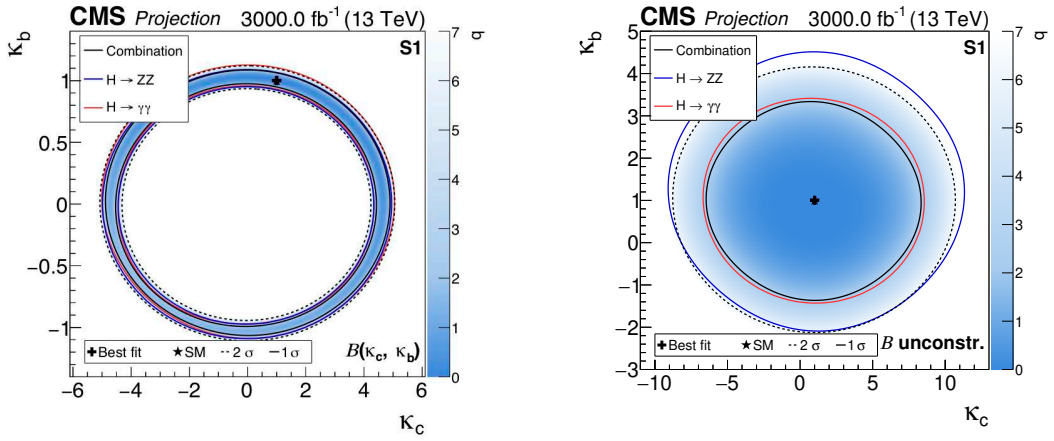

Fig. 72: Left: projected simultaneous fit of κ_b and κ_c from 3ab^{-1} 13 TeV data, assuming current systematics (Scenario 1). The one standard deviation contours are drawn for the $h \to \gamma\gamma$ channel (the $h \to ZZ$, the combination of $h \to \gamma\gamma$ and $h \to ZZ$) with solid red (blue, black). For the combination the two standard deviation contour is drawn as a black dashed line. The negative log-likelihood value are given on the coloured axis. Right: same as left, but with the branching fractions implemented as nuisance parameters with no prior constraint, i.e., the total Higgs width is floated freely. (Taken from [1369].).

9.2.4.2 $W^{\pm}h$ charge asymmetry

The $W^{\pm}h$ charge asymmetry,

$$A = \frac{\sigma(W^+h) - \sigma(W^-h)}{\sigma(W^+h) + \sigma(W^-h)}, \tag{132}$$

is a production-based probe of light quark Yukawa couplings [1370]. In the SM, the inclusive HE-LHC charge asymmetry is expected to be 17.3%, while the HL-LHC charge asymmetry is expected to be 21.6%. The dominant $W^{\pm}h$ production mode is due to Higgs boson radiating from $W^{\pm}$ intermediate lines, if the Yukawa-mediated diagrams are negligible. If the quark Yukawas are not SM-like, however, the charge asymmetry can either increase or decrease, depending on the overall weight of the relevant PDFs. In particular, the charge asymmetry will increase if the down or up quark Yukawa couplings are large, reflecting the increased asymmetry of $u\bar{d}$ vs. $\bar{u}d$ PDFs; the charge asymmetry will decrease if the strange or charm Yukawa couplings are large, reflecting the symmetric nature of $c\bar{s}$ vs. $\bar{c}s$ PDFs. The subleading correction from the Cabibbo angle-suppressed PDF contributions determines the asymptotic behavior for extremely large Yukawa enhancements.

The effect of individual d, u, s, or c quark Yukawa enhancements on the inclusive charge asymmetry is shown in Fig. 73, in units of $\bar{\kappa}_f = y_f/y_{b,\text{SM}}$, evaluated at the Higgs mass scale. Since $W^{\pm}h$ production probes lower Bjorken-x at the HE-LHC compared to the HL-LHC, the expected SM charge asymmetry is lower at the higher energy collider. The bands denote the change in the charge asymmetry from varying the renormalization and factorization scales within a factor of 2. The error bars denote the expected 0.45% (0.25%) statistical sensitivity to the charge asymmetry at HL-LHC (HE-LHC) in the $W^{\pm}h \to \ell^{\pm}\ell^{\pm}jj\nu\nu$ final state [1370]. The HE-LHC sensitivity was estimated by simply rescaling with the appropriate luminosity ratio, since we expect the increases in both signal and background electroweak rates to largely cancel. The constraint from the CMS Run I direct Higgs width upper bound is also shown [1370]. If the signal strengths are fixed to the SM expectation and the central prediction is used, the HE-LHC charge asymmetry measurement could constrain $\bar{\kappa}_f \lesssim 2-3$ for up and charm quarks, and $\bar{\kappa}_f \lesssim 7$ for down or strange quarks.

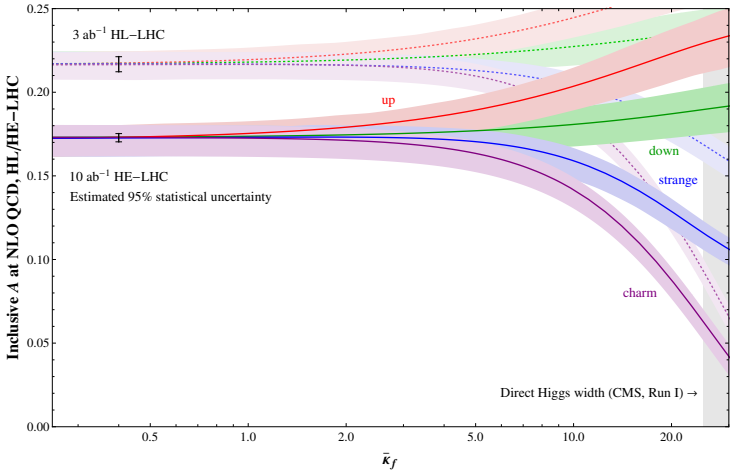

Fig. 73: Inclusive charge asymmetry for $W^{\pm}h$ production at the 27 TeV HE-LHC (solid colored bands), and 14 TeV HL-LHC (dotted colored bands), calculated at NLO QCD from MadGraph_aMC@NLO using NNPDF 2.3 as a function of individual Yukawa rescaling factors $\bar{\kappa}_f$ for $f = u$ (red), d (green), s (blue), and c (purple). Shaded bands correspond to scale uncertainties at 1σ from individual $\sigma(W^+h)$ and $\sigma(W^-h)$ production, which are conservatively taken to be fully uncorrelated. The expected statistical errors from this measurement using 10 ab^{-1} of HE-LHC data and 3 ab^{-1} of HL-LHC data are also shown.

9.3 LFV decays of the Higgs

The flavour violating Yukawa couplings are well constrained by the low-energy flavour-changing neutral current measurements [1344,1345,1371]. For instance, CMS bounds $\kappa^2_{\mu e}+\kappa^2_{e\mu} < (5.4\times10^{-4})^2$ from the $h \to e\mu$ search [1372], compared to indirect bound from $\mu \to e\gamma$, which is $\kappa^2_{\mu e} + \kappa^2_{e\mu} < (3.6 \times 10^{-6})^2$ [1345]. A notable exception are the flavour-violating couplings involving a tau lepton, where the strongest constraints on $\kappa_{\tau\mu}, \kappa_{\mu\tau}, \kappa_{\tau e}, \kappa_{e\tau}$ are from direct searches for flavour-violating Higgs decays at the LHC [1373, 1374]. Currently, the CMS 13 TeV search with 35.9 fb^{-1} [1373] gives the strongest constraint

$$\sqrt{\kappa^2_{\mu\tau} + \kappa^2_{\tau\mu}} < 1.43 \times 10^{-3}\,, \qquad \sqrt{\kappa^2_{e\tau} + \kappa^2_{\tau e}} < 2.26 \times 10^{-3}\,, \tag{133}$$

obtained from 95 % CL upper limits $\mathcal{B}(h \to \mu\tau) < 0.25\%$ and $\mathcal{B}(h \to e\tau) < 0.61\%$, respectively. One can also directly measure the difference between the branching ratios of $h \to \tau e$ and $h \to \tau\mu$, as proposed in [1375]. Assuming naively that both systematics and statistical error scale with square root of the luminosity, one can expect that the sensitivity of 3000 fb^{-1} HL-LHC will be around the half per-mil level for both the $h \to e\tau$ and $h \to \mu\tau$ branching ratios.

The LHC can also set bounds on rare FCNC top decays involving a Higgs [1182,1198,1376,1377]. The strongest current bounds are $|\kappa_{ct}|^2 + |\kappa_{tc}|^2 < (0.06)^2$ and $|\kappa_{ut}|^2 + |\kappa_{tu}|^2 < (0.07)^2$ at 95 % CL.

9.4 CP violating Yukawa couplings

The CP-violating flavour-diagonal Yukawa couplings, $\tilde{\kappa}_{f_i}$, are well constrained from bounds on the electric dipole moments (EDMs) [1286, 1378–1381] under the assumption of no cancellation with other contributions to EDMs. For the electron Yukawa, the latest ACME measurement [1253, 1382] results in an upper bound of $\tilde{\kappa}_e < 1.9 \times 10^{-3}$ [1286]. For the bottom and charm Yukawas the strongest limits come from the neutron EDM [1381]. Using the NLO QCD theoretical prediction, this translates into the upper bounds $\tilde{\kappa}_b < 5$ and $\tilde{\kappa}_c < 21$ when theory errors are taken into account. For the light quark

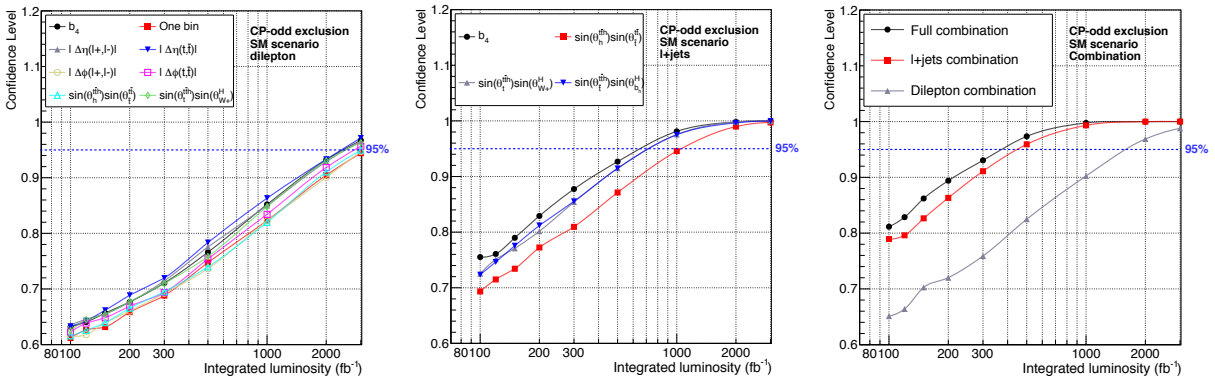

Fig. 74: Expected CL, assuming the SM, for exclusion of the pure CP-odd scenario, $\kappa_t = 0, \tilde{\kappa}_t = 1$, as a function of the integrated luminosity. Left: using the $t\bar{t}h$ ($h \to b\bar{b}$) dileptonic analysis only, middle: using the $t\bar{t}h$ ($h \to b\bar{b}$) semileptonic analysis only, right: combining observables in each individual channel and combining both channels, treating the observables as uncorrelated. A likelihood ratio computed from the binned distribution of the corresponding discriminant observable was used as test statistic.

CPV Yukawas, measurements of the Mercury EDM place strong bounds on the up and down Yukawas of $\tilde{\kappa}_u < 0.06$ and $\tilde{\kappa}_d < 0.03$ [1383] (no theory errors, 90% CL), while the neutron EDM measurement gives a weaker constraint on the strange quark Yukawa of $\tilde{\kappa}_s < 2.2$ [1383] (no theory errors, 90% CL).

The top and τ Yukawa phases can be directly probed at HL-LHC, as we discuss below. For constraints from EDMs and other phases see [1253, 1286, 1286, 1378, 1379, 1381, 1382].

9.4.1 $t\bar{t}h$

CP violation in the top quark-Higgs coupling is strongly constrained by EDM measurements [1378], if the light quark Yukawa couplings and hWW couplings have their SM values. If this is not the case, the indirect constraints on the phase of the top Yukawa coupling can be substantially relaxed. Assuming the EDM constraints can be avoided, the CP structure of the top quark Yukawa can be probed directly in $pp \to t\bar{t}h$. Many simple observables, such as $m_{t\bar{t}h}$ and $p_{T,h}$ are sensitive to the CP structure, but require reconstructing the top quarks and Higgs.

Recently, several $t\bar{t}h$ observables have been proposed that access the CP structure without requiring full event reconstruction. These include the azimuthal angle between the two leptons in a fully leptonic $t/\bar{t}$ decay with the additional requirement that the $p_{T,h} > 200\,\text{GeV}$ [1384], and the angle between the leptons, in a fully leptonic $t/\bar{t}$ system, projected onto the plane perpendicular to the h momentum [1385]. These observables only require that the Higgs is reconstructed and are inspired by the sensitivity of $\Delta\phi_{\ell^+\ell^-}$ to top/anti-top spin correlations in $pp \to t\bar{t}$ [1386]. The sensitivity of both of these observables improves at higher Higgs boost, and therefore higher energy, making them promising targets for the HE-LHC, though no dedicated studies have been carried out to date.

Fig. 74 shows the expected CL, assuming the SM, for exclusion of the pure CP-odd scenario, $\kappa_t = 0, \tilde{\kappa}_t = 1$, as a function of the integrated luminosity. Samples of $t\bar{t}h(h \to b\bar{b})$ events were generated at the LHC for $\sqrt{s} = 13$ TeV, with `MadGraph5_aMC@NLO` [372] using the `HC_NLO_X0` model [1387], as were all relevant SM background processes. The analyses of the $t\bar{t}h$ ($h \to b\bar{b}$) events were carried out in the dileptonic and semileptonic decay channels of the $t\bar{t}$ system. `Delphes` [374] was used for a parametrised detector simulation and both analyses used kinematic fits to fully reconstruct the $t\bar{t}h$ system. The results were extrapolated, as a function of luminosity, up to the 3000 fb^{-1}.

Fig. 74 left (middle) shows results using the dileptonic (semileptonic) analysis only. The CL were obtained from a signal-enriched region (with at least 3 b-tagged jets) in which a likelihood ratio was computed from binned distributions of various discriminant observables [1388, 1389]. Only statistical

uncertainties were considered. Fig. 74 right shows CL obtained from the combination of different observables in each channel i.e., $\Delta\eta(\ell^+,\ell^-)$, $\Delta\phi(t,\bar{t})$ and $\sin(\theta_t^{t\bar{t}H})\sin(\theta_{W^+}^{H})$ in the dileptonic channel and, b_4 and $\sin(\theta_{\bar{t}}^{t\bar{t}H})\sin(\theta_{b_H}^{H})$ in the semileptonic channel. The combination of the two channels is also shown for comparison. The observables were treated as uncorrelated.

The main conclusions of these studies can be summarized in what follows: *i)* many angular observables are available with the potential of discriminating between values of $\kappa_t, \tilde{\kappa}_t$ in the top quark Yukawa coupling; *ii)* the sensitivity of the semileptonic final state of $t\bar{t}h(h \to b\bar{b})$ is roughly a factor 3 better than that of the dileptonic channel alone (Fig. 74 left); *iii)* the combination of the two channels (semi- and dileptonic) is roughly a factor 5 more sensitive than the dileptonic channel, providing a powerful test of the top quark-Higgs interactions in the fermionic sector.

9.4.2 $\tau\bar{\tau}h$

The most promising direct probe of CP violation in fermionic Higgs decays is the $\tau^+\tau^-$ decay channel, which benefits from a relatively large τ Yukawa, resulting in a SM branching fraction of 6.3%. Measuring the CP violating phase in the tau Yukawa requires a measurement of the linear polarizations of both τ leptons and the azimuthal angle between them. This can be done by analyzing tau substructure, namely the angular distribution of the various components of the tau decay products.

The main τ decay modes studied include $\tau^\pm \to \rho^\pm(770)\nu$, $\rho^\pm \to \pi^\pm\pi^0$ [1390–1395] and $\tau^\pm \to \pi^\pm\nu$ [1396–1398]. Assuming CPT symmetry, collider observables for CP violation must be built from differential distributions based on triple products of three-vectors. In the first case, $h \to \pi^\pm\pi^0\pi^\mp\pi^0\nu\nu$, angular distributions built only from the outgoing charged and neutral pions are used to determine the CP properties of the initial τ Yukawa coupling. In the second case, $h \to \pi^\pm\pi^\mp\nu\nu$, there are not enough reconstructible independent momenta to construct an observable sensitive to CP violation, requiring additional kinematic information such as the τ decay impact parameter.

In the kinematic limit when each outgoing neutrino is taken to be collinear with its corresponding reconstructed $\rho^\pm$ meson, the acoplanarity angle, denoted Φ, between the two decay planes spanned by the $\rho^\pm \to \pi^\pm\pi^0$ decay products is exactly analogous to the familiar acoplanarity angle from $h \to 4\ell$ CP-property studies. Hence, by measuring the τ decay products in the single-prong final state, suppressing the irreducible $Z \to \tau^+\tau^-$ and reducible QCD backgrounds, and reconstructing the acoplanarity angle of ρ^+ vs. ρ^-, the differential distribution in Φ gives a sinusoidal shape whose maxima and minima correspond to the CP-phase in the τ Yukawa coupling, $\varphi_\tau = \arctan(\tilde{\kappa}_\tau/\kappa_\tau)$.

An optimal observable using the colinear approximation was derived in [1393]. Assuming 70% efficiency for tagging hadronic τ final states, and neglecting detector effects, the estimated sensitivity for the CP-violating phase φ_τ using 3 ab^{-1} at the HL-LHC is 8.0°. A more sophisticated analysis [1394] found that detector resolution effects on the missing transverse energy distribution degrade the expected sensitivity considerably, and as such, about 1 ab^{-1} is required to distinguish a pure scalar coupling ($\kappa_\tau = 1, \tilde{\kappa}_\tau = 0$) from a pure pseudoscalar coupling ($\kappa_\tau = 0, \tilde{\kappa}_\tau = 1$).

At the HE-LHC, the increased signal cross section for Higgs production is counterbalanced by the increased background rates, and so the main expectation is that improvements in sensitivity will be driven by the increased luminosity and more optimized experimental methodology. Rescaling with the appropriate luminosity factors, the optimistic sensitivity to the τ Yukawa phase φ_τ from acoplanarity studies is 4-5°, while the more conservative estimate is roughly an order of magnitude worse.

10 The high $p_{\rm T}$ flavour physics programme

Flavour and high $p_{\rm T}$ searches are intertwined in several ways. On the one hand the stringent bounds from low-energy constraints put severe bounds on the NP models that contain states with TeV masses with couplings to quarks. On the other hand, TeV scale New Physics is suggested by several solutions of long standing problems of the SM, e.g., the hierarchy problem. Quite often the low energy constraints are avoided by assuming Minimal Flavour Violation (MFV), where the only flavour breaking, even in the NP sector, is due to the SM Yukawa matrices. However, more general flavour structures for the NP states are still allowed. In fact such non-MFV couplings can have interesting consequences. In general we can group the NP models into two broad classes: *(i)* models that address outstanding problems of the SM, such at the SM flavour puzzle, the origin of dark matter, or the hierarchy problem, which may have non trivial flavour structure, and *(ii)* models designed to explain the $b \to s\ell\ell$ and $b \to c\tau\nu$ flavour anomalies, that almost inevitably have quite a distinct flavour structure. The NP mediators potentially responsible for the anomalies, Z', W' or leptoquarks, could be found at high $p_{\rm T}$ searches in the HL- or HE-LHC.

In the rest of this section we first briefly review the models that address the SM flavour puzzle and have states that could be probed at the HL-/HE-LHC, and their implications for high $p_{\rm T}$ searches. The second part of this section is devoted to high $p_{\rm T}$ implications of B physics anomalies.

10.1 Models of flavour and TeV Physics

10.1.1 Randall-Sundrum models of flavour

Models of flavour based on warped extra dimension [1316] attempt to simultaneously solve the hierarchy problem as well as the SM flavour problem [1325, 1326]. In the Randall-Sundrum (RS) models the 5-dimensional space-time has anti-de Sitter geometry (AdS_5), truncated by flat 4D boundaries, the Planck (UV) and the TeV (IR) branes. This setup gives a warped metric in the bulk [1316] $ds^2 = \exp(-2kr_c|\phi|)\eta_{\mu\nu}dx^\mu dx^\nu - r_c^2 d\phi^2$, where k is the 5D curvature scale, r_c the radius of compactification and $\phi \in [-\pi, \pi]$ the coordinate along the 5-th dimension. The warp factor, $\exp(-2kr_c|\phi|)$, leads to different length scales in different 4D slices along the ϕ direction, which provides a solution to the hierarchy problem. In particular, the Higgs field is assumed to be localized near the TeV-brane so that the metric "warps" $\langle H\rangle_5 \sim M_5 \sim M_P \sim 10^{19}$ GeV down to the weak scale, $\langle H\rangle_4 = \exp(-kr_c\pi)\langle H\rangle_5$. For $kr_c \approx 12$ then $\langle H\rangle_{\rm SM} \equiv \langle H\rangle_4 \sim 1$ TeV.

The hierarchies among the quark masses can be realized by localizing the Higgs on the IR brane, while the fermions have different profiles in the 5-th dimension. The first and second generation zero mode fermions are localized close to the UV-brane and have small overlaps with the Higgs, giving small effective 4D SM Yukawa interactions, and thus small quark masses after electroweak symmetry breaking. The top quark, on the other hand, is localized near the TeV brane resulting in a large top Yukawa coupling.

This configuration has a built in automatic suppression of FCNCs, which are suppressed by the same zero mode overlaps that gives the hierarchy of masses [1325, 1326]. This feature of the RS framework plays a similar role as the SM Glashow-Iliopoulos-Maiani (GIM) mechanism, and was dubbed RS-GIM in [1399, 1400]. Similarly to the SM GIM, the RS GIM is violated by the large top quark mass. In particular, $(t, b)_L$ needs to be localized near the TeV brane, otherwise the 5D Yukawa coupling becomes too large and makes the theory strongly coupled at the scale of the first Kaluza-Klein (KK) excitation. In general this leads to sizeable corrections to electroweak precision observables, such as the Zb_Lb_L couplings. Such problems can be largely ameliorated by enlarging the bulk symmetry such that it contains a custodial $SU(2)_L \times SU(2)_R$ symmetry [1401], which for instance lowers the KK scale bounds from EW precision tests from 5 TeV to about 2TeV [1402]. The consequences for flavour phenomenology have been worked out in a series of papers, see, e.g., [1403–1406], with $K - \bar{K}$ mixing for instance requiring the KK scale to be above 8 TeV [1402]. With flavour alignment the scale of KK modes could be substantially lowered [1407] and could be reachable by HL/HE-LHC.

The KK gluon resonances cannot be produced from gluons [1408], so that the LHC production is restricted to the quark-antiquark fusion, even though this is suppressed by the flavor dependent zero mode overlaps. This means that the LHC cross section for the first KK gluon resonances are small, suppressed also by the quark-anti-quark parton density functions (PDFs). The dominant decay mode is into $t\bar{t}$ final state, due to the large zero mode overlaps [1409]. Using the benchmark RS model from [1410], the most recent CMS analysis for $t\bar{t}$ resonance searches, using both hadronic and leptonic tops, sets a lower bound of 4.55 TeV on the mass of the KK gluon [1411]. The projected reach for 33TeV and 100TeV pp colliders can be found in [1402].

10.1.2 Partial compositeness

Partial compositeness as the origin of the flavour hierarchies in composite Higgs models [1412] is the holographic dual to the RS models of flavour. While the Higgs is the lightest state of the composite sector, usually a pseudo-Nambu Goldstone boson from global symmetry breaking, the SM fermions and gauge bosons are elementary (for a review, see, e.g, [1329]). The elementary fermions, Q, U, D, are coupled to the composite sector through linear mixing with the composite operators, $\mathcal{O}_Q$, $\mathcal{O}_U$, $\mathcal{O}_D$,

$$\mathcal{L} \supset \epsilon_Q \bar{Q}_L \mathcal{O}_Q + \epsilon_U \bar{U}_R \mathcal{O}_U + \epsilon_D \bar{D}_R \mathcal{O}_D. \tag{134}$$

The mixing parameters ϵ_a exhibit exponentially large hierarchies because of large, yet still $\mathcal{O}(1)$, differences in anomalous dimensions of the corresponding composite operators. This is the analog of the zero mode overlaps in the RS models. The SM Yukawa are given by $(Y_{U(D)})_{ij} \sim \epsilon^i_Q \epsilon^j_{U(D)}$. For $\epsilon^1_Q \ll \epsilon^2_Q \ll \epsilon^3_Q \sim 1$, $\epsilon^1_U \ll \epsilon^2_U \ll \epsilon^3_U \sim 1$, $\epsilon^1_D \ll \epsilon^2_D \ll \epsilon^3_D \ll 1$ one can obtain the SM structure of quark masses and CKM mixings.

The composite Higgs models are described by the compositeness scale f and the mass of the first composite resonances, $M_* \sim g_* f$, with g_* the typical strength of the resonances in the composite sector. The searches at the HL-/HE-LHC consist of Higgs coupling measurements, including deviations in Higgs Yukawa couplings, and searches for composite resonances preferably coupled to third generation fermions, electroweak gauge bosons, or the Higgs. Flavour observables put strong bounds on M_*, if the flavour structure is assumed to be generic. Such bounds can be relaxed in the case of approximate flavour symmetries, see, e.g., Ref. [1329] for a review.

10.1.3 Low scale gauge flavour symmetries

The SM has in the limit of vanishing Yukawa couplings a large global symmetry. In the quark sector this is $G_F = SU(3)_Q \times SU(3)_U \times SU(3)_D$. Ref. [1413] showed that the SM flavor symmetry group G_F is anomaly free, if one adds a set of fermions that are vector-like under the SM gauged group, but chiral under the G_F. This means that G_F can be gauged. It is broken by a set of scalar fields that have hiearchical vevs and lead to hierarchy of SM quark masses. This also implies a hierarchy for the masses of the flavoured gauge bosons, with gauge bosons that more strongly couple to third generation being lighter, while the flavoured gauge bosons that couple more strongly to the first two generations are significantly heavier. This pattern in the spectrum of flavoured gauge bosons then avoids too large contributions to FCNCs [1414].

At the LHC one searches for the lightest flavoured gauge bosons, with $\mathcal{O}(\mathrm{TeV})$ masses, which couple mostly to b quarks and t quarks, but could also have non-negligible couplings to the first two generations. The di-jet and $t\bar{t}$ resonance searches are thus sensitive probes. A signal could also come from production of the lightest vectorlike fermions, t', or b' [1413]. For several further benchmarks see, e.g., Ref. [1415], where also a connection with dark matter was explored.

10.1.4 2HDM and low scale flavour models

Authors (TH): Martin Bauer, Marcela Carena and Adrián Carmona.

In 2 Higgs Doublet Models (2HDMs), the two Higgs doublets, H_1 and H_2 are usually assumed not to carry flavour quantum numbers. The collider phenomenology, on the other hand, changes substantially, if they do. This is an interesting possibility that could solve the SM flavour puzzle via the Froggatt-Nielsen (FN) mechanism where the flavon is replaced by the $H_1 H_2 \equiv H_1^T (i\sigma_2) H_2$ operator. In this way, the NP scale Λ where the higher dimensional FN operators are generated is tied to the electroweak scale, leading to much stronger phenomenological consequences. Let us assume for concreteness a type-I like 2DHM with the following Yukawa Lagrangian in the quark sector [1306, 1416]

$$\mathcal{L}_Y \supset y^u_{ij} \left(\frac{H_1 H_2}{\Lambda^2}\right)^{n_{u_{ij}}} \bar{q}^i_L H_1 u^j_R + y^d_{ij} \left(\frac{H_1^\dagger H_2^\dagger}{\Lambda^2}\right)^{n_{d_{ij}}} \bar{q}^i_L \tilde{H}_1 d^j_R + \text{h.c.}\,, \tag{135}$$

where $\tilde{H}_1 \equiv i\sigma_2 H_1^*$ as usual, and the charges $n_{u,d,e}$ are a combination of the $U(1)$ charges of H_1, $(H_1 H_2)$ and the different SM fermion fields (for an alternative discussion, where H_1, H_2 carry flavour charges, but the Yukawa interactions are taken to be renormalizable, see [1417]). For simplicity, we set the flavour charges of H_1 and H_2 to 0 and 1, respectively, such that $n_{u_{ij}} = a_{q_i} - a_{u_j}, n_{d_{ij}} = -a_{q_i} + a_{d_j}$, if we denote by $a_{q_i}, a_{u_i}, \ldots,$ the $U(1)$ charges of the SM fermions. In general, the fermion masses are given by

$$m_\psi = y_\psi \varepsilon^{n_\psi} \frac{v}{\sqrt{2}}, \qquad \varepsilon = \frac{v_1 v_2}{2\Lambda^2} = \frac{t_\beta}{1+t_\beta^2} \frac{v^2}{2\Lambda^2}, \tag{136}$$

with the vacuum expectation values $\langle H_{1,2} \rangle = v_{1,2}$ and $t_\beta \equiv v_1/v_2$. For the right assignment of flavour charges one is able to accommodate the observed hierarchy of SM fermion masses and mixing angles. This framework also leads to enhanced diagonal Yukawa couplings between the Higgs and the SM fermions, while FCNCs are suppressed. If we denote by h and H the two neutral scalar mass eigenstates, with h the observed 125 GeV Higgs, the couplings between the scalars $\varphi = h, H$ and SM fermions $\psi_{L_i,R_i} = P_{L,R}\psi_i$ in the mass eigenbasis read

$$\mathcal{L} = g_{\varphi \psi_{L_i} \psi_{R_j}}\, \varphi\, \bar{\psi}_{L_i} \psi_{R_j} + \text{h.c.} \tag{137}$$

with i, such that $u_i = u, c, t,\ d_i = d, s, b$ and $e_i = e, \mu, \tau$. This induces flavour-diagonal couplings

$$g_{\varphi \psi_{L_i} \psi_{R_i}} = \kappa^\varphi_{\psi_i} \frac{m_{\psi_i}}{v} = \left(g^\varphi_{\psi_i}(\alpha,\beta) + n_{\psi_i}\, f^\varphi(\alpha,\beta)\right) \frac{m_{\psi_i}}{v}, \tag{138}$$

as well as flavour off-diagonal couplings

$$g_{\varphi \psi_{L_i} \psi_{R_j}} = f^\varphi(\alpha,\beta) \left(\mathcal{A}_{ij} \frac{m_{\psi_j}}{v} - \frac{m_{\psi_i}}{v} \mathcal{B}_{ij}\right). \tag{139}$$

The flavour universal functions in (138) and (139) are $g^h_{\psi_i} = c_{\beta-\alpha}/t_\beta + s_{\beta-\alpha}$, $g^H_{\psi_i} = c_{\beta-\alpha} - s_{\beta-\alpha}/t_\beta$, and $f^h(\alpha,\beta) = c_{\beta-\alpha}\big(1/t_\beta - t_\beta\big) + 2 s_{\beta-\alpha}$, $f^H(\alpha,\beta) = -s_{\beta-\alpha}\big(1/t_\beta - t_\beta\big) + 2 c_{\beta-\alpha}$, where $c_x \equiv \cos x$, $s_x \equiv \sin x$. The entries in matrices $\mathcal{A}$ and $\mathcal{B}$ are proportional to the flavour charges of the corresponding fermions that define the coefficients in (135). Unless all flavour charges for a given type of fermions are equal, the off-diagonal elements in matrices $\mathcal{A}$ and $\mathcal{B}$ lead to FCNCs which are chirally suppressed by powers of the ratio ε, see [1418] for more details and explicit examples for scalings of matrix elements in $\mathcal{A}$ and $\mathcal{B}$.

10.1.5 A Clockwork solution to the flavour puzzle

Author (TH): Adrián Carmona.

The clockwork mechanism, introduced in [1419, 1420] and later generalized to a broader context in Ref. [1421], allows one to obtain large hierarchies in couplings or mass scales. Ref. [1422] showed that

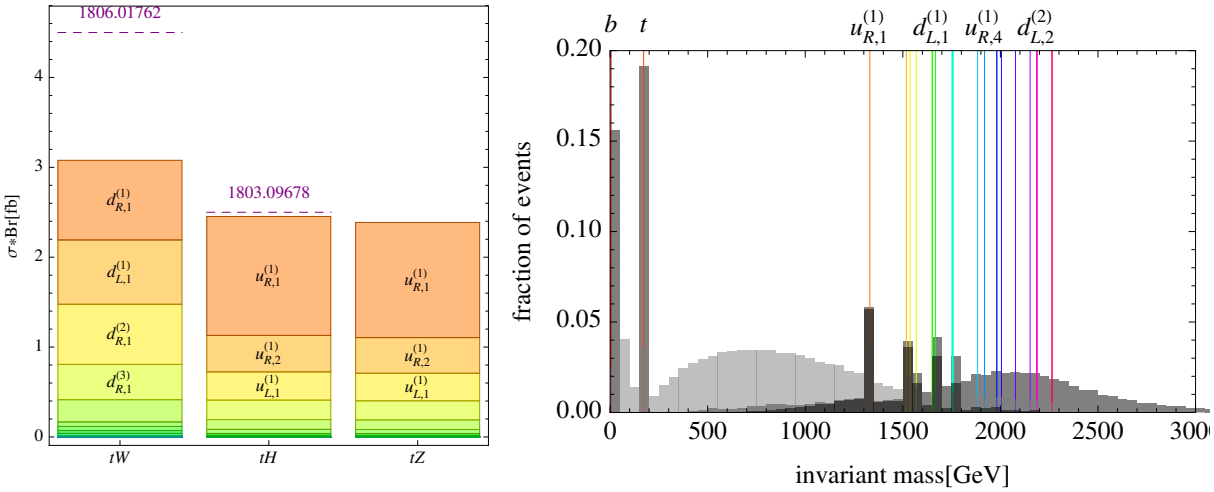

Fig. 75: *Left:* The total gear pair production cross-sections in the final states $tW + X$, $tH + X$ and $tZ + X$ for the benchmark model from Ref. [1422], with contributions from individual gears shown stacked. The currently most stringent upper bounds [1423, 1424] are denoted with dashed lines (for the $tZ + X$ [1424] final state the bound is too weak to be shown). *Right:* Invariant mass spectrum of individual pseudojets clustered using the hemisphere algorithm applied to partonic gear pair production and decay at the 13 TeV LHC. The original hemisphere clustering results are shown in light gray, and the modified hemisphere clustering results in mid-gray (dark gray if in addition the masses of the two pseudojets are required to differ by less than 30%)

it can also be used to generate the observed hierarchy of quark masses and mixing angles with anarchic Yukawa couplings, providing a solution to the flavour puzzle.

In the clockwork solution to the flavour puzzle, each SM chiral fermion ψ is accompanied with a N_ψ-node chain of vector-like fermions, $\psi_{L,j}, \psi_{R,j}$, with masses m, and a series of nearest neighbour mass terms, $qm\bar{\psi}_{L,j}\psi_{R,j-1}$, between the nodes, where $j = 1, \ldots, N_\psi$. The mass spectrum of each chain has one chiral zero mode, the would-be SM fermion, and N_ψ heavy Dirac fermion mass-eigenstates – the gears. For $q \gg 1$, the spectrum of the gears is compressed in a $2m$ band around qm, with $(M_{N_\psi} - M_1) \ll M_1$. The massless zero-mode interacts with the SM Higgs, which is on the 0-th node, through a set of Yukawa interactions described by $\mathcal{O}(1)$ Yukawa matrices, $Y_{U,D}$. The component of the massless mode on the 0-th node is, in the large q limit, given by $1/q^{N_\psi}$. This suppression is the origin of the SM Yukawa hierarchies,

$$\left(Y_u^{\rm SM}\right)_{ij} \sim q_{Q(i)}^{-N_{Q(i)}} \, (Y_U)_{ij} \, q_{u(j)}^{-N_{u(j)}}, \quad \left(Y_d^{\rm SM}\right)_{ij} \sim q_{Q(i)}^{-N_{Q(i)}} \, (Y_D)_{ij} \, q_{d(j)}^{-N_{d(j)}}. \tag{140}$$

The hierarchy of quark masses can be then naturally obtained for anarchical Y_U and Y_D Yukawa matrices if $q^{-N_{Q(i)}} \ll q^{-N_{Q(j)}}$, $q_{u(i)}^{-N_{u(i)}} \ll q_{u(j)}^{-N_{u(j)}}$, $q_{d(i)}^{-N_{d(i)}} \ll q_{d(j)}^{-N_{d(j)}}$, for $i < j$ (in the benchmark below we take q_i to be universal and equal to q).

The clockwork models of flavour are endowed with a powerful flavour protection against FCNCs, very similar to the RS models. The FCNCs with light quarks on the external legs are suppressed by the same small overlaps of the zero-modes, giving rise to hierarchies between the SM quark masses. This clockwork-GIM mechanism, along with the constraints on $Y_{U,D}$ arising from the stability of the Higgs potential, suffices to alleviate the flavour constraints to the level that TeV scale gear masses are compatible with experimental bounds [1422].

TeV scale gears can be searched for at the LHC, where they are produced through QCD pair production. The collider signatures depend on the gear decay patterns. The gears decay predominantly

through their coupling to the Higgs doublet into gears from a different-chirality chain. The lightest gears decay directly to SM fermions, mostly t and b, via the emission of W, Z or h, as do heavier gears for which these are the only kinematically allowed channels. The main existing collider constraints are from searches for pair production of vector-like quarks, in final states involving third generation SM quarks. Ref. [1422] found the two 35 fb^{-1} 13 TeV ATLAS searches for vector-like quarks decaying into tW final states [1423], as well as the analogous search employing the tZ and tH final states [1424], to be currently most sensitive, see Fig. 75.

The dense spectrum of gears and the potentially complex pattern of gear decays poses an experimental challenge. In the conventional vector-like quark searches the clockwork signal will appear as an excess of events with high transverse energies or H_T, but without a dominant single peak in the invariant mass of any particular final state, such as tH or tW. Ref. [1422] proposed a novel reconstruction strategy targeting pair production of heavy quarks with a-priori unknown but potentially long decay chains that result in a single heavy flavoured quark, t or b, plus any number of massive weak or Higgs bosons per decay chain. The proposed search strategy uses a modified hemisphere clustering algorithm, with $t-$ and $b-$tagged jets as seeds for clustering into exactly two pseudo-jets (the invariant mass of these is shown as mid-gray distribution in Fig. 75 right). The original hemisphere clustering uses instead the jets with highest invariant mass as seeds and shows no sharp features (light gray). Requiring that the masses of the two pseudo-jets differ by less then 30% gives the dark grey distribution, with clearly visible gears (in the exploratory study of [1422] tops, b-quarks, W, Z and the Higgs were not decayed).

10.2 Flavour implications for high p_{T} new physics searches

In this subsection we collect several signatures of flavour models or models where nontrivial flavour structure is relevant for high p_{T} searches: the FCNC top decays to exotica, the (model dependent) implications for di-Higgs production, and the set of signatures that are related to neutrino mass models.

10.2.1 Top decays to exotica

Authors (TH): S. Banerjee, M. Chala, M. Spannowsky.

The FCNC mediated processes are rare within the SM. However, LHC is a top factory and significant number of events are expected even for top decays with very small branching ratios. In light of this, studies of top FCNC decays to SM particles have garnered a strong interest in the community [1175, 1176, 1180, 1181, 1198, 1239, 1425–1434]. The FCNC top decays to SM particles, $t \to qZ, q\gamma, qg, qH$, $q = u, c$, and the related constraints from FCNC production processes, were discussed in Sections 8.1 and 8.1.6.

In the presence of light NP, other exotic top FCNC decays are possible. We highlight one such possibility, where the NP spectrum contains a light scalar singlet, S, with mass m_S below the top quark mass. Such a scalar particle is predicted in a number of well-motivated NP models, e.g., in the NMSSM [1435] and in non-minimal composite Higgs models [1319, 1320, 1329, 1436]. Moreover, quite often the induced $t \to cS, uS$ FCNC decays are easier to probe than, for instance the ones involving the SM Higgs, $t \to ch, uh$ [1437]. The reason is three-fold; *(i)* The top FCNCs mediated by S are usually suppressed by one less power of the heavy physics scale; *(ii)* S may have a larger decay width into cleaner final states, such as $\ell^+\ell^-$, $b\bar{b}$ or $\gamma\gamma$; *(iii)* S can be much lighter than the Higgs, reducing the phase space suppression. Note that very light S, i.e., with $m_S < m_h/2 \sim 62.5$ GeV, need not be excluded by the LHC constraints on the Higgs width, $\Gamma(h \to SS) \lesssim 10$ MeV [1438]. Indeed, for a quartic coupling $\lambda_{HS} S^2 |H|^2$, this bound is avoided for $\lambda_{HS} < 0.05$.

There are no direct experimental limits on $t \to qS$ from colliders. The indirect constraints from 1-loop box diagrams in $D^0 - \bar{D}^0$ oscillations constrain the products of two S Yukawas, $\tilde{Y}_{ut}\tilde{Y}_{ct(tc)}$, and $\tilde{Y}_{tu}\tilde{Y}_{ct(tc)}$, to be small [198, 1345, 1439]. The $S\bar{t}c$ or $S\bar{t}u$ couplings can still be sizeable, but not both at the same time. Inspired by the CMS $t \to hc$ search [1183], Ref. [1440] developed a dedicated analysis

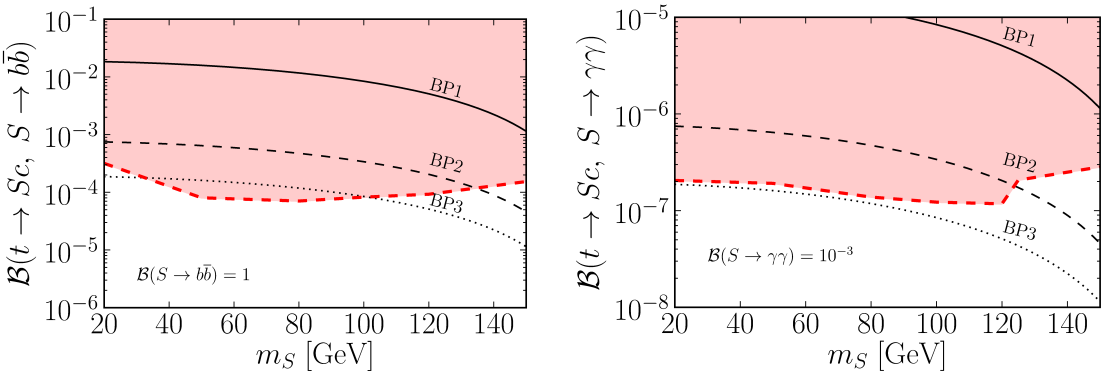

Fig. 76: Branching ratios that can be tested in the $b\bar{b}$ (left) and $\gamma\gamma$ (right) channels at 14 TeV HL-LHC with 3000 fb^{-1} (95% CL upper limit is denoted by red dashed line). The three benchmark points, Eq. (142), are denoted with black lines.

for $t \to qS$, by varying m_S, the mass of S. The projections at the 14 TeV LHC for $S \to b\bar{b}$ and $S \to \gamma\gamma$ decays are shown in Fig. 76 . Assuming that S is the only light NP state, its couplings to the SM quarks are induced by dimension 5 effective operator (not displaying generational indices)

$$\mathcal{L} = -\bar{q}_L \tilde{Y} \frac{S}{f} \tilde{H} u_R + \text{h.c.} \supset \tilde{g} \frac{m_t}{f} \bar{t}_L S c_R + \text{h.c.}, \tag{141}$$

where f is the NP scale, and on the r.h.s. we introduced a new flavour violating coupling $\tilde{g}$. The three Benchmark Points (BP) shown in Figs. 76 are

$$\text{BP1(2,3)}: \quad \tilde{g} = 1.0(1.0, 0.1),\ f = 2(10, 2)\ \text{TeV} \implies \mathcal{B}(t \to Sc) \sim 10^{-3(4,5)} - 10^{-2(3,4)}. \tag{142}$$

If the flavour conserving couplings of S to the SM fermions, ψ, are $c_\psi m_\psi S(\bar{\psi}\psi)/f$, and to the photons $c_\gamma \alpha S F_{\mu\nu}\tilde{F}^{\mu\nu}/(4\pi f)$, then $\mathcal{B}(S \to \gamma\gamma)/\mathcal{B}(S \to \overline{\psi}\psi) \sim (\alpha/\pi)^2 (m_S/m_\psi)^2$, taking $c_\psi \sim c_\gamma \sim \mathcal{O}(1)$. The suppression of $S \to \gamma\gamma$ can be partially compensated by scaling with m_S, so that $\mathcal{B}(S \to \gamma\gamma)$ can possibly be significantly larger than $\mathcal{B}(h \to \gamma\gamma)$. Searches should thus use both $S \to b\bar{b}$ and $S \to \gamma\gamma$. The details on how to reduce the backgrounds can be found in [1440]. Current searches for $S \to b\bar{b}$ in the gluon fusion channel [1441] constrain only values of c_ψ above ~ 10 for $f \sim 1$ TeV. Our analysis works instead for very small values of c_ψ provided the branching ratio is sizable.

For projections at future colliders we find that the increase in cross-section for the background at $\sqrt{s} = 27$ TeV (100 TeV) when compared to $\sqrt{s} = 14$ TeV is similar to that for the signal, and is $\sim 4(40)$. Assuming an integrated luminosity of 10 ab^{-1}, we expect an increase in significance by a factor of ~ 3.7 (~ 11.5). Similar results hold for the $b\bar{b}$ channel.

10.2.2 Implications for di-Higgs production

Authors (TH): Martin Bauer, Marcela Carena and Adrián Carmona.

Interestingly, in some models the flavour structure can feed back into nontrivial constraints on the scalar potential. This was demonstrated in the 2HDM model with FN charges, introduced in Sec. 10.1.4. The scalar couplings to gauge bosons are the same as in the normal type-I 2HDM while the scalar coupling between the heavy Higgs H and two SM Higgs scalars h, as well as the triple Higgs coupling can be expressed as [1442, 1443]

$$g_{Hhh} = \frac{c_{\beta-\alpha}}{v}\left[\left(1 - f^h(\alpha,\beta) s_{\beta-\alpha}\right)\left(3M_A^2 - 2m_h^2 - M_H^2\right) - M_A^2\right], \tag{143}$$

$$g_{hhh} = -\frac{3}{v}\left[f^h(\alpha,\beta) c_{\beta-\alpha}^2 (m_h^2 - M_A^2) + m_h^2 s_{\beta-\alpha}\right], \tag{144}$$

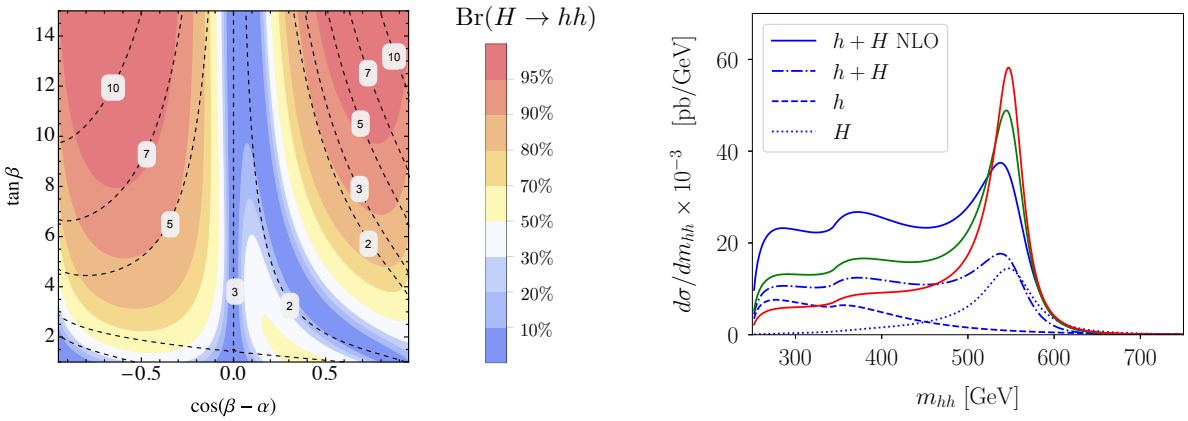

Fig. 77: Left: Br($H \to hh$) as a function of $\cos(\beta - \alpha)$ and $\tan\beta$ for $M_H = M_{H^\pm} = 550$ GeV and $M_A = 450$ GeV. The dashed contours correspond to constant $|\kappa^h_\psi|$ (we set $n_\psi = 1$). Right: Invariant mass distribution for the different contributions to the $pp \to hh$ signal with $c_{\beta-\alpha} = -0.45$ and $\kappa^h_\psi = 5$ (blue), $\kappa^h_\psi = 4$ (green) and $\kappa^h_\psi = 3$ (red) at $\sqrt{s} = 27$ TeV, respectively.

where M_A is the pseudoscalar mass. The $U(1)$ flavour symmetry restricts the number of allowed terms in the scalar potential forbidding, e.g., terms proportional to $H_1 H_2$. Interestingly, one can rewrite such self scalar interactions with the help of function $f^h(\alpha, \beta)$, since it is related to the combination $H_1 H_2^\dagger$ appearing in both the scalar potential and the higher dimensional operators generating different Yukawa couplings. Therefore, the parameter space for which $f^h(\alpha, \beta) \gg 1$ and $c_{\beta-\alpha} \neq 0$ leads to maximally enhanced diagonal couplings of the SM Higgs to fermions (138) as well as to enhanced trilinear couplings (143) and (144). For maximally enhanced Yukawa couplings, the mass of the heavy Higgs H cannot be taken arbitrarily large and resonant Higgs pair production has to be present. This correlation between the enhancement of the Higgs Yukawa couplings κ^h_ψ and Br($H \to hh$) is illustrated for $M_H = M_A = M_{H^\pm} = 500$ GeV in Fig. 77 (left) where we plot the dependence of Br($H \to hh$) on $c_{\beta-\alpha}$ and t_β [1418]. The dashed contours correspond to constant values of $|\kappa^h_\psi|$ for $n_\psi = 1$. The correlation does not depend on the factor n_ψ, although $n_\psi > 1$ leads to a larger enhancement. The two exceptions for which this correlation breaks down are the limits $c_{\beta-\alpha} \approx 0$ (disfavored in the flavour model) and $c_{\beta-\alpha} \approx \pm 1$ (disfavoured by SM Higgs couplings strength measurements). Depending on the structure of the Yukawa couplings, the value of κ^h_ψ in Fig. 77 (left) can be larger or smaller than the value $n = 1$ chosen to illustrate the relation between g_{Hhh} and κ^h_ψ. Current experimental limits constrain this structure. For example, since $\kappa^h_\mu < 2.1$ [1444], either $n = 0$ for the muon, or one is constrained to the $\kappa^h_\mu < 2.1$ parameter space in Fig. 77 (left).

There is a non-trivial interplay between resonant and non-resonant contributions to $pp \to hh$, as shown in Fig. 77 (right), for $\sqrt{s} = 27$ TeV, setting $M_A = 450$ GeV and $M_H = M_{H^\pm} = 550$ GeV, $c_{\beta-\alpha} = -0.45$ and three different values of $\kappa^h_\psi = 3, 4$ and 5. When the enhancement in the Higgs Yukawa couplings is large enough, the interference between non-resonant and resonant contributions turns the broad peak into a shoulder in the $d\sigma/dm_{hh}$ distribution for the total cross section, as shown for the case $\kappa^h_\psi = 5$ by the blue line.

10.2.3 Neutrino Mass Models at the HL/HE LHC

Authors (TH): T. Han, T. Li, X. Marcano, S. Pascoli, R. Ruiz, C. Weiland.

The questions pertaining to neutrino masses: whether or not neutrinos are Majorana particles, the origin of smallness of the neutrino masses, as well as the reason for large mixing angles, remain some of the most pressing open issues in particle physics today. A set of potential solutions is provided by the

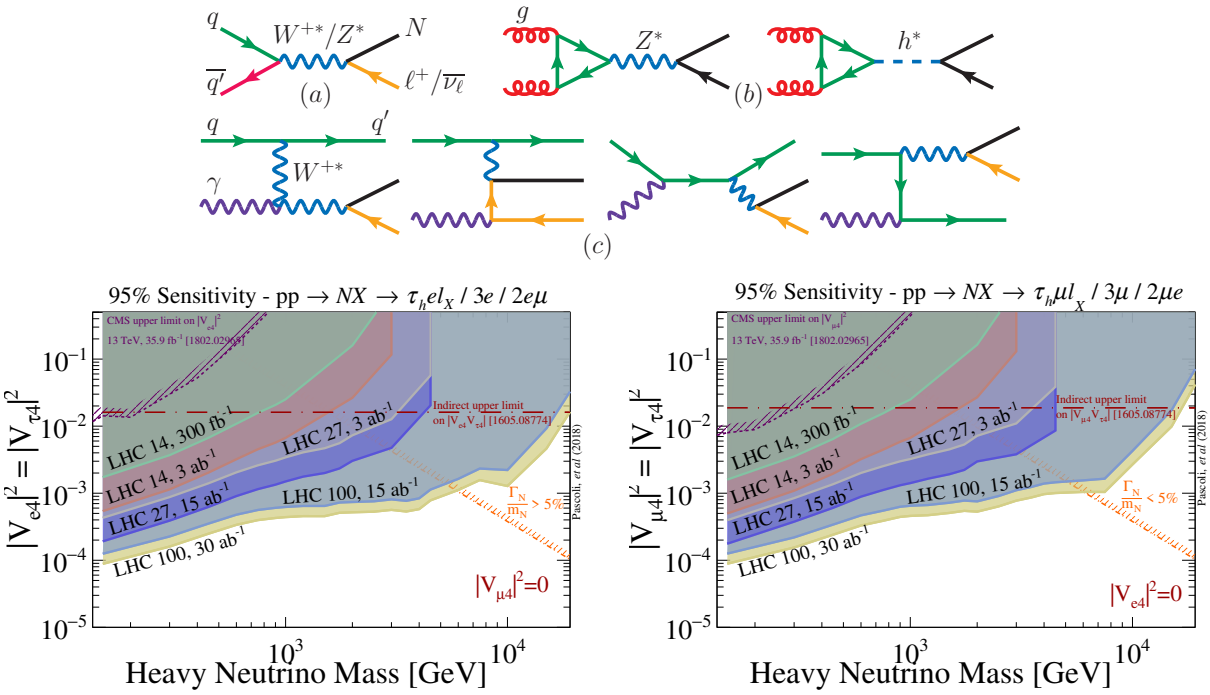

Fig. 78: Upper: Born-level diagrams for heavy neutrino, N, production via (a) Drell-Yan (DY), (b) gluon fusion (GF), and (c) vector boson fusion (VBF). Lower: for the benchmark mixing hypotheses $|V_{e4}| = |V_{\tau 4}|$ with $|V_{\mu 4}| = 0$ (left panel) and $|V_{\mu 4}| = |V_{\tau 4}|$ with $|V_{e4}| = 0$ (right panel), the projected sensitivity at $\sqrt{s} = 14,\ 27$ and 100 TeV using the tri-lepton + dynamic jet veto analysis of Ref. [1451].

seesaw models. These postulate new particles that couple to SM fields via mixing/Yukawa couplings, SM gauge currents, and/or new gauge symmetries. If accessible, a plethora of rich physics can be studied in considerable detail at hadron colliders. This would complement low energy and oscillation probes of neutrinos [1146, 1445]. In the following, we summarize the discovery potential of seesaw models at hadron colliders with collision energies of $\sqrt{s} = 14$ and 27 TeV. For a more comprehensive reviews on the sensitivity of colliders to neutrino mass models, see [1146, 1445–1448] and references therein.

The Type I Seesaw and Variants

In Type I seesaw the light neutrino masses and mixing are generated from couplings of SM leptons to new fermionic gauge singlets with Majorana masses. For low-scale seesaw models with only fermionic singlets, lepton number has to be nearly conserved and light neutrino masses are proportional to small lepton number violating (LNV) parameters [1449, 1450]. For high-scale seesaws with only fermionic singlets, light neutrino masses are inversely proportional to large LNV mass scales, and again lepton number is approximately conserved at low energies. Thus LNV processes are suppressed in type I seesaw models (unless additional particles are introduced to decouple the light neutrino mass generation from heavy neutrino production).

If kinematically accessible, heavy neutrinos N can be produced in hadron collisions through neutral current and charged current processes, as shown in Fig. 78 (upper). The expected suppression of LNV processes in type I seesaw models motivates the study of lepton number conserving (LNC) processes, such as the heavy neutrino N production via DY and VBF, with subsequent decays to only leptons,

$$pp \to \ell_N N + X \to \ell_N \ell_W W + X \to \ell_N \ell_W \ell_\nu \nu + X, \tag{145}$$

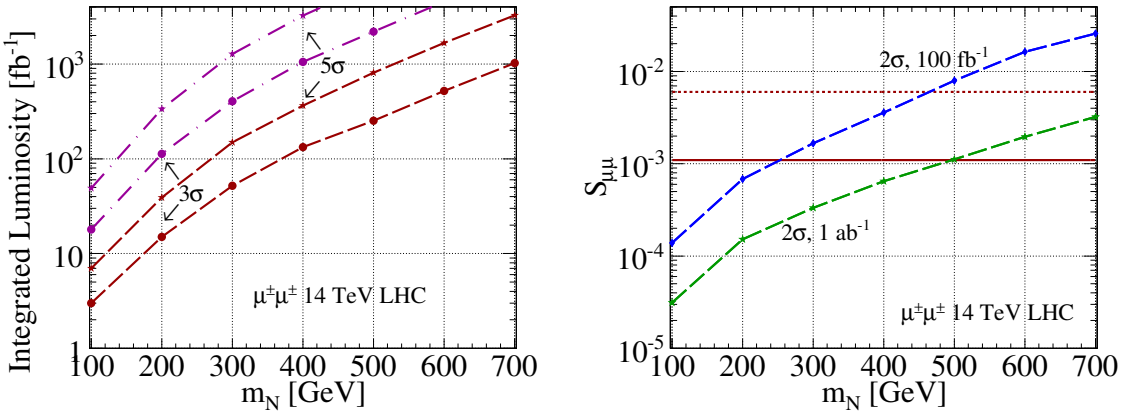

Fig. 79: Left: required luminosity for 3 $(5)\sigma$ evidence (discovery) using the LNV final state $\mu^{\pm}\mu^{\pm}jj$, as a function of the heavy neutrino mass, m_N, assuming optimistic (brown) and pessimistic (purple) mixing scenarios [1454]. Right: sensitivity to $N-\mu$ mixing [1454] with the optimistic (pessimistic) mixing scenario is given by the horizontal dashed (full) line.

giving the trilepton final state, $\ell_i^{\pm}\ell_j^{\mp}\ell_k^{\pm}+$MET. Projections from a new tri-lepton search strategy recently proposed in Ref. [1451], based on a dynamical jet veto selection cut, are shown in Fig. 78, assuming the benchmark mixing hypotheses $|V_{e4}| = |V_{\tau 4}|$ with $|V_{\mu 4}| = 0$ (left panel) and $|V_{\mu 4}| = |V_{\tau 4}|$ with $|V_{e4}| = 0$ (right panel), for $\sqrt{s} = 14,\ 27$ and 100 TeV. For benchmark luminosities, the colliders can probe active-sterile mixing as small as (approximately) $|V_{\ell 4}|^2 \sim 5\times 10^{-4} - 9\times 10^{-5}$ and masses as heavy as (approximately) $1.5-15$ TeV for $|V_{\ell 4}|^2 \sim 10^{-2}$.

Another possibility is to search for lepton flavor violating (LFV) final states such as

$$q\,\overline{q}' \to\ N\,\ell_1^{\pm} \to\ \ell_1^{\pm}\,\ell_2^{\mp}\,W^{\mp} \to\ \ell_1^{\pm}\,\ell_2^{\mp}\,j\,j. \tag{146}$$

This was, e.g., studied in Ref [1452] in the context of the inverse seesaw (ISS), a low-scale variant of the type I seesaw. Due to strong experimental limits on $\mu \to e\gamma$ by MEG [1453], the event rates involving taus are more promising than those for $e^{\pm}\mu^{\mp}jj$. After $\mathcal{L} = 3\ \mathrm{ab}^{-1}$ of data taking, more than 100 LFV events of $\tau^{\pm}\mu^{\mp}jj$ type could be produced for neutrino masses below 700 (1000) GeV for pp collisions at 14 (27) TeV.

In the presence of additional particles that can decouple the heavy neutrino production from the light neutrino mass generation, e.g., new but far off-shell gauge bosons [1455], the Majorana nature of the heavy neutrinos can lead to striking LNV collider signatures, such as the well-studied same-sign dilepton and jets process [1456]

$$pp \to\ N\,\ell_1^{\pm} \to\ \ell_1^{\pm}\,\ell_2^{\pm}\,W^{\mp} \to\ \ell_1^{\pm}\,\ell_2^{\pm} + nj. \tag{147}$$

Assuming that a low-scale type I seesaw is responsible for the heavy neutrino production, Fig. 79 displays the discovery potential and active-heavy mixing sensitivity of the $\mu^{\pm}\mu^{\pm}$ channel [1454]. Assuming the pessimistic/conservative mixing scenario of $S_{\mu\mu} = 1.1\times 10^{-3}$ [1454], the HL-LHC with 3 ab^{-1} would be able to discover a heavy neutrino with a mass of $m_N \simeq 400\,\mathrm{GeV}$ and is sensitive to masses up to $550\,\mathrm{GeV}$ at 3σ. Using only 1 ab^{-1}, the HL-LHC can improve on the preexisting mixing constraints summarized in the pessimistic scenario for neutrino masses up to $500\,\mathrm{GeV}$.

Heavy Neutrinos and the Left-Right Symmetric Model

The Left-Right Symmetric Model (LRSM) addresses the origin of both tiny neutrino masses via a Type I+II seesaw hybrid mechanism as well as the SM $V-A$ chiral structure through spontaneous breaking

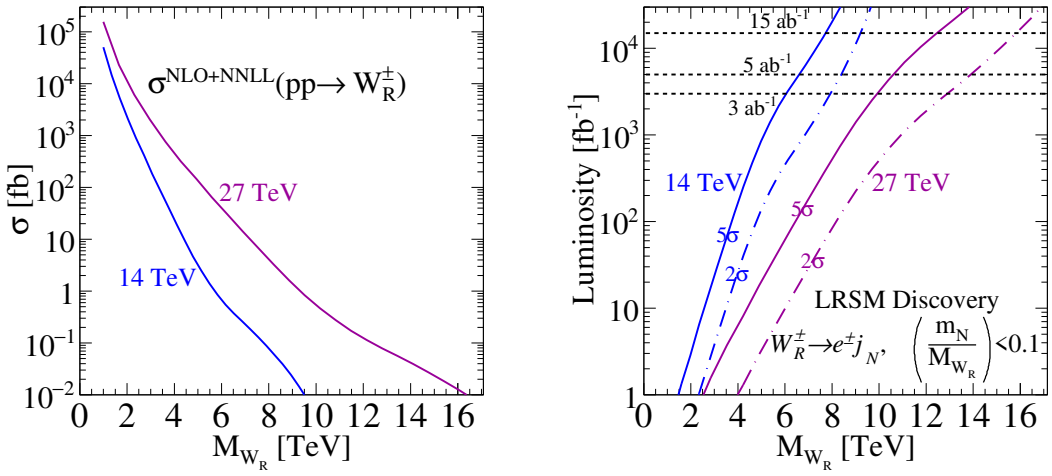

Fig. 80: Left: The total $pp \to W_R$ cross section at NLO+NNLL(Threshold). Right: $5(2)\sigma$ discovery potential (sensitivity) via W_R decaying to an electron and neutrino jet (j_N), as a function of W_R mass, at $\sqrt{s} = 14$ and 27 TeV [1457].

of the $SU(2)_L \times SU(2)_R$ symmetry. The model predicts new heavy gauge bosons $(W_R^{\pm},\ Z_R')$, heavy Majorana neutrinos (N), and a plethora of neutral and electrically charged scalars $(H_i^0,\ H_j^{\pm},\ H_k^{\pm\pm})$. The LRSM gauge couplings are fixed to the SM Weak coupling constant, up to (small) RG-running corrections. As a result, the Drell-Yan production mechanisms for W_R and Z_R result in large rates at hadron colliders.

One of the most promising discovery channels is the production of heavy Majorana neutrinos from resonant W_R, with N decaying via a lepton number-violating final state. At the partonic level, the process is [1456] (for details see [1445] and references therein)

$$q_1\overline{q}_2 \to W_R \to N\,\ell_i^{\pm} \to \ell_i^{\pm}\ell_j^{\pm}W_R^{\mp *} \to \ell_i^{\pm}\ell_j^{\pm}q_1'\overline{q_2'}. \tag{148}$$

Due to the ability to fully reconstruct the final state of Eq. (148), many properties of W_R and N can be extracted, including a complete determination of W_R chiral couplings to quarks independent of leptons [1458]. Beyond the canonical $pp \to W_R \to N\ell \to 2\ell + 2j$ channel, it may be the case that the heavy neutrino is hierarchically lighter than the right-handed (RH) gauge bosons. Notably, for $(m_N/M_{W_R}) \lesssim 0.1$, N is sufficiently Lorentz boosted that its decay products, particularly the charged lepton, are too collimated to be resolved experimentally [1457, 1459]. Instead, one can consider the $(\ell_j^{\pm}q_1'\overline{q_2'})$-system as a single object, a *neutrino jet* [1457, 1460]. The hadronic process is then $pp \to W_R \to N\ell_i^{\pm} \to j_N\,\ell_i^{\pm}$, and inherits much of the desired properties of (148), such as the simultaneous presence of high-$p_{\rm T}$ charged leptons and lack of MET [1457, 1460], resulting in a very strong discovery potential. Fig. 80 (right) shows the requisite integrated luminosity for $5(2)\sigma$ discovery at $\sqrt{s} = 14$ and 27 TeV.

Type II Scalars

Type II seesaw introduces a new scalar $\mathrm{SU}(2)_L$ triplet that couples to SM leptons. The light neutrinos obtain Majorana masses through $\mathrm{SU}(2)_L$ triplet vev, so that type II scenario notably does not have sterile neutrinos. The most appealing production mechanisms at hadron colliders of triplet Higgs bosons are

$$pp \to Z^*/\gamma^* \to H^{++}H^{--}, \quad pp \to W^* \to H^{\pm\pm}H^{\mp}, \tag{149}$$

followed, by lepton flavor- and lepton number-violating decays to the SM charged leptons. In Type II scenarios, $H^{\pm\pm}$ decays to $\tau^{\pm}\tau^{\pm}$ and $\mu^{\pm}\mu^{\pm}$ pairs are comparable or greater than the $e^{\pm}e^{\pm}$ channel by two

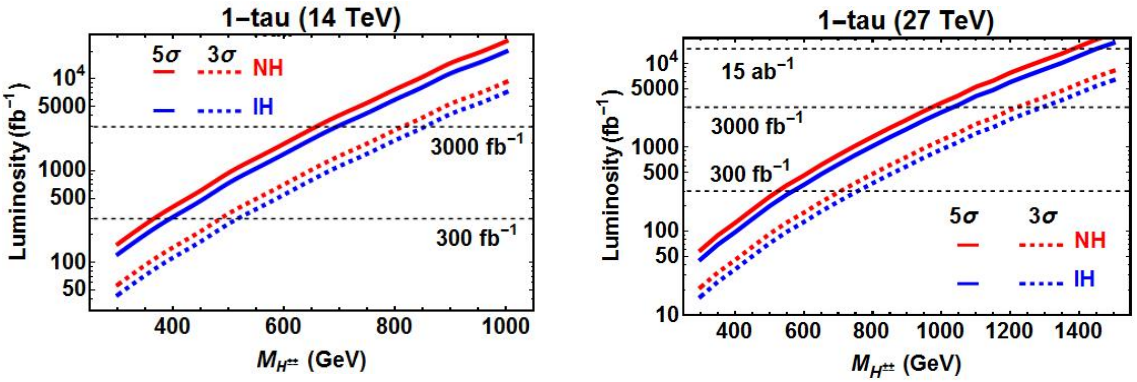

Fig. 81: Requisite luminosity for $5(3)\sigma$ discovery (evidence) as a function of $M_{H^{\pm\pm}}$ for the process $pp \to H^{++}H^{--} \to \tau_h \ell^{\pm}\ell^{\mp}\ell^{\mp}$, where $\tau^{\pm} \to \pi^{\pm}\nu$, for the NH and IH at $\sqrt{s} = 14, 27$ TeV.

orders of magnitude. Moreover, the $\tau\mu$ channel is typically dominant in decays involving different lepton flavors [1461, 1462]. If such a seesaw is realized in nature, tau polarizations can help to determine the chiral property of triplet scalars. One can discriminate between different heavy scalar mediated neutrino mass mechanisms, e.g., between Type II seesaw and Zee-Babu model, by studying the distributions of tau lepton decay products [1462,1463]. Due to the low τ_h identification efficiencies, future colliders with high energy and/or luminosity enables one to investigate and search for doubly charged Higgs decaying to τ_h pairs. Accounting for constraints from neutrino oscillation data on the doubly charged Higgs branching ratios, as well as tau polarization effects [1462], Figs. 81 displays the 3σ and 5σ significance in the plane of integrated luminosity versus doubly charged Higgs mass for $pp \to H^{++}H^{--} \to \tau^{\pm}\ell^{\pm}\ell^{\mp}\ell^{\mp}$ at $\sqrt{s} = 14, 27$ TeV, for single τ channel with $\tau \to \pi\nu$, both for normal (NH) and inverted hierarchy (IH).

Type III Leptons

Low-scale Type III seesaws introduce heavy electrically charged $(E^{\pm})$ and neutral (N) leptons, part of $\mathrm{SU}(2)_L$ triplet, that couple to both SM charged and neutral leptons through mixing/Yukawa couplings. Triplet leptons couple appreciably to EW gauge bosons, and thus do not have suppressed production cross section, contrary to seesaw scenarios with gauge singlet fermions. Up to small (and potentially negligible) mixing effects the triplet lepton pair production cross sections are fully determined, see Fig. 82 (upper) for relevant tree level diagrams for the production of heavy charged leptons. Drell-Yan processes are the dominant production channel of triplet leptons when kinematically accessible [1445]. Fig. 82 (lower left) shows the summed cross sections for the Drell-Yan processes, $pp \to \gamma^*/Z^* \to E^+E^-$, and $pp \to W^{\pm *} \to E^{\pm}N$, at NLO in QCD, following [1464], as a function of triplet masses (assuming $m_N = m_E$), at $\sqrt{s} = 14$ and 27 TeV.

Another consequence of the triplet leptons coupling to all EW bosons is the adherence to the Goldstone Equivalence Theorem. This implies that triplet leptons with masses well above the EW scale will preferentially decay to longitudinal polarized W and Z bosons as well as to the Higgs bosons. For decays of EW boson to jets or charged lepton pairs, triplet lepton can be fully reconstructed from their final-state enabling their properties to be studied in detail. For fully reconstructible final-states,

$$NE^{\pm} \to \ell\ell' + WZ/Wh \to \ell\ell' + nj + mb, \tag{150}$$

$$E^+E^- \to \ell\ell' + ZZ/Zh/hh \to \ell\ell' + nj + mb, \tag{151}$$

which correspond approximately to the branching fractions $\mathcal{B}(NE) \approx 0.115$ and $\mathcal{B}(EE) \approx 0.116$, search strategies such as those considered in [1465, 1466] can be enacted. Assuming a fixed detector

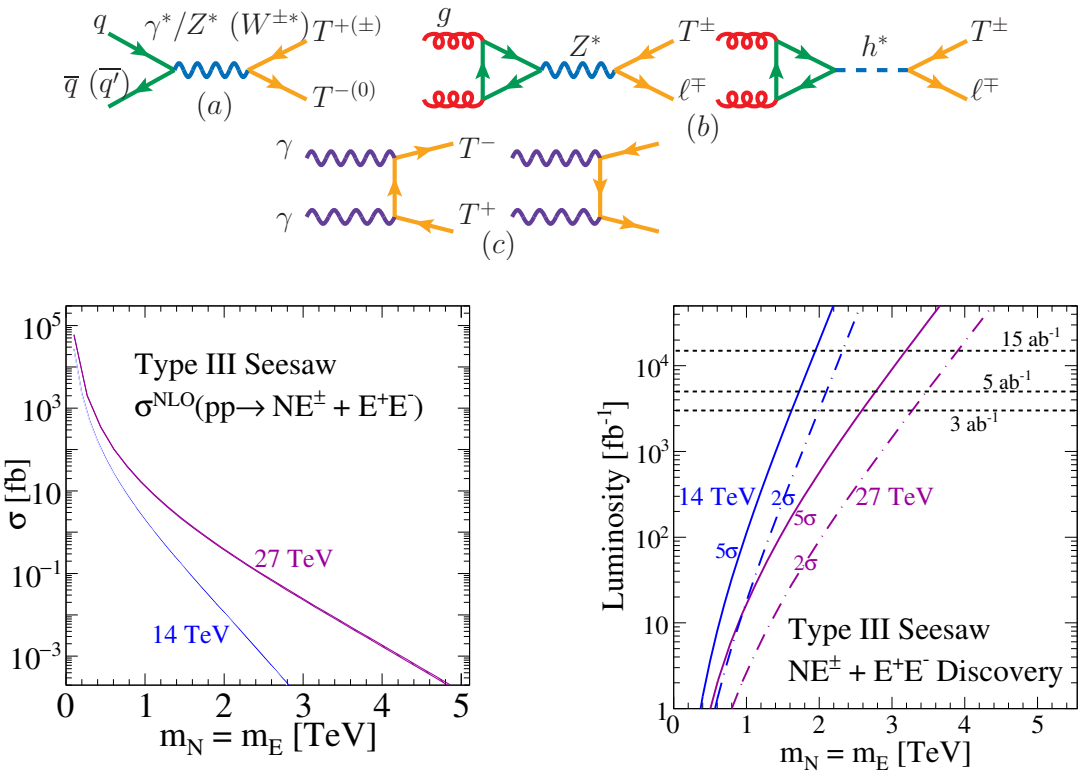

Fig. 82: Upper: Born level production of Type III leptons via (a) Drell-Yan, (b) gluon fusion, and (c) photon fusion; from [1445]. Lower left: the inclusive production cross section for $pp \to NE^{\pm} + E^+E^-$, at NLO in QCD [1464] for $\sqrt{s} = 14$ and 27 TeV, as a function of heavy triplet lepton mass. Lower right: the required integrated luminosity for 5(2)σ discovery (sensitivity) to $NE^{\pm} + E^+E^-$, based on the analyses of [1465, 1466].

acceptance and efficiency of $\mathcal{A} = 0.75$, which is in line to those obtained by [1465, 1466], Fig. 82(lower right) shows as a function of triplet mass the requisite luminosity for a 5σ discovery (solid) and 2σ evidence (dash-dot) of triplet leptons at $\sqrt{s} = 14$ and 27 TeV. With $\mathcal{L} = 3 - 5$ ab^{-1}, the 14 TeV HL-LHC can discover states as heavy as $m_N, m_E = 1.6 - 1.8$ TeV. For the same amount of data, the 27 TeV HE-LHC can discover heavy leptons $m_N, m_E = 2.6 - 2.8$ TeV; with $\mathcal{L} = 15$ ab^{-1}, one can discover (probe) roughly $m_N, m_E = 3.2$ (3.8) TeV.

10.3 Implications of TeV scale flavour models for electroweak baryogenesis

Authors (TH): Oleksii Matsedonskyi, Geraldine Servant.

In most solutions to the SM flavour puzzle, Yukawa couplings have a dynamical origin, which means that they potentially impact the cosmological evolution. In Refs. [1467–1474], such connections between flavour and cosmology, in particular with the electroweak baryogenesis, have been investigated in detail.

Electroweak baryogenesis (EWBG) is a framework where the matter-antimatter asymmetry of the universe was created during the electroweak phase transition. It relies on a charge transport mechanism in the vicinity of bubble walls during a first-order electroweak (EW) phase transition. EWBG uses EW scale physics only and is therefore testable experimentally. It requires an extension of the Higgs sector, giving a first-order EW phase transition as well as new sources of *CP* violation. Typically, there are stringent constraints on EWBG models from bounds on Electric Dipole Moments. In the following, we

consider situations where the source of CP violation has changed with time, which is a natural way to evade constraints. The main motivation is to link EWBG to low-scale flavour models. If the physics responsible for the structure of the Yukawa couplings is linked to EW symmetry breaking, we can expect the Yukawa couplings to vary at the same time as the Higgs is acquiring a VEV, in particular if the flavour structure is controlled by a new scalar field which couples to the Higgs. This is precisely what can happen in Composite Higgs (CH) models [1320, 1329], on which we focus in the following.

The Composite Higgs (CH) models assume that the Higgs boson arises as a bound state of a new strong interaction, confining around the TeV scale f. Other composite resonances are naturally heavier than the Higgs, due to an approximate Goldstone symmetry suppressing the Higgs mass. The rest of the SM fields do not belong to the strong sector and are elementary. The nature of the EW phase transition in CH models can be substantially different with respect to the SM. One of the reasons is that the CH models naturally feature new scalar resonances that participate in the EW phase transition and change its properties (see Refs. [1475, 1476]). On the other hand, the EW transition may become strongly first order even without the help of such additional states, if the EW transition happens simultaneously with the deconfinement-confinement phase transition of the new strong sector (see Refs. [1471, 1472] and also Refs. [1469, 1477] for the dual description in the warped 5D space).

The flavour structure of the CH models is intimately tied with the viability of EWBG. The requirement of having a sizeable top quark Yukawa coupling, while suppressing the unwanted flavour-violating effects, suggests that the new sector is nearly scale-invariant for a large range of energies above the confinement scale. As a result, one may expect that the transition dynamics is mostly determined by a single light field – the dilaton χ (see e.g Ref. [1478]). Depending on its mass, whose size can be related to the separation of the UV flavour scale and the EW scale, the EW phase transition may happen separately from the confinement, or simultaneously with it [1471, 1472].

Moreover, the mechanism for generating the SM flavour hierarchy in CH models may also be a source of CP asymmetry during the EW phase transition. The hierarchy of SM Yukawas λ_q is generated by the renormalization group running of the couplings y_q between the elementary fermions and the strong sector operators,

$$\lambda_q \propto y_q^2, \quad \text{with} \quad y_q = y_q^{\rm UV} \left(\frac{\mu}{\Lambda_{\rm UV}}\right)^{\gamma_{y_q}}, \tag{152}$$

where $\mu \sim \chi$ is the confinement scale, $\Lambda_{\rm UV}$ is some large scale at which all the mixings are generated with a similar size, $y_q^{\rm UV}$, and γ_{y_q} is the anomalous dimension of the operator responsible for the mixing. This means that the size of the Yukawa couplings changes with the evolution of the confinement scale during the confinement phase transition. Such a change of the Yukawa interactions may efficiently source the CP-violation required for the baryogenesis [1470].

For both types of transitions mentioned, one can expect to observe deviations of the Higgs couplings from the SM predictions. These deviations are a result of contributions generic to CH models, as well as those linked to the features of the phase transition and new sources of CP-violation. For concreteness we focus on the more minimal example, the combined electroweak and strong sector phase transition. The potential of the Higgs boson can be parametrized in terms of trigonometric functions of h/f, with the overall size of the potential controlled by the mixings between the elementary and composite fermions [1480, 1481],

$$V = c_1 \sin^2 \frac{h}{f} + c_2 \sin^4 \frac{h}{f}, \tag{153}$$

where $c_1 \sim c_2 \sim \sum_q (3y_q^2/(4\pi)^2) g_\star^2 f^4$. The dependence of the y_q mixings on the dilaton field is responsible for the mass mixing between the dilaton and the Higgs field, which we parametrise by an angle δ. To generate sufficient amount of CP violation, such mass mixing needs to be sizeable. Let us

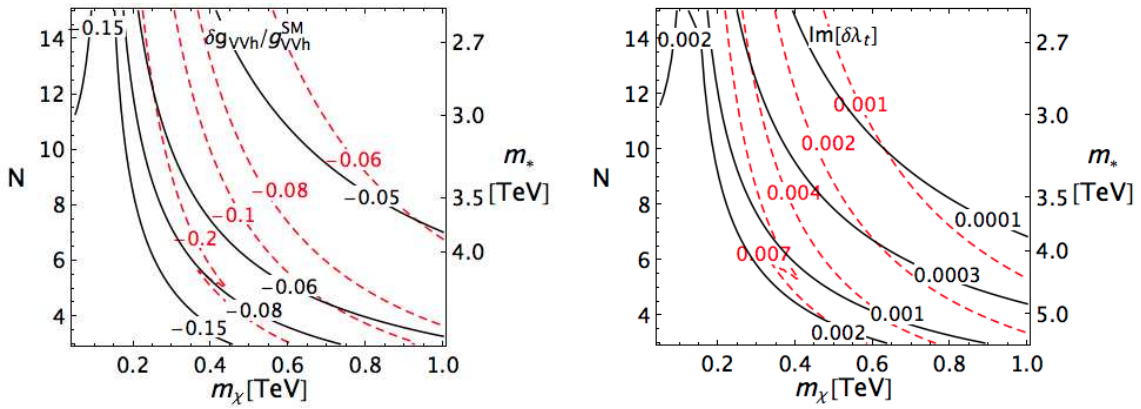

Fig. 83: Relative deviation of the Higgs couplings to W and Z bosons (left panel) and the imaginary part of the correction to the top quark Yukawa coupling (right panel), as functions of the dilaton mass, m_χ, the number of colours, N, in the new confining sector, and generic mass of composite states, m_*. Solid black (red dashed) contours correspond to the glueball-like (meson-like) dilaton. The current and near future experimental sensitivities of electron EDM experiments to the imaginary part of the top yukawa correspond respectively to approximately 2×10^{-3} [1253, 1378] and 2×10^{-4} [1479].

consider its effect on the quark Yukawa coupling:

$$\mathcal{L}_{\text{Yukawa}} = \lambda(\chi)\left(\chi \sin\frac{h}{f}\right)\bar{q}_L q_R = \bar{q}_L q_R h\left(\lambda(f)\frac{\chi}{f} + \beta_\lambda \frac{\chi - f}{f}\right) + \ldots, \tag{154}$$

where we performed an expansion in χ around its present day value, f. Similar, but CP-preserving, modifications are also generated in the couplings of the Higgs boson to the SM gauge fields and the Higgs self-interactions. The complex phase of the Yukawa beta-function, β_λ, in (154) has to be different from that of the quark mass $\lambda(f)h$, as the Yukawa phase changes with energy. Choosing the mass parameter to be real, the CP-violating interaction resides in the term $\propto \beta_\lambda$. Rotating the h and χ fields to the mass basis, the CP-even and CP-odd corrections to the Higgs Yukawa interaction are

$$\text{Re}[\delta\lambda] \sim \text{Re}[\beta_\lambda]\delta(v/f) + \lambda(\delta^2/2 + \delta(v/f)), \quad \text{Im}[\delta\lambda] \sim \text{Im}[\beta_\lambda]\delta(v/f). \tag{155}$$

In Fig. (83) we show the values of the CP-violating top quark Yukawa modification and the deviations of the Higgs couplings to the W and Z bosons. Such couplings can be tested directly at the LHC, and also in the measurements of electric dipole moments. The strength of the phase transition can be tested in gravitational waves signals at the future space-based observatory LISA [1482].

10.4 Phenomenology of high p_{T} searches in the context of flavour anomalies

Authors (TH): Alejandro Celis, Admir Greljo, Lukas Mittnacht, Marco Nardecchia, Tevong You.

Precision measurements of flavour transitions at low energies, such as flavour changing B, D and K decays, are sensitive probes of hypothetical dynamics at high energy scales. These can provide the first evidence of new phenomena beyond the SM, even before direct discovery of new particles at high energy colliders. Indeed, the current anomalies observed in B-meson decays, in particular, the charged current one in $b \to c\tau\nu$ transitions, and neutral current one in $b \to s\ell^+\ell^-$, may be the first hint of new dynamics which is still waiting to be discovered at high-p_{T}. When considering models that can accommodate the anomalies, it is crucial to analyse the constraints derived from high-p_{T} searches at the LHC, since these can often rule out significant regions of model parameter space. Below we review these constrains, and assess the impact of the High Luminosity and High Energy LHC upgrades (see also the discussion in Sections 7.1.3,7.1.2, and 7.2.3).

10.4.1 EFT analysis

If the dominant NP effects give rise to dimension-six SMEFT operators, the low-energy flavour measurements are sensitive to C/Λ^2, with C the dimensionless NP Wilson coefficient and Λ the NP scale. The size of the Wilson coefficient is model dependent, and thus so is the NP scale required to explain the $R_{D^{(*)}}$and $R_{K^{(*)}}$ anomalies. Perturbative unitarity sets an upper bound on the energy scale below which new dynamics need to appear [1483]. The conservative bounds on the scale of unitarity violation are $\Lambda_U = 9.2$ TeV and 84 TeV for $R_{D^{(*)}}$and $R_{K^{(*)}}$, respectively, obtained when the flavour structure of NP operators is exactly aligned with what is needed to explain the anomalies. More realistic frameworks for flavour structure, such as MFV, $U(2)$ flavour models, or partial compositeness, give rise to NP effective operators with largest effects for the third generation. This results in stronger unitarity bounds, $\Lambda_U = 1.9$ TeV and 17 TeV for $R_{D^{(*)}}$ and $R_{K^{(*)}}$, respectively. These results mean that: *(i)* the mediators responsible for the $b \to c\tau\nu$ charged current anomalies are expected to be in the energy range of the LHC, *(ii)* the mediators responsible for the $b \to s\ell\ell$ neutral current anomalies could well be above the energy range of the LHC. However, in realistic flavour models also these mediators typically fall within the (HE-)LHC reach.

If the neutrinos in $b \to c\tau\nu$ are part of a left-handed doublet, the NP responsible for $R_{D^{(*)}}$ anomaly generically implies a sizeable signal in $pp \to \tau^+\tau^-$ production at high-$p_{\rm T}$. For realistic flavour structures, in which $b \to c$ transition is $\mathcal{O}(V_{cb})$ suppressed compared to $b \to b$, one expects rather large $bb \to \tau\tau$ NP amplitude. Schematically, $\Delta R_{D^{(*)}} \sim C_{bb\tau\tau}(1 + \lambda_{bs}/V_{cb})$, where $C_{bb\tau\tau}$ is the size of effective dim-6 interactions controlling $bb \to \tau\tau$, and λ_{bs} is a dimensionless parameter controlling the size of flavour violation. Recasting ATLAS 13 TeV, 3.2 fb^{-1} search for $\tau^+\tau^-$ [1484], Ref. [369] showed that $\lambda_{bs} = 0$ scenario is already in slight tension with data. For $\lambda_{bs} \sim 5$, which is moderately large, but still compatible with FCNC constraints, HL (or even HE) upgrade of the LHC would be needed to cover the relevant parameter space implied by the anomaly (see Fig. [5] in [265]). For large λ_{bs} the limits from $pp \to \tau^+\tau^-$ become comparable with direct the limits on $pp \to \tau\nu$ from the bottom-charm fusion. The limits on the EFT coefficients from $pp \to \tau\nu$ were derived in Ref. [378], and the future LHC projections are promising. The main virtue of this channel is that the same four-fermion interaction is compared in $b \to c\tau\nu$ at low energies and $bc \to \tau\nu$ at high-$p_{\rm T}$. Since the effective NP scale in $R(D^{(*)})$ anomaly is low, the above EFT analyses are only indicative. For more quantitative statements we review below bounds on explicit models.

The hints of NP in $R_{K^{(*)}}$ require a $(bs)(\ell\ell)$ interaction. Correlated effects in high-$p_{\rm T}$ tails of $pp \to \mu^+\mu^-(e^+e^-)$ distributions are expected, if the numerators (denominators) of LFU ratios $R_{K^{(*)}}$ are affected. Ref. [1485] recast the 13 TeV 36.1 fb^{-1} ATLAS search [1486] (see also [1487]), to set limits on a number of semi-leptonic four-fermion operators, and derive projections for HL-LHC (see Table 1 in [1485]). These show that direct limits on the $(bs)(\ell\ell)$ operator from the tails of distributions will never be competitive with those implied by the rare B-decays [1485, 1488]. On the other hand, flavour conserving operators, $(qq)(\ell\ell)$, are efficiently constrained by the high $p_{\rm T}$ tails of the distributions. The flavour structure of an underlining NP could thus be probed by constraining ratios $\lambda^q_{bs} = C_{bs}/C_{qq}$ with C_{bs} fixed by the $R_{K^{(*)}}$ anomaly. For example, in models with MFV flavour structure, so that $\lambda^{u,d}_{bs} \sim V_{cb}$, the present high-$p_{\rm T}$ dilepton data is already in slight tension with the anomaly [1485]. Instead, if couplings to valence quarks are suppressed, e.g., if NP dominantly couples to the 3rd family SM fermions, then $\lambda^b_{bs} \sim V_{cb}$. Such NP will hardly be probed even at the HL-LHC, and it is possible that NP responsible for the neutral current anomaly might stay undetected in the high-$p_{\rm T}$ tails at HL-LHC and even at HE-LHC. Future data will cover a significant part of viable parameter space, though not completely, so that discovery is possible, but not guaranteed.

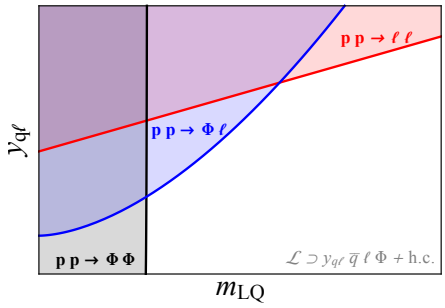

Fig. 84: Schematic of the LHC bounds on LQ showing complementarity in constraining the (m_{LQ}, y_{q_ℓ}) parameters. The three cases are: pair production $\sigma \propto y^0_{q_\ell}$, single production $\sigma \propto y^2_{q_\ell}$ and Drell-Yan $\sigma \propto y^4_{q_\ell}$ (from [1490]).

10.4.2 Constraints on simplified models for $b \to c\tau\nu$

Since the $b \to c\tau\nu$ decay is a tree-level process in the SM that receives no drastic suppression, models that can explain these anomalies necessarily require a mediator that contributes at tree-level:

- *SM-like W'*: A SM-like W' boson, coupling to left-handed fermions, would explain the approximately equal enhancements observed in $R(D)$ and $R(D^*)$. A possible realization is a color-neutral real $SU(2)_L$ triplet of massive vector bosons [946]. However, typical models encounter problems with current LHC data since they result in large contributions to $pp \to \tau^+\tau^-$ cross-section, mediated by the neutral partner of the W' [369, 926, 946]. For $M_{W'} \gtrsim 500$ GeV, solving the $R(D^{(*)})$ anomaly within the vector triplet model while being consistent with $\tau^+\tau^-$ resonance searches at the LHC is only possible if the related Z' has a large total decay width [369]. Focusing on the W', Ref. [1489] analyzed the production of this mediator via gg and gc fusion, decaying to $\tau\nu_\tau$. Ref. [1489] concluded that a dedicated search using that b-jet is present in the final state would be effective in reducing the SM background compared to an inclusive analysis that relies on τ-tagging and E_T^{miss}. Nonetheless, relevant limits will be set by an inclusive search in the future [378].

- *Right-handed W':* Refs. [1056, 1057] recently proposed that W' could mediate a right-handed interaction, with a light sterile right-handed neutrino carrying the missing energy in the B decay. In this case, it is possible to completely decorelate FCNC constraints from $R(D^{(*)})$. The most constraining process in this case is instead $pp \to \tau\nu$. Ref. [378] performed a recast of the latest ATLAS and CMS searches at 13 TeV and about 36 fb^{-1} to constrain most of the relevant parameter space for the anomaly.

- *Charged Higgs $H^\pm$:* Models that introduce a charged Higgs, for instance a two-Higgs-doublet model, also contain additional neutral scalars. Their masses are constrained by electroweak precision measurements to be close to that of the charged Higgs. Accommodating the $R(D^{(*)})$ anomalies with a charged Higgs typically implies large new physics contributions to $pp \to \tau^+\tau^-$ via the neutral scalar exchanges, so that current LHC data can challenge this option [369]. Note that a charged Higgs also presents an important tension between the current measurement of $R(D^*)$ and the measured lifetime of the B_c meson [1031, 1046, 1063, 1064].

- *Leptoquarks:*

The observed anomalies in charged and neutral currents appear in semileptonic decays of the B-mesons. This implies that the putative NP has to couple to both quarks and leptons at the fundamental level. A natural BSM option is to consider mediators that couple simultaneously quarks and leptons at the tree level. Such states are commonly referred as leptoquarks. Decay and production mechanisms of the LQ are directly linked to the physics required to explain the anomalous data.

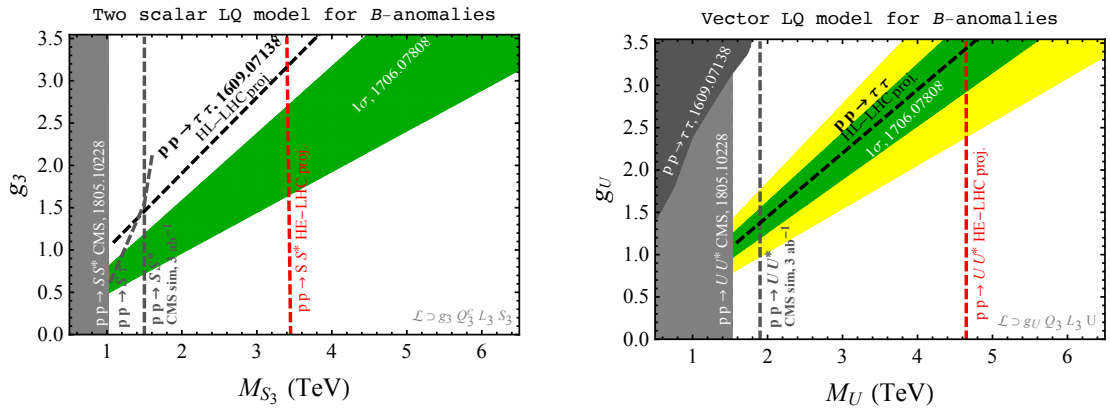

Fig. 85: Present constraints and HL(HE)-LHC projections in the leptoquark mass versus coupling plane for the scalar leptoquark S_3 (left), and vector leptoquark U_1 (right). The grey and dark grey solid regions are the current exclusions. The grey and black dashed lines are the projected reach for HL-LHC (pair and single leptoquark production prospects are based on the CMS simulation from Section 10.4.5). The red dashed lines are the projected reach at HE-LHC (see Section 10.4.6). The green and yellow bands are the 1σ and 2σ preferred regions from the fit to B physics anomalies. The second coupling required to fit the anomaly does not enter in the leading high-$p_{\rm T}$ diagrams but it is relevant for fixing the preferred region shown in green, for more details see Ref. [265].

– **Leptoquark decays:** the fit to the $R(D^*)$ observables suggest a rather light leptoquark (at the TeV scale) that couples predominately to the third generation fermions of the SM. A series of constraints from flavour physics, in particular the absence of BSM effects in kaon and charm mixing observables, reinforces this picture.
– **Leptoquark production mechanism:** The size of the couplings required to explain the anomaly is typically very large, roughly $y_{q\ell} \approx m_{LQ}/$ (1 TeV). Depending of the actual sizes of the leptoquark couplings and its mass we can distinguish three regimes that are relevant for the phenomenology at the LHC:

  1. LQ pair production due to strong interactions,
  2. Single LQ production plus lepton via a single insertion of the LQ coupling, and
  3. Non-resonant production of di-lepton through t-channel exchange of the leptoquark.

  Interestingly all three regimes provide complementary bounds in the (m_{LQ}, y_{q_ℓ}) plane, see Fig. 84.

Several simplified models with leptoquark as a mediator were shown to be consistent with the low-energy data. A vector leptoquark with $SU(3)_c \times SU(2)_L \times U(1)_Y$ SM quantum numbers $U_\mu \sim (\mathbf{3}, \mathbf{1}, 2/3)$ was identified as the only single mediator model which can simultaneously fit the two anomalies (see e.g. [265] for a recent fit including leading RGE effects). In order to substantially cover the relevant parameter space, one needs future HL- (HE-) LHC, see Fig. 85 (right) (see also Fig. 5 of [265] for details on the present LHC constraints). A similar statement applies to an alternative model featuring two scalar leptoquarks, S_1, S_3 [955]. The pair of plots in Fig. 85 summaries the current exclusion and the discovery reach for the HE and HL-LHC in the LQ coupling versus mass plane.

Leptoquarks states are emerging as the most convincing mediators for the explanations of the flavour anomalies. It is then important to explore all the possible signatures at the HL- and HE-LHC. The experimental programme should focus not only on the final states containing quarks and leptons of the third generation, but also on the whole list of decay channels including the off-diagonal ones ($b\mu$, $s\tau, \ldots$). The completeness of this approach would allow to shed light on the flavour structure of the putative New Physics.

Another aspect to be emphasized regarding leptoquark models is that the UV complete models often require extra fields. The accompanying particles would leave more important signatures at high

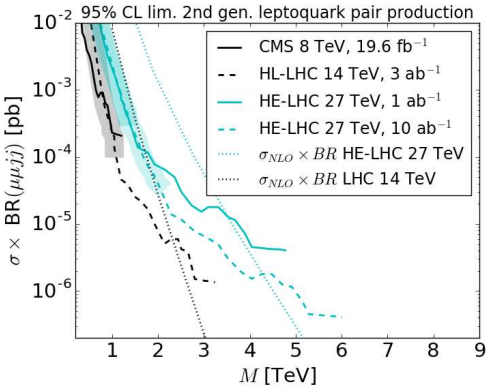

Fig. 86: Current and projected 95% CL limits on $\mu\mu jj$ final state at CMS (solid black) and HL-LHC (cyan) with 1 (10) ab^{-1} in solid (dashed) lines. The pair production cross-section for scalar leptoquarks is shown in dotted lines for 14 (27) TeV in black (cyan) (Fig. taken from [1493]).

p_T than the leptoquarks, which is particularly true for vector leptoquark extensions (see for example [963, 1491])

10.4.3 Constraints on simplified models for $b \to sll$

The $b \to sll$ transition is both loop and CKM suppressed in the SM. The explanations of the $b \to sll$ anomalies can thus have both tree level and loop level mediators. Loop-level explanations typically involve lighter particles. Tree-level mediators can also be light, if sufficiently weakly coupled. However, they can also be much heavier—possibly beyond the reach of the LHC.

• *Tree-level mediators:*
For $b \to sll$ anomaly there are two possible tree-level UV-completions, the Z' vector boson and leptoquarks, either scalar or vector (see Fig. 41 in Sec. 7.1.3). For leptoquarks, Fig. 86 shows the current 95% CL limits from 8 TeV CMS with 19.6 fb^{-1} in the $\mu\mu jj$ final state (solid black line), as well as the HL-LHC (dashed black line) and 1 (10) ab^{-1} HE-LHC extrapolated limits (solid (dashed) cyan line). Dotted lines give the cross-sections times branching ratio at the corresponding collider energy for pair production of scalar leptoquarks, calculated at NLO using the code of Ref. [1492]. We see that the sensitivity to a leptoquark with only the minimal $b-\mu$ and $s-\mu$ couplings reaches around 2.5 and 4.5 TeV at the HL-LHC and HE-LHC, respectively. This pessimistic estimate is a lower bound that will typically be improved in realistic models with additional flavour couplings. Moreover, the reach can be extended by single production searches [1493], albeit in a more model-dependent way than pair production. The cross section predictions for vector leptoquark are more model-dependent and are not shown in Fig. 86. For $\mathcal{O}(1)$ couplings the corresponding limits are typically stronger than for scalar leptoquarks. Searches in other decay channels should also be considered, such at $t\bar{t}$+MET for which HL-LHC projections can be found in Ref. [1494].

For the Z' mediator the minimal couplings in the mass eigenstate basis are obtained by unitary transformations from the gauge eigenstate basis, which necessarily induces other couplings. Ref. [1496] defined the "mixed-up" model (MUM) and "mixed-down" model (MDM) such that the minimal couplings are obtained via CKM rotations in either the up or down sectors respectively. For MUM there is no sensitivity at the HL-LHC. The predicted sensitivity at the HL-LHC for the MDM is shown in Fig. 87 as functions of Z' muon coupling $g_{\mu\mu}$ and the Z' mass, setting the Z' coupling to b and s quarks such that it solves the $b \to s\ell\ell$ anomaly. The solid blue (orange) contours give the 95% and 99% CL sensitivity. The red and green regions are excluded by B_s mixing [906] and neutrino trident production [1497, 1498], respectively. The more stringent B_s mixing constraint from Ref. [1495] is denoted by the dashed blue

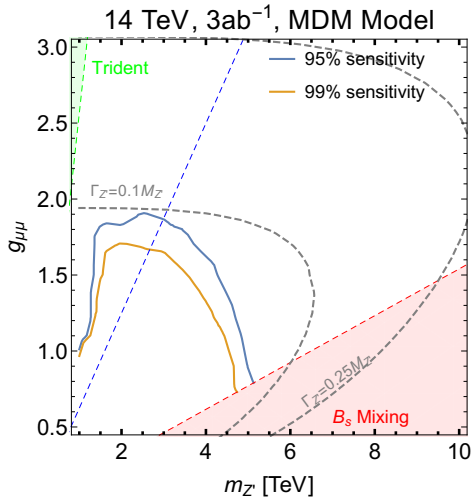

Fig. 87: HL-LHC 95% (blue) and 99% (orange) CL sensitivity contours to Z' in the "mixed-down" model for $g_{\mu\mu}$ vs Z' mass in TeV. The dashed grey contours give the Z' width as a fraction of mass. The green and red regions are excluded by trident neutrino production and B_s mixing, respectively. The dashed blue line is the stronger B_s mixing constraint from Ref. [1495] (Fig. taken from [1496]).

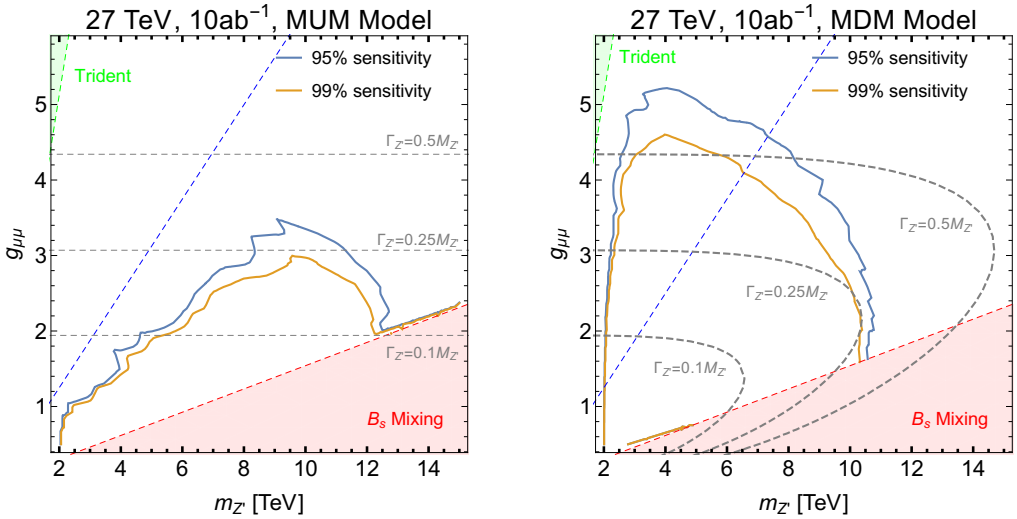

Fig. 88: HE-LHC 95% (blue) and 99% (orange) CL sensitivity contours to Z' in the "mixed-up" (left) and "mixed-down" (right) model in the parameter space of $g_{\mu\mu}$ vs Z' mass in TeV. The dashed grey contours are the width as a fraction of mass. The green and red regions are excluded by trident neutrino production and B_s mixing. The dashed blue line is the stronger B_s mixing constraint from Ref. [1495] (Figs. taken from [1496]).

line; see, however, Ref. [948] for further discussion regarding the implications of this bound. The dashed grey contours denote the width as a fraction of the mass. We see that the HL-LHC will only be sensitive to Z' with narrow width, up to masses of 5 TeV.

At the HE-LHC, the reach for 10 ab^{-1} is shown in Fig. 88 for the MUM and MDM on the left and right, respectively. In this case the sensitivity may reach a Z' with wider widths up to 0.25 and 0.5 of its mass, while the mass extends out to 10 to 12 TeV. We stress that this is a pessimistic estimate of the projected sensitivity, particular to the two minimal models; more realistic scenarios will typically be easier to discover.

• *Explanations at the one-loop level:*
It is possible to accomodate the $b \to s\ell^+\ell^-$ anomalies even if mediators only enter at one-loop. One possibility is the mediators coupling to right-handed top quarks and to muons [346, 907, 1499–1501]. Given the loop and CKM suppression of the NP contribution to the $b \to s\ell^+\ell^-$ amplitude, these models can explain the $b \to s\ell^+\ell^-$ anomalies for a light mediator, with mass around $\mathcal{O}(1)$ TeV or lighter. Constraints from the LHC and future projections for the HL-LHC were derived in [1501] by recasting di-muon resonance, $pp \to t\bar{t}t\bar{t}$ and SUSY searches. Two scenarios were considered: *i)* a scalar LQ $R_2(3, 2, 7/6)$ combined with a vector LQ $\widetilde{U}_{1\alpha}(3, 1, 5/3)$, *ii)* a vector boson Z' in the singlet representation of the SM gauge group. Ref. [1500] also analyzed the HL-LHC projections for the Z'. The constraints from the LHC already rule out part of the relevant parameter space and the HL-LHC will be able to cover much of the remaining regions. Dedicated searches in the $pp \to t\bar{t}t\bar{t}$ channel and a dedicated search for $t\mu$ resonances in $t\bar{t}\mu^+\mu^-$ final state can improve the sensitivity to these models [1501].

10.4.4 Conclusions regarding high p_{T} probes of flavour anomalies

The anomalous results in B-meson decays cannot be considered yet as a convincing evidence of New Physics. On the other hand, the number (and quality) of observables that are not in complete agreement with the SM prediction is growing with time in a coherent way. If true, the implications for HEP will be profound. The conclusions we draw are the following:

- A conservative argument based on perturbative unitarity [1483] sets an upper bound on the New Physics scale to be 9 TeV for charged current anomalies and 80 TeV for neutral current ones. The analysis of explicit models show that the high-luminosity programme has a clear potential to probe a large portion of the possible BSM options.
- The explanation of the anomalies in $b \to c\tau\nu$ transitions requires non trivial model building. In particular, it is not possible to simply isolate the physics that mediate the flavour anomalous transitions. In complete models other signature have to be considered. Typically it would be very difficult to escape direct detection at HL/HE-LHC.
- Even though the naive scale associated with the $b \to s\ell\ell$ anomalies is much higher than the energy accessible at HL/HE-LHC, in motivated models the flavour suppressions and weak couplings guarantee a large coverage of the parameter space for leptoquark and Z' mediators [1496].

More generally, the probes of lepton flavour universality such as the ratios of inclusive $\tau^+\tau^-$ vs. $\mu^+\mu^-$ (or $\mu^+\mu^-$ vs. e^+e^-) mass distributions, are important, theoretically clean, tests of the SM and are well motivated observables both at HL- and HE-LHC, whether or not the current B-meson anomalies become statistically significant.

As a final remark, it is important to remember that the anomalies are not yet experimentally established. Among others, this also means that the statements on whether or not the high p_T LHC constraints rule out certain $R(D^{(*)})$ explanations assumes that the actual values of $R(D^{(*)})$ are given by their current global averages. If future measurements decrease the global average, the high p_T constraints can in some cases be greatly relaxed so that HL- and/or HE-LHC may be essential even for these, at present tightly constrained, cases.

10.4.5 Experimental prospects for high p_T searches at HL-LHC relevant for B anomalies

We give next the experimental prospects for leptoquark searches, with leptoquarks decaying to the final states relevant for B physics anomalies.

10.4.5.1 Prospects for leptoquark searches assuming t+τ and/or t+μ decays

The reach of searches for pair production of leptoquarks (LQs) with decays to $t + \mu$ and $t + \tau$ is studied for the HL-LHC with target integrated luminosities of $\mathcal{L}_{\text{int}}^{\text{target}} = 300$ and $3000\,\text{fb}^{-1}$ [1502]. The studies

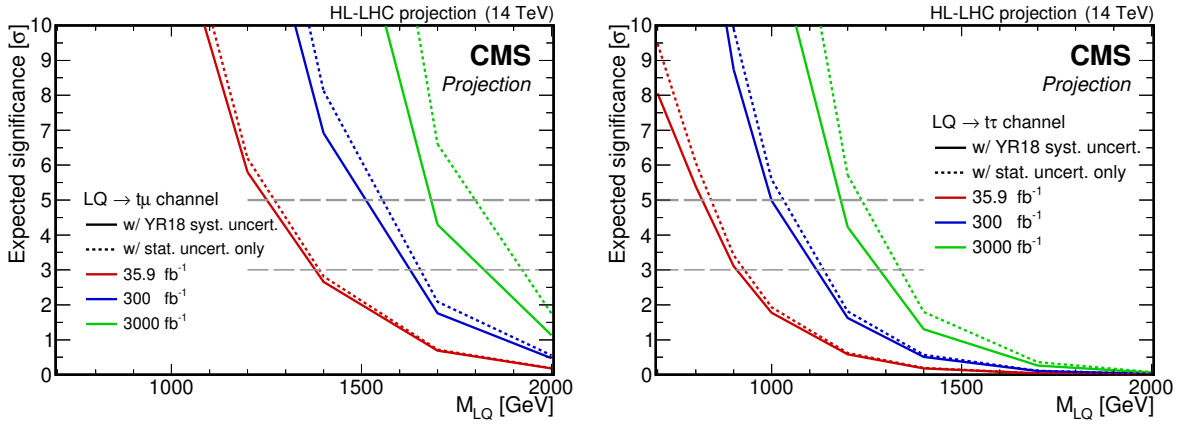

Fig. 89: Expected significances for an LQ decaying exclusively to top quarks and muons (left) or top quarks and τ leptons (right).

are based on published CMS results of the t+μ [1503] and t+τ [1504] LQ decay channels which use data of proton-proton collisions at $\sqrt{s} = 13\,\text{TeV}$ corresponding to $\mathcal{L}_{\text{int}} = 35.9\,\text{fb}^{-1}$ recorded in 2016. While the analysis strategies are kept unchanged with respect to the ones in Refs. [1503, 1504], different total integrated luminosities, the higher center-of-mass energy of 14 TeV, and different scenarios of systematic uncertainties are considered. In the first scenario (denoted "w/ YR18 syst. uncert."), the relative experimental systematic uncertainties are scaled by a factor of $1/\sqrt{f}$, with $f = \mathcal{L}_{\text{int}}^{\text{target}}/35.9\,\text{fb}^{-1}$, until they reach a defined lower limit based on estimates of the achievable accuracy with the upgraded detector [1]. The relative theoretical systematic uncertainties are halved. In the second scenario (denoted "w/ stat. uncert. only"), no systematic uncertainties are considered. The relative statistical uncertainties in both scenarios are scaled by $1/\sqrt{f}$.

Figure 89 presents the expected signal significances of the analyses as a function of the LQ mass for different assumed integrated luminosities in the "w/ YR18 syst. uncert." and "w/ stat. uncert. only" scenarios. Increasing the target integrated luminosity to $\mathcal{L}_{\text{int}}^{\text{target}} = 3000\,\text{fb}^{-1}$ greatly increases the discovery potential of both analyses. The LQ mass corresponding to a discovery at 5σ significance with a dataset corresponding to $3000\,\text{fb}^{-1}$ increases by more than 500 GeV compared to the situation at $\mathcal{L}_{\text{int}}^{\text{target}} = 35.9\,\text{fb}^{-1}$, from about 1200 GeV to roughly 1700 GeV, in the LQ $\to t\mu$ decay channel. For LQs decaying exclusively to top quarks and τ leptons, a gain of 400 GeV is expected, pushing the LQ mass in reach for a 5σ discovery from 800 GeV to 1200 GeV.

In Fig. 90, the expected projected exclusion limits on the LQ pair production cross section are shown. Leptoquarks decaying only to top quarks and muons are expected to be excluded below masses of 1900 GeV for $3000\,\text{fb}^{-1}$, which is a gain of 500 GeV compared to the limit of 1420 GeV obtained in the published analysis of the 2016 dataset [1503]. The mass exclusion limit for LQs decaying exclusively to top quarks and τ leptons are expected to be increased by 500 GeV, from 900 GeV to approximately 1400 GeV.

Figure 91 shows the expected signal significances and upper exclusion limits on the pair production cross section of scalar LQs allowed to decay to top quarks and muons or τ leptons at the 95% CL as a function of the LQ mass and a variable branching fraction $\mathcal{B}(\text{LQ} \to t\mu) = 1 - \mathcal{B}(\text{LQ} \to t\tau)$ for an integrated luminosity of $3000\,\text{fb}^{-1}$ in the two different scenarios. For all values of $\mathcal{B}$, LQ masses up to approximately 1200 GeV and 1400 GeV are expected to be in reach for a discovery at the 5σ level and a 95% CL exclusion, respectively.

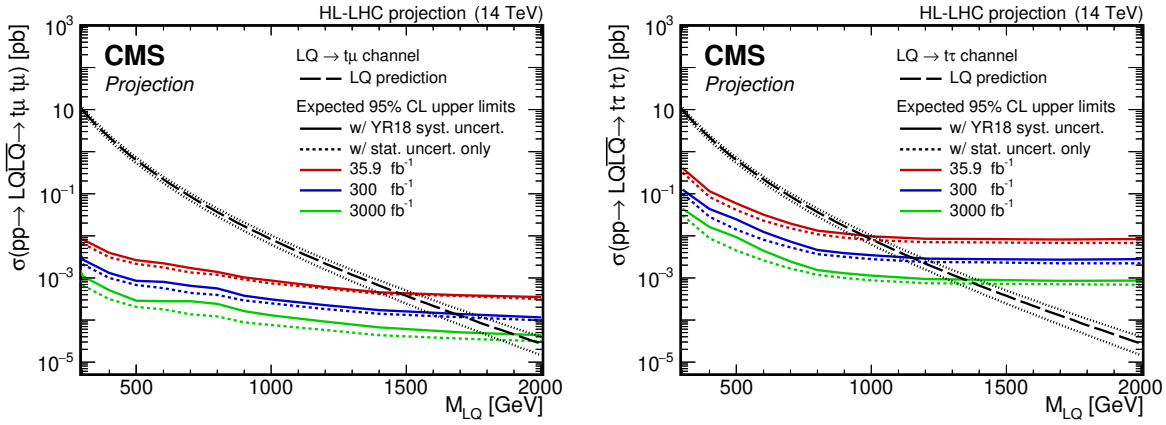

Fig. 90: Expected upper limits on the LQ pair production cross section at the 95% CL for an LQ decaying exclusively to top quarks and muons (left) or τ leptons (right).

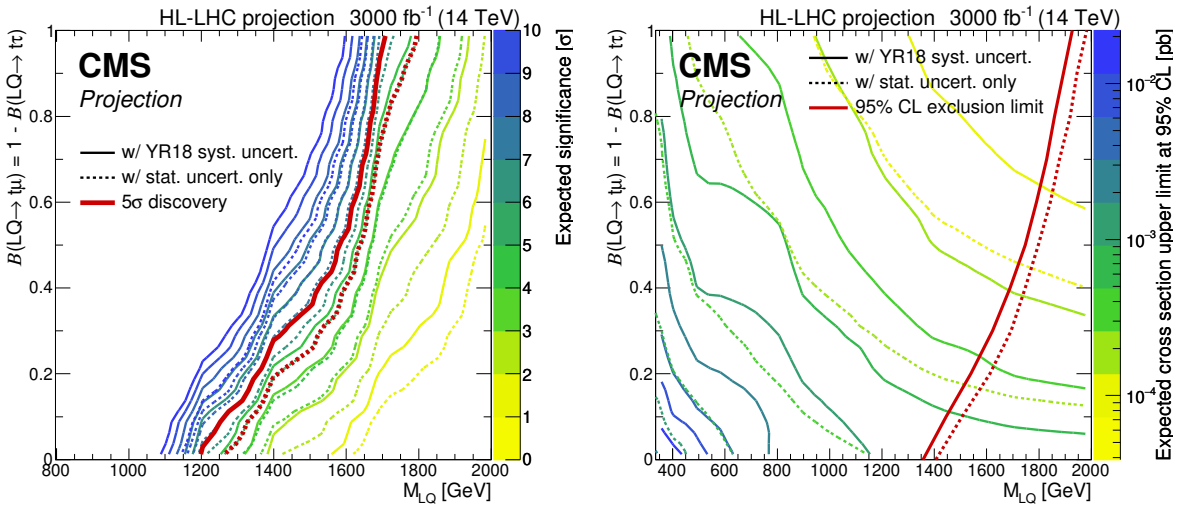

Fig. 91: Expected significances (left) and expected upper limits on the LQ pair-production cross section at the 95% CL (right) as a function of the LQ mass and the branching fraction. Color-coded lines represent lines of a constant expected significance or cross section limit, respectively. The red lines indicate the 5σ discovery level (left) and the mass exclusion limit (right).

10.4.5.2 CMS Search for leptoquarks decaying to τ and b

This analysis from CMS [1505] presents future discovery and exclusion prospects for singly and pair produced third-generation scalar LQs, each decaying to τ_h and a bottom quark. Here, τ_h denotes a hadronically decaying τ lepton. The relevant Feynman diagrams of the signal processes at leading order (LO) are shown in Fig. 92.

The analysis uses DELPHES [374] event samples of simulated pp collisions at a center-of-mass energy of 14 TeV, corresponding to integrated luminosities of 300 and 3000 fb^{-1}. The matrix elements of LQ signals for both single and pair LQ production are generated at LO using version 2.6.0 of `MadGraph5_aMC@NLO` [372] for m_{LQ} =500, 1000, 1500, and 2000 GeV. The branching fraction β of the LQ to a charged lepton and a quark, in this case LQ$\rightarrow \tau b$, is assumed to be $\beta = 1$. The unknown Yukawa coupling λ of the LQ to a τ lepton and a bottom quark is set to $\lambda = 1$. The width Γ is calculated using $\Gamma = m_{LQ}\lambda^2/(16\pi)$ [1506], and is less than 10% of the LQ mass for most of the considered search range. The signal samples are normalized to the cross section calculated at LO, multiplied by a K factor to account for higher order contributions [1490].

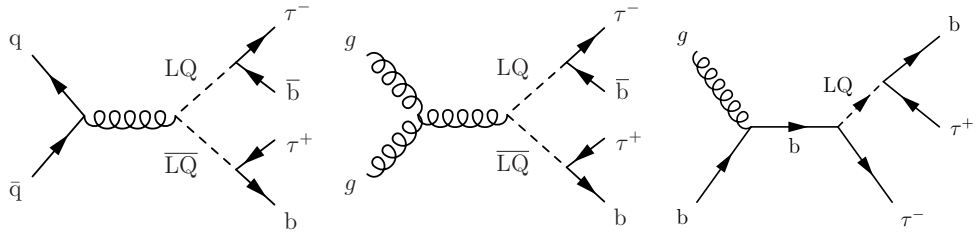

Fig. 92: Leading order Feynman diagrams for the production of a third-generation LQ in the single production s-channel (left) and the pair production channel via gluon fusion (center) and quark fusion (right).

Similar event selections are used in both the singly and pair produced LQ searches, except for the requirement on the number of jets. In both channels, two reconstructed τ_h with opposite-sign charge are required, each with transverse momentum $p_{T,\tau} > 50$ GeV and a maximum pseudorapidity $|\eta_\tau| < 2.3$. In the search for single production, the presence of at least one reconstructed jet with $p_T > 50$ GeV is required, while at least two are required in the search for pair production. Jets are reconstructed with FASTJET [1507], using the anti-k_{T} algorithm [1508], with a distance parameter of 0.4.

To reduce background due to Drell-Yan (particularly Z$\rightarrow \tau\tau$) events, the invariant mass of the two selected τ_h, $m_{\tau\tau}$, is required to be > 95 GeV. In addition, at least one of the previously selected jets is required to be b-tagged to reduce QCD multijet backgrounds. Finally, an event is rejected if it contains identified and isolated electrons (muons), with $p_T > 10$ GeV, $|\eta|$ <2.4 (2.5). The acceptance of the signal events is 4.9% (11%) for single (pair) production, where the branching ratio of two τ leptons decaying hadronically is included in the numerator of the acceptance.

Signal extraction is based on a binned maximum likelihood fit to the distribution of the scalar p_T sum $\mathrm{S_T}$, which is defined as the sum of the transverse momenta of the two τ_h and either the highest-p_T jet in the case of single LQ production, or the two highest-p_T jets in the case of LQ pair production. These distributions are shown in Fig. 93 for the HL-LHC 3000 fb^{-1} scenario.

Systematic uncertainties are calculated by scaling the current experimental uncertainties. For uncertainties limited by statistics, including the uncertainty on the DY (3.3%) and QCD (3.3%) cross sections, a scale factor of $1/\sqrt{L}$ is applied, for an integrated luminosity ratio L. For uncertainties coming from theoretical calculations, a scale factor of 1/2 is applied with respect to current uncertainties, as is the case for the uncertainties on the cross section for top (2.8%) or diboson (3%) events. Other experimental systematic uncertainties are scaled by the square root of the integrated luminosity ratio until the uncertainty reaches a minimum value, including uncertainties on the integrated luminosity (1%), τ identification (5%) and b-tagging/misidentification (1%-5%).

Figure 94 shows an upper limit at 95% CL on the cross section times branching fraction β as a function of m_{LQ} by using the asymptotic CLs modified frequentist criterion [1509–1512]. Upper limits are calculated considering two different scenarios. The first one, hereafter abbreviated as "stat. only" considers only statistical uncertainties, to observe how the results are affected by the increase of the integrated luminosity. The second scenario, hereafter abbreviated as "stat.+syst.," also includes the estimate of the systematic uncertainties at the HL-LHC. For the single LQ production search, the theoretical prediction for the cross section assumes $\lambda = 1$ and $\beta = 1$.

Comparing the limits with theoretical predictions assuming unit Yukawa coupling $\lambda = 1$, third-generation scalar leptoquarks are expected to be excluded at 95% confidence level for LQ masses below 732 (1249) GeV for a luminosity of 300 fb^{-1}, and below 1130 (1518) GeV for 3000 fb^{-1} in the single (pair) production channel, considering both statistical and systematic uncertainties.

Since the single-LQ signal cross section scales with λ^2, it is straightforward to recast the results presented in Fig. 94 in terms of expected upper limits on m_{LQ} as a function of λ, as shown in Fig. 95. The

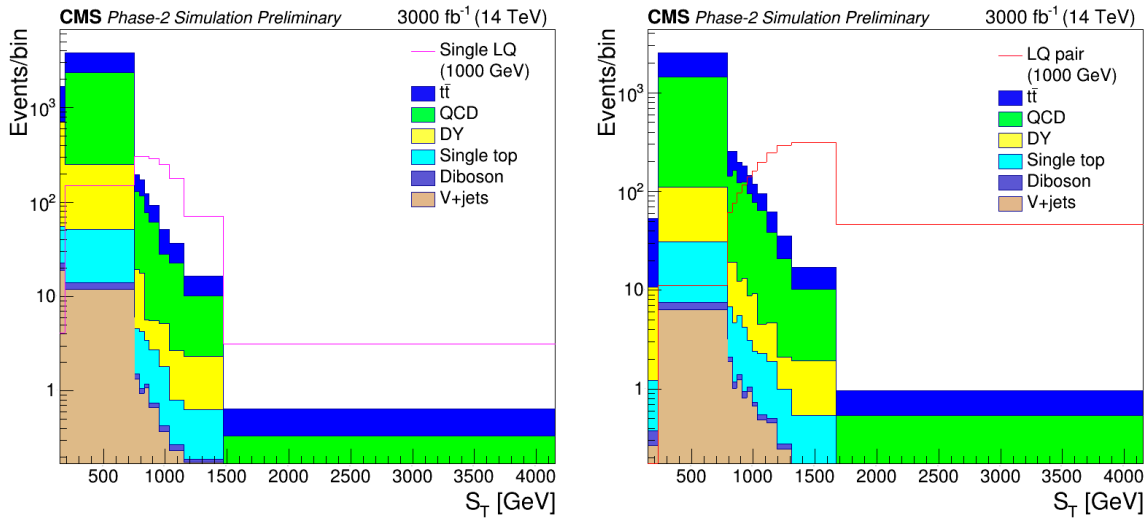

Fig. 93: Left: scalar sum of the p_{T} of the two selected τ leptons and the highest-p_T jet in the single LQ selection region. Right: scalar sum of the p_T of the two selected τ leptons and the two highest-p_T jets in the LQ pair search region. The considered backgrounds are shown as stacked histograms, while empty histograms for signals for the single LQ and LQ pair channels (for $m_{LQ} = 1000$ GeV) are overlaid to illustrate the sensitivity. Both signal and backround are normalised to a luminosity of 3000 fb^{-1}.

blue band shows the parameter space (95% CL) for the scalar LQ preferred by the B physics anomalies: $\lambda = (0.95 \pm 0.50) m_{LQ}(\text{ TeV})$ [265]. For the 300 (3000) fb^{-1} luminosity scenario, the leptoquark pair production channel is more sensitive if $\lambda < 2.7\ (2.3)$, while the single leptoquark production is dominant otherwise.

Using the predicted cross section [1490] of the signal, it is also possible to estimate the maximal LQ mass expected to be in reach for a 5σ discovery. Figure 96 shows the expected local significance of a signal-like excess as a function of the LQ mass hypothesis.

In summary, this study shows that future LQ searches under higher luminosity conditions are promising, as they are expected to greatly increase the reach of the search. They also show that the pair production channel is expected to be the most sensitive. A significance of 5σ is within reach for LQ masses below 800 (1200) FeV for the single (pair) production channels in the 300 fb^{-1} scenario and 1000 (1500) GeV for the 3000 fb^{-1} scenario.

10.4.5.3 CMS Searches for $W' \to \tau + E_{\mathrm{T}}^{\mathrm{miss}}$

New heavy gauge bosons are predicted by various SM extensions. The charged version of such heavy gauge bosons is generally referred to as W$'$. The decay W$' \to \tau\nu$ yields a single hadronically decaying tau (τ_h) as the only detectable object and missing energy due to the neutrinos. Hadronically decaying tau leptons are selected since the corresponding branching fraction, about 60%, is the largest among all τ decays. Tau-jets are experimentally distinctive because of their low charged hadron multiplicity, unlike QCD multi-jets, which have high charged hadron multiplicity, or other leptonic W$'$ boson decays, which yield no jet. This Phase-2 study [1513] follows closely the recently published Run 2 result [1514], using hadronically decaying tau leptons.

The signature of a W$'$ boson (see Fig. 97), is considered similar to a high-mass W boson. It could be observed in the distribution of the transverse mass (M_T) of the transverse momentum of the τ (p_T^τ) and the missing transverse momentum ($\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$): $M_T = \sqrt{2 p_T^\tau p_T^{miss} (1 - cos\Delta\phi(\tau, p_T^{miss}))}$. Unlike the

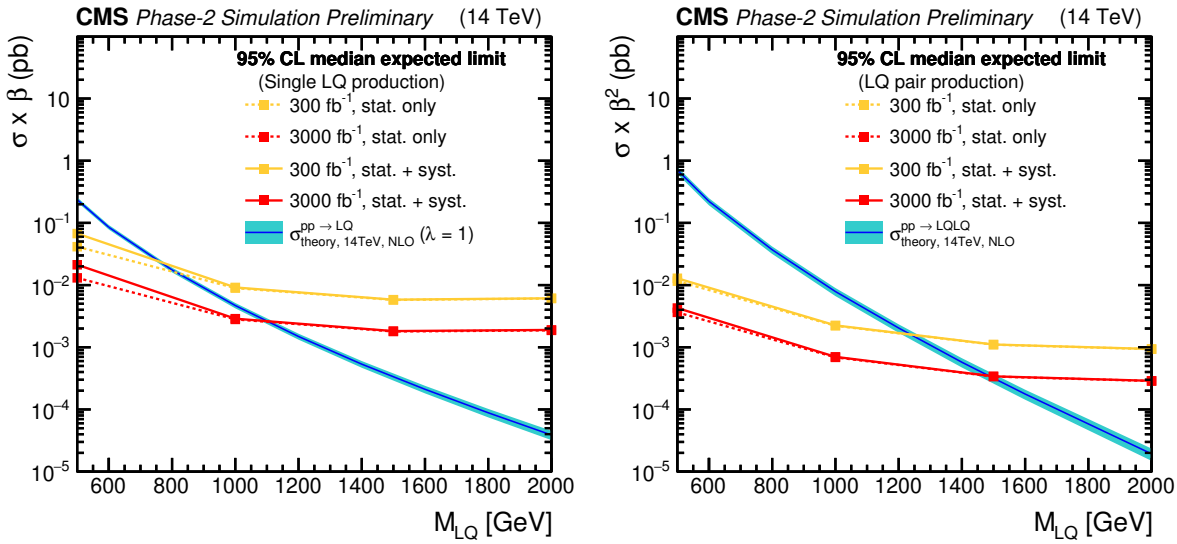

Fig. 94: Expected limits at 95% CL on the product of the cross section σ and the branching fraction β, as a function of the LQ mass, for the two high luminosity projections, 300 fb^{-1} (red) and 3000 fb^{-1} (orange), for both the stat. only (dashed lines) and the stat.+syst. scenarios (solid lines). This is shown in conjunction with the theoretical predictions at NLO [1490] in cyan. Projections are calculated for both the single LQ (left) and LQ pair production (right).

leptonic search channels, the signal shape of W' bosons with hadronically decaying tau leptons does not show a Jacobian peak structure because of the presence of two neutrinos in the final state. Despite the multi-particle final state, the decay appears as a typical two-body decay; the axis of the hadronic tau jet is back to back with $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ and the magnitude of both is comparable such that their ratio is about unity.

The results are interpreted in the context of the sequential standard model (SSM) [1515] in terms of W$'$ mass and coupling strength. A model-independent cross section limit allows interpretations in other models. The signal was simulated in LO and the detector performance simulated with DELPHES. The W$'$ boson coupling strength, $g_{\mathrm{W}'}$, is given in terms of the SM weak coupling strength $g_W = e/\sin^2\theta_W \approx 0.65$. Here, θ_W is the weak mixing angle. If the W$'$ boson is a heavier copy of the SM W boson, their coupling ratio is $g_{\mathrm{W}'}/g_W = 1$ and the SSM W$'$ boson theoretical cross sections, signal shapes, and widths apply. However, different couplings are possible. Because of the dependence of the width of a particle on its couplings the consequent effect on the transverse mass distribution, a limit can also be set on the coupling strength.

The dominant background appears in the off-shell tail of the M_T distribution of the SM W boson. Subleading background contributions arise from $t\bar{t}$ and QCD multijet events. The number of background events is reduced by the event selection. These backgrounds primarily arise as a consequence of jets misidentified as τ_h candidates and populate the lower transverse masses while the signal exhibits an excess of events at high M_T. Events with one hadronically decaying τ and $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ are selected if the ratio of p_{T}^{τ} to $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ satisfies $0.7 < p_{\mathrm{T}}^{\tau}/\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}} < 1.3$ and the angle $\Delta\phi(\vec{p_T}^{\,\tau}, \vec{p_T}_{miss})$ is greater than 2.4 radians.

The physics sensitivity is studied based on the M_T distribution in Fig. 97-right. Signal events are expected to be particularly prominent at the upper end of the M_T distribution, where the expected SM background is low. So far, there are no indications for the existence of a SSM W$'$ boson [1514]. With the high luminosity during Phase-2, the W$'$ mass reach for potential observation increases to 6.9 TeV and 6.4 TeV for 3 σ evidence and 5 σ discovery, respectively, as shown in Fig. 98-left. Alternatively, in case of no observation, one can exclude SSM W$'$ boson masses up to 7.0 TeV with 3 ab^{-1}. These are multi-bin limits taking into account the full M_T shape.

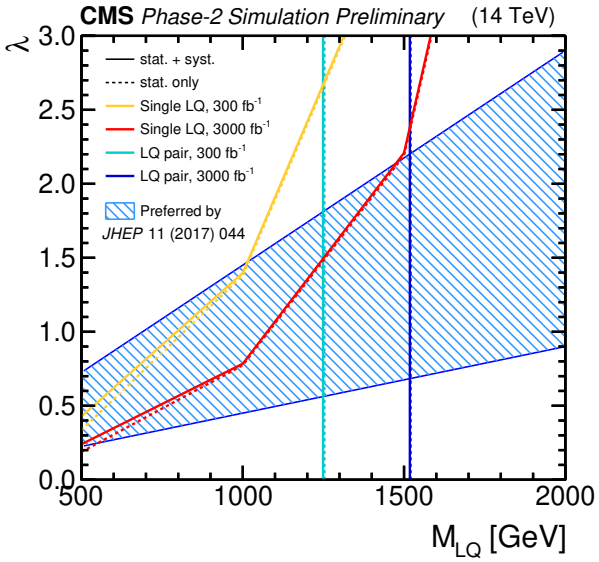

Fig. 95: Expected exclusion limits at 95% CL on the Yukawa coupling λ at the LQ-lepton-quark vertex, as a function of the LQ mass. A unit branching fraction β of the LQ to a τ lepton and a bottom quark is assumed. Future projections for 300 and 3000 fb^{-1} are shown for both the stat. only and stat.+syst. scenarios, shown as dashed and filled lines respectively, and for both the single LQ and LQ pair production, where the latter corresponds to the vertical line (since it does not depend on λ). The left hand side of the lines represents the exclusion region for each of the projections, whereas the region with diagonal blue hatching shows the parameter space preferred by one of the models proposed to explain anomalies observed in B physics [265].

While the SSM model assumes SM-like couplings of the fermions, the couplings could well be weaker if further decays occur. The HL-LHC has good sensitivity to study these couplings. The sensitivity to weaker couplings extends significantly. A model-independent cross section limit for new physics with τ+MET in the final state is depicted in Fig. 98-right, calculated as a single-bin limit by counting the number of events above a sliding threshold $M_T^{\min}$.

10.4.6 High p_T searches at HE-LHC relevant for B physics anomalies

We show next the sensitivity of the 27 TeV pp collider with 15 ab^{-1} integrated luminosity to probe pair production of the scalar and vector leptoquarks decaying to $(b\tau)$ final state. The investigated events contain either one electron or muon, one hadronically decaying tau lepton, and at least two jets. The signal events and the dominant background events ($t\bar{t}$) were generated with `MadGraph5_aMC@NLO` at leading-order. `Pythia6` was used to shower and hadronise events and `DELPHES3` was used to simulate the detector response. The scalar leptoquark (S_3) and the vector leptoquark (U_1) UFO model files were taken from [1490].

To verify the procedure, the $t\bar{t}$ background and the scalar leptoquark signal were simulated at 13 TeV and compared to the predicted shapes in the S_T distribution from the existing CMS analysis [1516]. After verifying the 13 TeV analysis, the signal and the dominant background events at 27 TeV were simulated. From these samples, all events satisfying the particle content requirements and applied the lower cut in the S_T variable were selected. The cut threshold was chosen to maximize $S/\sqrt{B}$ while requiring at least 2 expected signal events at an integrated luminosity of 15 ab^{-1}. In the case of the vector leptoquark two options were considered, the Yang-Mills ($\kappa = 1$), and the minimal coupling ($\kappa = 0$) scenario for the couplings to the gluon field strength, $\mathcal{L} \supset -ig\kappa U_{1\mu}^{\dagger} T^a U_{1\nu} G^a_{\mu\nu}$ [1490]. From the simulations of the scalar and vector leptoquark events, the ratio of the cross-sections was obtained,

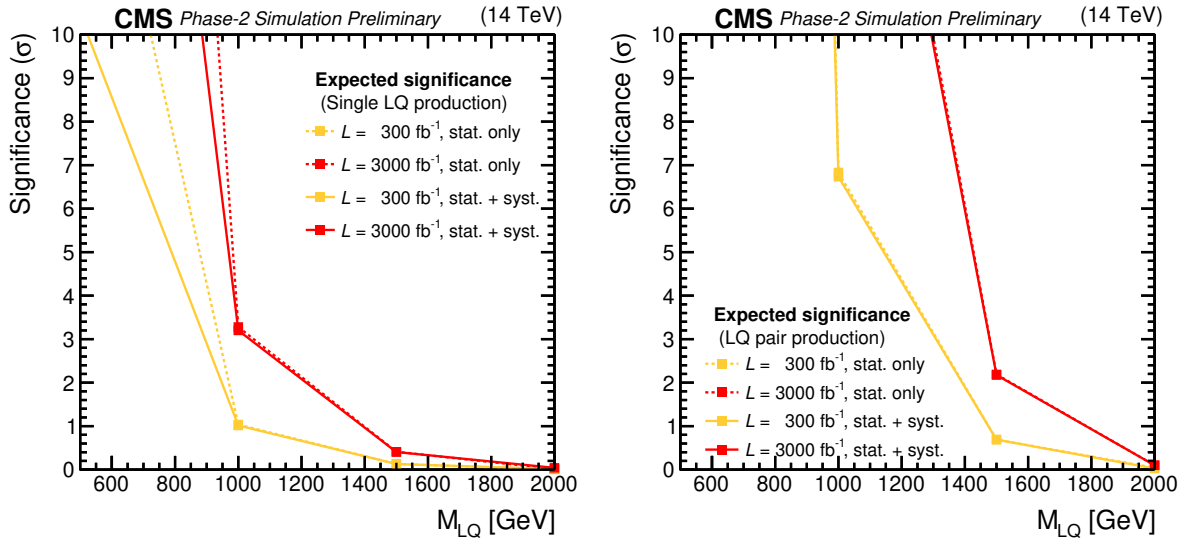

Fig. 96: Expected local significance of a signal-like excess as a function of the LQ mass, for the two high luminosity projections, 300 fb^{-1} (red) and 3000 fb^{-1} (orange), assuming the theoretical prediction for the LQ cross section at NLO [1490], calculated with $\lambda = 1$ and $\beta = 1$. Projections are calculated for both single LQ (left) and LQ pair production (right).

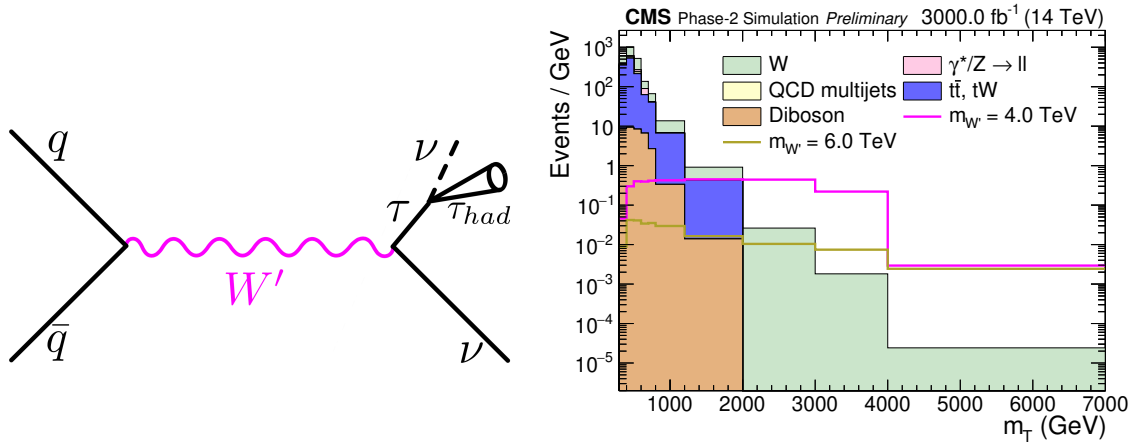

Fig. 97: Left: Illustration of the studied channel $W' \to \tau\nu$ with the subsequent hadronic decay of the tau (τ_h). Right: The discriminating variable, M_T, after all selection criteria for the HL-LHC conditions of 3 ab^{-1} and 200 PU. The relevant SM backgrounds are shown according to the labels in the legend. Signal examples for W′ boson masses of 1 TeV, 5 TeV and 6 TeV are scaled to their SSM LO cross section and 3 ab^{-1}.

and assuming similar kinematics, also the sensitivity for the vector leptoquark U_1.

As shown in Fig. 99, the HE-LHC collider will be able to probe pair produced third generation scalar leptoquark (decaying exclusively to $b\tau$ final state) up to mass of ~ 4 TeV and vector leptoquark up to ~ 4.5 TeV and ~ 5.2 TeV for the minimal coupling and Yang-Mills scenarios, respectively. While this result is obtained by a rather crude analysis, it shows the impressive reach of the future high-energy pp-collider. In particular, the HE-LHC will cut deep into the relevant perturbative parameter space for $b \to c\tau\nu$ anomaly. As a final comment, this is a rather conservative estimate of the sensitivity to leptoquark models solving $R(D^*)$ anomaly, since a dedicated single leptoquark production search is

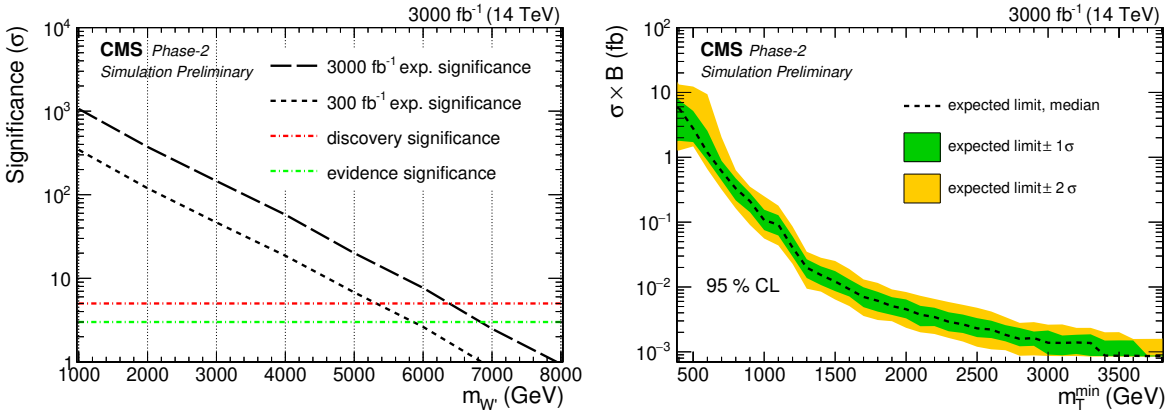

Fig. 98: Left: Discovery significance for SSM W′ to tau leptons. Right: Model-independent cross section limit. For this, a single-bin limit is calculated for increasing $M_T^{\min}$ while keeping the signal yield constant in order to avoid including any signal shape information on this limit calculation.

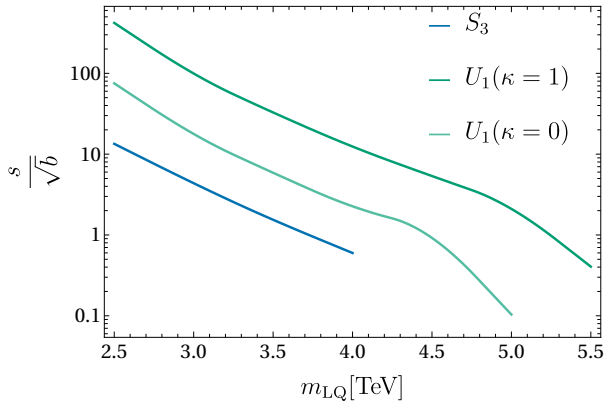

Fig. 99: Expected sensitivity for pair production of scalar (S_3) and vector (U_1) leptoquark at 27 TeV pp collider with an integrated luminosity of 15 ab^{-1}.

expected to yield even stronger bounds [265, 1490].

11 Lattice QCD in the HL/HE-LHC era

Authors (TH): Michele Della Morte, Elvira Gámiz, Enrico Lunghi.

We discuss the ten-year projections described in Sect. 2 for the lattice inputs on hadronic parameters, by presenting the current status and reviewing the main sources of uncertainty for different quantities. A naive application of Moore's law (computing power doubling each two years) would give a reduction in the errors by a factor around 3 by 2025. However, such an extrapolation is not always appropriate since the dominant uncertainties are often systematic. For this reason attempting to extrapolate even farther in the future is subject to very large uncertainties. The lattice approach is systematically improvable by construction, however in order to almost completely remove the main systematic affecting current computations one would have to extrapolate the performance of present algorithms to unexplored regions of parameters. Any such extrapolation would be quite unreliable. It is anyway reasonable to expect that by 2030 the uncertainties related to the inclusion of electromagnetic effects, where relevant, will be removed.

The last FLAG review [66], or its online version [10], still provides an almost up-to-date picture of the precision reached so far. For example, the target accuracy on f_{B_s} and the ratio f_{B_s}/f_{B_d} of about 0.4% has already been achieved. The latest $N_f = 2+1+1$ results by the FNAL/MILC Collaboration in [822] quote very similar errors for those two quantities. Electromagnetic corrections (together with the known long- and short-distance electroweak contributions) in that case are directly subtracted from the experimental decay rate quoted by PDG, such that the decay constant, which is purely a QCD quantity, is the only hadronic parameter needed for the extraction of $|V_{ub}|$ from leptonic B-decays. Alternatively, one could consider the full transition rate on the lattice, as proposed in [1517], and further discussed in [1518] concerning several subtleties arising in a straightforward application of the method to heavy-meson decays.

In addition to the inclusion of isospin breaking corrections, the most important limiting factor in the achievable precision of future lattice computations of decay constants is probably going to be the scale setting, i.e., the conversion from lattice units to MeV. This is quite obviously important for dimensionful quantities, but it is also critical for some dimensionless ones, e.g., the hadronic contribution to the anomalous magnetic moment of the muon, where one needs to convert the muon mass to lattice units (see [1519] for a detailed discussion of this point). The current precision in the knowledge of the lattice spacing is at the half-percent level. Going beyond that is challenging, as one needs a quantity which is both very well known experimentally and precisely computable on the lattice, with both small statistical as well as systematic uncertainties. Future strategies may involve combining/averaging several quantities for the scale setting. [11] On the other hand, ratios of decay constants can be obtained very precisely from lattice simulations, especially for light mesons, in which case discretization effects are not as severe as for heavy-light mesons. For example, the last calculations of the ratio of decay constants $f_{K^\pm}/f_{\pi^\pm}$ has reached a 0.15% error [822].

We turn next to the bag parameter B_K, relevant for the theoretical prediction of ε_K, which encodes indirect CP-violation in the neutral kaon system. The global estimate from FLAG for the $N_f = 2+1$ theory has a 1.3% error. Again, the error is systematic-dominated. In particular, one of the largest uncertainties comes from the conversion between the lattice renormalization scheme (e.g., Schrödinger Functional (SF) or MOM) and $\overline{\text{MS}}$. This is typically done at one-loop and to improve on that one needs either a higher order computation [12], or to follow the non-perturbative running up to as large a scale as possible. In the SF scheme, but only in the two-flavor case, the matching scale has been pushed to the elctroweak scale, where truncation errors can be safely neglected [1521]. The FLAG averages of the B_K parameter have been very stable throughout different reviews. The main reason is, at least for the

[10] `http://flag.unibe.ch/`

[11] We acknowledge S. Gottlieb and R. Van de Water for a discussion on this issue.

[12] See Ref. [1520] for recent work in this direction.

2+1 flavor setup, that the final value is dominated by a single computation from 2011 [1522]. It should therefore be possible to significantly reduce the error in the next few years. In fact, with current methods and existing configurations several collaborations can probably reach that precision.

The main hadronic uncertainty in the theoretical prediction of ε_K is currently due to long-distance contributions not captured by the short-distance parameter B_K. An approach for computing those non-perturbatively has been put forward in [1523] and preliminary results have been reported at the last Lattice conferences, with the most recent update in [1524]. Although the parameters in the lattice simulations are not physical, producing rather heavy pions (329 MeV), and only one lattice resolution with $a > 0.1$ fm has been considered, the long distance correction to ε_K is found to be rather large, amounting to about 8(5)% of the experimental value. For a more accurate estimate, the calculation is being repeated with physical kinematics and finer lattice spacings [13]. It is worth pointing out that other approaches (e.g., in [55]) produce values corresponding to a 4% contribution at most. Finally, it has been emphasized in [1525] that the theoretical estimate of ε_K based on lattice inputs strongly depends on the value of V_{cb}. Its current uncertainty, due to the tension between inclusive and exclusive determinations, represents then the largest source of systematic error.

In the B-sector, theoretical predictions of $B_q - \bar{B}_q$ mixing observables in the SM and beyond depend on hadronic matrix elements of local four-fermion operators. Historically, these matrix elements have been parametrized in terms of the so-called bag parameters. In the SM, the mass difference for a B_q^0 meson depends on a single matrix element, proportional to $f_{B_q}^2 \hat{B}_{B_q}$, or, equivalently, on a single bag parameter, $\hat{B}_{B_q}$.

There has been steady progress in the last decade in lattice determinations of these matrix elements, with errors $\sim 4 - 5\%$ for $\hat{B}_{B_q}$ [66]. However, there is still a lot of room for improvement. First of all, current calculations are not done on the last generation ensembles with $N_f = 2 + 1 + 1$, physical light-quark masses, the smallest lattice spacings, and/or the most improved lattice actions. Performing simulations on those ensembles will reduce, and in some cases eliminate, the dominant errors in B-mixing: statistics, continuum and chiral extrapolations, no inclusion of charm quarks on the sea, and heavy-quark discretization. In addition, current calculations with $N_f = 2 + 1$ flavors of sea quarks rely on effective field theories for the description of the b quark. Using a fully relativistic description instead, will further reduce the heavy-quark discretization uncertainty and will also allow more precise renormalization techniques, the other large source of uncertainty. For a particular lattice calculation, either the decay constants f_B and f_{B_s} are obtained within the same analysis in a correlated way, or external inputs are used to get the bag parameters from the extracted matrix elements. The recent and projected progress on the determination of these decay constants will thus partly contribute to the reduction in the bag parameters uncertainty.

All the improvements described above could considerably reduce the error in $\hat{B}_{B_s}$ to a 0.8% level. For the ratio of bag parameters, B_{B_s}/B_{B_d}, the error could be reduced from the current 2% to 0.5% or even less. A similar reduction can be achieved for the bag parameters describing the BSM contributions to the mixing. On-going calculations of hadronic matrix elements of NLO operators [1526] will also contribute to a substantial reduction in the uncertainty of $\Delta\Gamma_q$ in the next years.

Matrix elements describing the short-distance contribution to D-meson mixing in the SM and beyond could benefit from a similar error reduction. However, in contrast to B-mixing, D-mixing is dominated by long-distance contributions and thus reducing the error of the short-distance contribution is not so pressing.

Next we review the status and the prospects for lattice computations of form factors for a number of semileptonic decays. The vector form factor at zero momentum transfer, $f_+^{K^0\pi^-}(q^2 = 0)$, needed to extract $|V_{us}|$ from experimental measurements of $K \to \pi\ell\nu$ decay widths, is among the most accurate quantities obtained on the lattice. The most recent calculation of this form factor, not included in the last

[13] See `https://indico.fnal.gov/event/15949/session/3/contribution/151/material/slides/0.pdf`.

FLAG review, has reduced the error to 0.20% [1527], the same level as the experimental error [1528]. The main source of uncertainty on the lattice side is now statistics, which could be reduced by several lattice collaborations, both with $N_f = 2+1$ and $N_f = 2+1+1$, extending their simulations to existing and planned ensembles. Those ensembles include set of configurations with smaller lattice spacings than those that are currently being used for calculations of $f_+^{K^0\pi^-}(q^2=0)$, which will further reduce the total uncertainty. Other important sources of error on current calculations arise from the scale setting and the uncertainty in the input parameters: quark masses and ChPT low energy constants. Better determinations of those parameters, which are needed in the analyses of many observables, are underway or expected. With those improvements the error in $f_+^{K^0\pi^-}(q^2=0)$, including strong isospin-breaking corrections, will be soon enterely dominated by statistics and could achieve the 0.12% level in ten years.

The uncertainty of the experimental average $|V_{us}|f_+^{K^0\pi^-}$, 0.19%, includes errors of the estimated long-distance electromagnetic effects and the difference between strong isospin-breaking effects in charged and neutral modes. Those estimates, which use phenomenology and ChPT techniques, will become dominant sources of error in the future. There are proposals to extend the study of full leptonic transition rates to semileptonic decays [14]. Future calculations on the lattice thus should be able to not only reduce the error on the QCD form factor, but also the electromagnetic and strong isospin-breaking corrections contributing to the experimental uncertainty.

Lattice calculations are not limited to $q^2 = 0$ determination of $f_+^{K^0\pi^-}$. There exist results for the momentum depedence of both the vector and scalar form factors [1529]. The q^2 dependence of $f_+^{K\pi}(q^2)$ obtained in Ref. [1529] agrees very well with experimental data, although the determination of the constants entering in the dispersive parametrization of the energy dependence, usually adopted in experiment, is still less precise when using lattice data. However, in the future, with the improvements discussed above, lattice could provide the most precise evaluation of the phase-space integral for kaon semileptonic decays.

We discuss next three groups of b-hadron form factors of crucial phenomenological importance: heavy meson to stable pseudoscalar meson transitions, $B \to (\pi, K, D)$ and $B_s \to (K, D_s)$; heavy meson to unstable vector meson transitions, $B \to (D^*, K^*))$; and heavy baryon to baryon transitions, $\Lambda_b \to (p, \Lambda_c)$. Form factors in the first group have been calculated by several collaborations, since the presence of a stable final state particle simplifies the analysis. Form factors in the second group are complicated by the presence of an unstable final state meson. While there is a solid theoretical foundation to treat such situation on the lattice [1530], it should be noted that the huge hierarchy $\Gamma_{D^*}/M_{D^*} \sim 4\times10^{-5} \ll \Gamma_{K^*}/M_{K^*} \sim 6\times10^{-2}$ reduces the impact of the final state meson decay for the D^* case. In all cases, lattice calculations have higher accuracy for kinematical configurations in which the final state hadron has low recoil(large q^2) while experimental measurements tend to have better efficiency at large recoil (small q^2).

Moreover, it is important to stress the role of form factors parametrizations which must be used to extrapolate the lattice results at low-q^2, for example the $B \to D^{(*)}$ form factors, or when combining lattice and experimental results in order to extract CKM parameters, e.g., $|V_{cb}|$ and $|V_{ub}|$. As mentioned above, lattice and experiments present differential (binned) distributions which tend to have higher accuracy at low and high recoil, respectively. Their combination covers the whole kinematic spectrum, thus reducing drastically the sensitivity to any given form factor parametrization. In situations in which experiments and/or lattice collaborations perform one sided extrapolations, the impact of the chosen parametrization can be very large (see, for instance, the extraction of $|V_{cb}|$ from $B \to D^*\ell\nu$ discussed in Refs. [31, 32]).

The state of the art for the form factor determinations is represented by the averages in the latest FLAG review [66]. In the following we estimate the theoretical accuracy on the form factors that can

[14] See talk by Chris Sachrajda at Lattice 2018, https://indico.fnal.gov/event/15949/session/3/contribution/163

be achieved over the next eight years and their impact on the extraction of $|V_{ub}|$ and $|V_{cb}|$. As a general rule, we estimate the overall drop in uncertainty to be a factor of 3 both in its statistical and systematic components. Thus, for many calculations the total extrapolated lattice uncertainty drops below the 1% level, at which point QED effects need to be included. This can be done on the lattice either in the quenched QED limit or by explicitly generating mixed QCD-QED configurations. The inclusion of QED corrections to form factors is complicated by IR safety issues which can, nonetheless, be addressed in lattice calculations [1517]. It is likely, but not guaranteed, that QED corrections to the form factors we discuss below will be calculated in the time frame we consider. We consider two scenarios according to whether QED corrections have or have not been calculated; in the latter case we add in quadrature an extra 1% uncertainty.

- $B \to \pi$ and $|V_{ub}|$. The overall point-by-point uncertainty should reduce to the sub-percent level due the adoption of Highly Improved Staggered Quark (HISQ) for heavy quarks on the finer lattices and physical light quark masses. Currently the uncertainty on the extraction of $|V_{ub}|$ from a simultaneous fit of lattice form factors [72, 1531] and binned measurements of the semileptonic branching ratio is 3.7%. The theoretical and experimental contributions to this error can be estimated at the 2.9% and 2.3% level, respectively. A reduction of the lattice uncertainties along the lines mentioned above would naively reduce the former uncertainty to about 1%. As a cautionary note we point out that these estimates are sensitive to the information pertaining to the shape of the form factor, which is controlled by the correlation in the synthetic data and by the accuracy of future experimental results. In conclusion, the theory uncertainty on $|V_{ub}|$ is expected to decrease from 2.9% to 1% (1.4% if QED corrections are not calculated).
- $B \to K$. These form factors have been calculated in Refs. [1532, 1533]. The FLAG average of the various form factors has uncertainties on the first coefficient in the BCL z-expansion of about 2%. Future improvements can push this uncertainty to the 0.7% (1.2%) level according to the assumption on the inclusion of QED corrections.
- $B \to D$ and $|V_{cb}|$. A simultaneous fit of the lattice $B \to D$ form factor [977,978], and experimental data on the semileptonic $B \to D\ell\nu$ branching ratio yields an uncertainty on $|V_{cb}|$ at the 2.5% level. The theoretical and experimental contributions to this error can be estimated as 1.4% and 2.0%, respectively. The lattice contribution to the uncertainty is essentially controlled by the 1.5% error on the coefficients a_0^+ of the BCL z-expansion. Note that in the FLAG fit the zero-recoil value has an uncertainty of only 0.7%: $\mathcal{G}^{B\to D}(1) = 1.059(7)$. Leaving aside the issue that this uncertainty is lower than the conservative ballpark of the missing QED corrections, in order to use this very precise result one needs the corresponding zero-recoil experimental branching ratio which has an uncertainty of about 3%. Clearly the zero-recoil extraction of $|V_{cb}|$ is inferior to the simultaneous fit method. The uncertainty on the form factors is expected to drop by about a factor of 3 and to reach the 0.5% (1.1%) level. Correspondingly, the theory uncertainty on $|V_{cb}|$ is expected to decrease from 1.4% to 0.3% (1%).
- $B_s \to K$, $B_s \to D_s$ and $|V_{ub}|/|V_{cb}|$. These form factors have been calculated in Refs. [72, 1534]. The FLAG average of the various form factors has uncertainties on the first coefficient in the BCL z-expansion of about 4%. Future improvements can push this uncertainty to the 1.3% (1.7%) level according to the assumption on the inclusion of QED corrections. Very recently the authors of Ref. [1535] presented a calculation of the ratio $f_+^{(B\to K)}(0)/f_+^{(B_s\to D_s)}(0)$ with a total uncertainty of 13%, which is expected to reduce to about 4% in the time frame we consider. This would also be the expected theory uncertainty on the extraction of the CKM ratio $|V_{ub}|/|V_{cb}|$ from future measurements. Note that Ref. [1535] presents full information on the q^2 distribution of the two form factors and that once differential experimental results become available the above mentioned theory uncertainty will further decrease.
- $B \to D^*$ and $|V_{cb}|$. There are two calculations of the form factor at zero-recoil [980, 981]. The most precise one in Ref. [980] quotes an uncertainty of 1.4% on $\mathcal{F}^{B\to D^*}(1)$. This uncertainty

includes an estimate of the size of missing QED effects at the 0.5% level. Assuming a factor 3 reduction on lattice uncertainties one projects uncertainties on this form factor at the 0.4% level (the estimate increases to 0.7%, (1.1%) in case QED corrections are not calculated, and are estimated to be 0.5% (1%) in size). We should point out that the Fermilab/MILC collaboration is about to publish a calculation of the form factor at non-zero recoil. This will allow simultaneous theory/experiment fits which are expected to further reduce the uncertainty on $|V_{cb}|$.

- $B \to K^*$. The $B \to K^*$ form factors have been calculated in Refs. [1536, 1537]. These calculations are performed for a stable K^* and, as we mentioned, receive potentially large corrections from the relatively large K^* width. Currently an effort towards implementing the proper decay chain $B \to K^* \to K\pi$ along the lines described in Refs. [221, 536, 1530, 1538–1544] is undergoing. This type of calculation will remove the uncontrolled uncertainty due to the assumption of a stable final state vector meson. Unfortunately, it is too soon to present an estimate on what the expected form factor uncertainty is going to be. Once the first complete result will become available, it will be possible to estimate the expected progression in error reduction as for all the other quantities we have considered.
- $\Lambda_b \to p$, $\Lambda_b \to \Lambda_c$ and $|V_{ub}|/|V_{cb}|$. Currently there is only one calculation of these form factors [71] which allows an extraction of the ratio $|V_{ub}|/|V_{cb}|$ with a theory uncertainty of 4.9%. Over the next few years the total lattice uncertainty on these form factors is expected to reduce by a factor of 2 [1545]. We estimate the improvement over the following decade to be another factor of 2 [15]. This implies that in the time frame we are considering we expect a reduction in the theory uncertainty on $|V_{ub}|/|V_{cb}|$ to the 1.2% (1.6%) level.

An important development from the phenomenological point of view is related to the computation of long-distance effects for rare decays as $K \to \pi\ell^+\ell^-$. A lattice approach has been put forward in [1546] and exploratory results have appeared in [1547]. The extension to $b \to s$ transitions however is by no means straightforward.

In order to make it easily accessible, we collect all the information presented in this Section, including our projections for 2025, in Table 41:

- In the second and third columns we quote the current published best averages of lattice results with references.
- In the fourth column we quote the error corresponding to the published value in the second column and, in parenthesis, the error coming from a couple of recent calculations, significantly reducing current errors, but that either are not published yet ($f_+(0)^{K\to\pi}$) or are not included in the FLAG-2016 averages (decay constants). The latest will be included in the next release of the FLAG averages in 2019.
- Significant reduction of current errors in the decay constants are very unlikely, so we did not quote any numbers for these quantities.
- For semileptonic decays:
  - $X \to Y$ for $|V_{ab}|$ means the theory error in the extraction of $|V_{ab}|$ from that exclusive mode.
  - Fifth column: The two errors correspond to assuming that isospin breaking corrections are calculated by that time (first number) or that they are still estimated phenomenologically (second number in parenthesis).

[15] We thank S. Meinel for a discussion on this point.

Quantity	Published averages	Reference	error (to be published/not in FLAG-2016)	Phase I	Phase II

Table 41: Current estimates and projections for lattice QCD determinations of hadronic inputs. In the fourth column we quote the error corresponding to the published value in the second column and, in parenthesis, the error for forthcoming calculations that either are not published yet or are not included in the FLAG-2016 averages. See text for further explanations.

12 Conclusions

Flavour physics has many faces. This becomes already obvious in the Standard Model (SM), where the origin of the flavour structure are the Higgs Yukawa couplings, but which exhibits itself in the flavour non-diagonal couplings of W boson, once we rotate to the quark mass eigenbases. As a result, we can search for signs of New Physics (NP) using flavour probes in many sectors: the Higgs couplings to the SM fermions, be it deviations in the flavour diagonal Yukawa couplings or in searches for flavour violating couplings, or in the flavour changing transitions of top, bottom, charm and strange quarks or of leptons.

HL-LHC and HE-LHC experiments are set to make great strides in almost all of these probes, as exhibited in great detail in this document. The high luminosity programs at ATLAS and CMS are unmatched in their ability to push the precision frontier in measuring Higgs couplings and searching for rare top decays, at the same time expanding their flavour-physics contribution. LHCb with its planned Upgrade II can quite impressively cover a very wide range of low-energy probes in bottom, charm and strange flavor transitions.

These low-energy measurements will bloom in competition with the upgraded Belle-II super B factory, which is coming on line at this very moment. There is also large complementarity between the two programs: The LHC hadronic environment gives access to a larger set of hadronic states such as heavy baryons and a larger sample of B_s mesons. The HL/HE-LHC upgrades will push well past the benchmarks set by Belle-II for many measurements in the near future.

In turn, this complementarity is very timely, given the tantalizing hints for NP surfacing in measurements of semi-tauonic and rare semi-muonic B-decays which suggest that Lepton Universality may be broken by new dynamics in the TeV range. The flavor anomalies thus lead to a different type of complementarity, between the low-energy flavor probes and the direct searches of NP at high $p_{\rm T}$ in ATLAS and CMS. This interplay is especially prolific in the context of model building, where the anomalies can be fitted into the more ambitious BSM program. Therefore, the HL/HE-LHC programme has the potential to shape the NP to come, in case the anomalies are confirmed in the coming years.

Finally, it is important to note that the projected advancements in experiments are set to be accompanied by improvements in theory most notably in the calculations of the hadronic matrix elements by lattice QCD simulations. These matrix elements are required for the precision flavour-physics program, to convert the measurements in constraints or to lead to unambiguous discoveries of NP through the effects of their virtual corrections. In addition, the capabilities of LHCb to chart the spectrum and properties of resonances and exotic states in QCD, will lead to a better understanding of the nonperturbative phenomena. The combined improvements in the theoretical predictions, along with HL/HE-LHC experimental achievements are set to enhance the current reach on the NP physics mass scale by a factor as large as four. This represents a significant advance, with real discovery potential.

13 Acknowledgements

We would like to thank the LHC experimental Collaborations and the WLCG for their essential support. We are especially grateful for the efforts by the computing, generator and validation groups who were instrumental for the creation of large simulation samples. We thank the detector upgrade groups as well as the physics and performance groups for their input. We acknowledge support from CERN and from the national agencies: CAPES, CNPq, FAPERJ and FINEP (Brazil); MOST and NSFC (China); CNRS/IN2P3 (France); BMBF, DFG and MPG (Germany); INFN (Italy); NWO (Netherlands); MNiSW and NCN (Poland); MEN/IFA (Romania); MSHE (Russia); MinECo (Spain); SNSF and SER (Switzerland); NASU (Ukraine); STFC (United Kingdom); NSF (USA). Appendices

A Details on experimental extrapolations

A.1 Analysis methods and objects definitions

Different approaches have been used by the experiments and in theoretical prospect studies, hereafter named projections, to assess the sensitivity in searching for new physics at the HL-LHC and HE-LHC. For some of the projections, a mix of the approaches described below is used, in order to deliver the most realistic result. The total integrated luminosity for the HL-LHC dataset is assumed to be 3000 fb^{-1} at a center-of-mass energy of 14 TeV. For HE-LHC studies the dataset is assumed to be 15 ab^{-1} at a center-of-mass of 27 TeV. The effect of systematic uncertainties is taken into account based on the studies performed for the existing analyses and using common guidelines for projecting the expected improvements that are foreseen thanks to the large dataset and upgraded detectors, as described in Section A.2.

Detailed-simulations are used to assess the performance of reconstructed objects in the upgraded detectors and HL-LHC conditions, as described in Sections A.1.1,A.1.2. For some of the projections, such simulations are directly interfaced to different event generators, parton showering (PS) and hadronisation generators. Monte Carlo (MC) generated events are used for standard model (SM) and beyond-the-standard-model (BSM) processes, and are employed in the various projections to estimate the expected contributions of each process.

Extrapolations of existing results rely on the existent statistical frameworks to estimate the expected sensitivity for the HL-LHC dataset. The increased center-of-mass energy and the performance of the upgraded detectors are taken into account for most of the extrapolations using scale factors on the individual processes contributing to the signal regions. Such scale factors are derived from the expected cross sections and from detailed simulation studies.

Fast-simulations are employed for some of the projections in order to produce a large number of Monte Carlo events and estimate their reconstruction efficiency for the upgraded detectors. The upgraded CMS detector performance is taken into account encoding the expected performance of the upgraded detector in `Delphes` [374], including the effects of pile-up interactions. Theoretical contributions use `Delphes` [374] with the commonly accepted HL-LHC card corresponding to the upgraded ATLAS and CMS detectors.

Parametric-simulations are used for some of the projections to allow a full re-optimization of the analysis selections that profit from the larger available datasets. Particle-level definitions are used for electrons, photons, muons, taus, jets and missing transverse momentum. These are constructed from stable particles of the MC event record with a lifetime larger than 0.3×10^{-10} s within the observable pseudorapidity range. Jets are reconstructed using the anti-k_t algorithm [1508] implemented in the `Fastjet` [1548] library, with a radius parameter of 0.4. All stable final-state particles are used to reconstruct the jets, except the neutrinos, leptons and photons associated to W or Z boson or τ lepton decays. The effects of an upgraded ATLAS detector are taken into account by applying energy smearing, efficiencies and fake rates to generator level quantities, following parameterisations based on detector performance studies with the detailed simulations. The effect of the high pileup at the HL-LHC is incorporated by overlaying pileup jets onto the hard-scatter events. Jets from pileup are randomly selected as jets to be considered for analysis with $\sim 2\%$ efficiency, based on studies of pile-up jet rejection and current experience.

A.1.1 ATLAS and CMS performance

The expected performance of the upgraded ATLAS and CMS detectors has been studied in detail in the context of the Technical Design Reports and subsequent studies; the assumptions used for this report and a more detailed description are available in Ref. [1,1549]. For CMS, the object performance in the central region assumes a barrel calorimeter aging corresponding to an integrated luminosity of 1000 fb^{-1}.

The triggering system for both experiments will be replaced and its impact on the triggering abilities of each experiment assessed; new capabilities will be added, and, despite the more challenging conditions, most of the trigger thresholds for common objects are expected to either remain similar to the current ones or to even decrease [1550, 1551]. The inner detector is expected to be completely replaced by both experiments, notably extending its coverage to $|\eta| < 4.0$. The performance for reconstructing charged particles has been studied in detail in Ref. [168, 1552, 1553]. Electrons and photons are reconstructed from energy deposits in the electromagnetic calorimeter and information from the inner tracker [4, 1554–1556]. Several identification working points have been studied and are employed by the projection studies as most appropriate. Muons are reconstructed combining muon spectrometer and inner tracker information [436, 1557].

Jets are reconstructed by clustering energy deposits in the electromagnetic and hadronic calorimeters [1554, 1555, 1558] using the anti-k_T algorithm [1508]. B-jets are identified via b-tagging algorithms. B-tagging is performed if the jet is within the tracker acceptance ($|\eta| < 4.0$). Multivariate techniques are employed in order to identify $b-$jets and $c-$jets, and were fully re-optimized for the upgraded detectors [168, 1552]. An 70% $b-$jet efficiency working point is used, unless otherwise noted. High p_T boosted jets are reconstructed using large-radius anti-k_T jets with a distance parameter of 0.8. Various jet substructure variables are employed to identify boosted W/Z/Higgs boson and top quark jets with good discrimination against generic QCD jets.

Missing transverse energy is reconstructed following similar algorithms as employed in the current data taking. Its performance has been evaluated for standard processes, such as top pair production [1552, 1559]. The addition of new precise-timing detectors and its effect on object reconstruction has also been studied in Ref. [4, 1560], although its results are only taken into account in a small subset of the projections in this report.

A.1.2 LHCb

The LHCb upgrades are shifted with respect to those of ATLAS and CMS. A first upgrade will happen at the end of Run 2 of the LHC, to run at a luminosity five times larger ($2 \times 10^{33}\text{cm}^{-2}\text{s}^{-1}$) in LHC Run 3 compared to those in Runs 1 and 2, while maintaining or improving the current detector performance. This first upgrade phase (named Upgrade I) will be followed by by the so-called Upgrade II phase (planned at the end of Run 4) to run at an even more challenging luminosity of $\sim 2\times10^{34}\text{cm}^{-2}\text{s}^{-1}$.

The LHCb MC simulation used in this document mainly relies on the `Pythia8` generator [1561] with a specific LHCb configuration [1562], using the CTEQ6 leading-order set of parton density functions [1563]. The interaction of the generated particles with the detector, and its response, are implemented using the `Geant4` toolkit [1564, 1565], as described in Ref. [1566].

The reconstruction of jets is done using a particle flow algorithm, with the output of this clustered using the anti-kT algorithm as implemented in `Fastjet`, with a distance parameter of 0.5. Requirements are placed on the candidate jet in order to reduce the background formed by particles which are either incorrectly reconstructed or produced in additional pp interactions in the same event. Concerning the increased pile-up, different assumptions are made, but in general the effect is assumed to be similar to the one in Run 2.

A.2 Treatment of systematic uncertainties

It is a significant challenge to predict the expected systematic uncertainties of physics results at the end of HL-LHC running. It is reasonable to anticipate improvements to techniques of determining systematic uncertainties over an additional decade of data-taking. To estimate the expected performance, experts in the various physics objects and detector systems from ATLAS and CMS have looked at current limitations to systematic uncertainties in detail to determine which contributions are limited by statistics and where there are more fundamental limitations. Predictions were made taking into account the increased

integrated luminosity and expected potential gains in technique. These recommendations were then harmonized between the experiments to take advantage of a wider array of expert opinions and to allow the experiments to make sensitivity predictions on equal footing [1, 1549]. For theorists' contributions, a simplified approach is often adopted, loosely inspired by the improvements predicted by experiments.

General guide-lining principles were defined in assessing the expected systematic uncertainties. Theoretical uncertainties are assumed to be reduced by a factor of two with respect to the current knowledge, thanks to both higher-order calculation as well as reduced PDF uncertainties [1567]. All the uncertainties related to the limited number of simulated events are neglected, under the assumption that sufficiently large simulation samples will be available by the time the HL-LHC becomes operational. For all scenarios, the intrinsic statistical uncertainty in the measurement is reduced by a factor $1/\sqrt{\mathrm{L}}$, where L is the projection integrated luminosity divided by that of the reference Run 2 analysis. Systematics driven by intrinsic detector limitations are left unchanged, or revised according to detailed simulation studies of the upgraded detector. Uncertainties on methods are kept at the same value as in the latest public results available, assuming that the harsher HL-LHC conditions will be compensated by method improvements.

The uncertainty in the integrated luminosity of the data sample is expected to be reduced down to 1% by a better understanding of the calibration methods and their stability employed in its determination, and making use of the new capabilities of the upgraded detectors.

In addition to the above scenario (often referred to as "YR18 systematics uncertainties" scenario), results are often compared to the case where the current level of understanding of systematic uncertainties is assumed ("Run 2 systematic uncertainties") or to the case of statistical-only uncertainties.

Abstract

The future opportunities for high-density QCD studies with ion and proton beams at the LHC are presented. Four major scientific goals are identified: the characterisation of the macroscopic long wavelength Quark-Gluon Plasma (QGP) properties with unprecedented precision, the investigation of the microscopic parton dynamics underlying QGP properties, the development of a unified picture of particle production and QCD dynamics from small (pp) to large (nucleus–nucleus) systems, the exploration of parton densities in nuclei in a broad (x, Q^2) kinematic range and the search for the possible onset of parton saturation. In order to address these scientific goals, high-luminosity Pb–Pb and p–Pb programmes are considered as priorities for Runs 3 and 4, complemented by high-multiplicity studies in pp collisions and a short run with oxygen ions. High-luminosity runs with intermediate-mass nuclei, for example Ar or Kr, are considered as an appealing case for extending the heavy-ion programme at the LHC beyond Run 4. The potential of the High-Energy LHC to probe QCD matter with newly-available observables, at twice larger center-of-mass energies than the LHC, is investigated.

1 Introduction

Experiments with heavy-ion collisions at the LHC create and diagnose strongly-interacting matter under the most extreme conditions of high density and temperature accessible in the laboratory. Under these conditions, QCD calculations on the lattice predict that matter undergoes a phase transition to a Quark–Gluon Plasma (QGP) in which colour charges are deconfined and chiral symmetry is restored. Aside of its intrinsic interest, this line of research is central to our understanding of the Early Universe and the evolution of ultra-dense stars. In practice, the main focus of experimentation with nuclear beams at the LHC is on learning how collective phenomena and macroscopic properties, involving many degrees of freedom, emerge under extreme conditions from the microscopic laws of strong-interaction physics. In doing so, proton–nucleus (p–A) and nucleus–nucleus (A–A) collision experiments at the LHC aim at applying and extending the Standard Model of particle physics to matter properties that govern dynamically evolving systems of finite size.

Recent experiments with nuclear beams at collider energies have identified opportunities to further strengthen the connection between the rich phenomenology of ultra-dense matter, and its understanding in terms of the fundamental laws of strong-interaction physics. Two broad classes of phenomena may be highlighted in this context.

First, the observation of flow-like phenomena in essentially all measured soft particle spectra and particle correlations lends strong support to understanding bulk properties of heavy-ion collisions in terms of viscous fluid dynamics. The fluid-dynamic evolution is solely based on combining conservation laws with thermodynamic transport theories that are calculable from first principles in quantum field theory. Hence, this provides an experimentally accessible inroad to constraining QCD matter properties via soft flow, correlation and fluctuation measurements. As further explained in this document, this motivates future improved measurements of flow and transport phenomena, including in particular measurements of soft heavy flavour and electromagnetic radiation. It also motivates improved experimental control over the system-size dependence of flow phenomena to better constrain under which conditions and in which kinematic regime ultra-relativistic p–A and A–A collisions show fluid dynamic behaviour and where this picture fails.

Second, the observation of quantitatively-large quenching phenomena in essentially all measured hard hadronic observables in A–A collisions has established the feasibility of testing the produced QCD matter with a broad set of probes whose production rates are controlled with good precision with pp reference measurements and perturbative QCD calculations. Hard quarks and gluons are known to interact with the medium and they thus *probe* medium properties. As detailed in this document, important physics opportunities are related to analysing hard probes in p–A and A–A collisions with the greater precision and kinematic reach accessible in future LHC runs. For instance, the identification of (Rutherford-type) large-angle jet-medium scattering could constrain the quasi-particle nature of the fluid-like medium. This is of central importance since it critically tests the working hypothesis that the matter produced in A–A collisions is a fluid with a ratio of shear viscosity over entropy density η/s close to the theoretical minimum value. Such a fluid would be void of quasi-particles, while QCD is definitive in predicting that a microscope with sufficiently high resolution will reveal partonic (quasi-)particle structure. Identifying the scale at which inner structure (such as quasi-particles and related non-vanishing mean free paths) arises would provide a microscopic understanding of how fluid-like behaviour arises in nucleus–nucleus collisions. Therefore, probing the inner workings of the QGP by resolving its properties at shorter and shorter length scales is one of the main motivations for future experimentation with hard probes. Also at intermediate transverse momentum, this document identifies important questions that will be accessible experimentally. For instance, more differential studies of quarkonium bound-state dissociation as a function of transverse momentum, rapidity and system size are expected to yield further insights into the mechanisms of colour deconfinement and recombination. Moreover, there is the general question of how fluid-like phenomena at low momentum scales transition

to quenching phenomena at intermediate and high momentum scales.

Capitalizing on previous discoveries at RHIC, the LHC experimental programme with Pb–Pb and p–Pb collisions has significantly advanced the state of the art in both the soft- and the hard-physics sector. In the soft-physics sector, differential measurements at the LHC have in particular allowed for precise p_{T}, particle species and rapidity-dependent measurements of all higher flow harmonics v_{n}, their mode–mode couplings and the resulting reaction-plane correlations. This flow systematics extends to charmed flavoured hadrons and possibly even to beauty ones. It is at the basis of constraining QCD transport properties today. In the hard-physics sector, the wider kinematic reach of LHC has given qualitatively novel access to quarkonium suppression and jet-quenching phenomenology, including precision measurements of bottomonium, novel observations of charmonium enhancement, and a rich phenomenology of calorimetrically defined jets and jet substructure in nuclear collisions.

LHC experiments have also led to surprises that pose significant novel challenges for the understanding of p–A and A–A collisions. Most notable in this context is the discovery that flow-like phenomena are not limited to nucleus–nucleus collisions but they persist with significant magnitude in p–A collisions and in high-multiplicity pp collisions at the LHC and some of their signatures have been observed even in minimum-bias pp collisions. However, pp collisions are typically expected to show vanishingly small re-interaction rates between produced final-state particles. In contrast, the perfect-fluid paradigm, that underlies the successful phenomenology of flow-like phenomena in nucleus–nucleus collisions implicitly, assumes that re-interaction rates are so large that even the notions of quasi-particle and mean-free path become meaningless. Does the persistence of flow-like phenomena in p–A and pp collisions indicate, in contrast to previous belief, that the perfect-fluid paradigm applies to these smaller collision systems? Or, if the prefect-fluid paradigm is not applicable to pp and p–A collisions, is it conceivable that significant corrections to a fluid-dynamic picture of vanishing mean free path persist also in the larger A–A collision systems? The LHC discoveries in pp and p–A collisions that give rise to these questions provide arguably the strongest motivation for a future programme of detailed experimentation that aims at constraining microscopic structures and length-scales in the produced QGP matter and that is expected to clarify in this way the microscopic mechanisms underlying the apparent fluid-dynamic behaviour of pp, p–A and A–A collisions.

Historically, experimental heavy-ion programmes have always addressed a very diverse set of phenomenological opportunities. Some of the proposed experimental measurements have always reached out to other areas of science and could be clearly related to fundamental open question such as the origin of mass in the Universe, QCD deconfinement, or the determination of thermodynamic transport properties (that led in the past to unforeseen connections between string theory and the thermodynamics of quantum field theories). Other parts of the experimental programme were originally not related to a working hypothesis based on an open fundamental question, but they sometimes revealed themselves a posteriori as elements of crucial insight. This can be said for instance about the LHC p–A programme, that was not part of the original LHC design, that was first conceived mainly as a set of benchmark measurements for establishing the cold nuclear matter baseline for interpretation of heavy-ion data, and that has resulted in one of the most surprising discoveries made in the LHC nuclear-beams programme. We therefore emphasize that heavy-ion physics at the LHC, in the future as well as in the past, is likely to have multiple ways of reaching out and contributing to physics at large. At the time of writing this report, questions about the origin of collectivity in small pp and p–A collision systems, and their implications for the interpretation of collective phenomena observed in A–A collisions, are arguably identified as the most pressing conceptual issue in the scientific debate. As outlined so far, they are clearly related to further experimentation with soft processes, and to research on the internal structure of QGP matter utilizing hard processes. However, future experimentation at the LHC is not limited to this set of questions. From improved constraints on nuclear parton distribution functions that may inform us about the physics reach of future electron–ion facilities, to improved measurements of anti-nuclei, to ultra-peripheral colli-

sions of electromagnetic Weizsäcker-Williams photons at unprecedented field strength, to the search for qualitatively novel signatures of ultra-strong QED magnetic fields, the LHC nuclear beams programme can provide new insight in a much broader range of subject areas.

As detailed in this report, the HL/HE-LHC physics working group 5 has identified future physics opportunities for high-density QCD with ions and proton beams that can be grouped broadly into the following four goals that are coming now within experimental reach:

1. Characterizing the macroscopic long-wavelength QGP properties with unprecedented precision.
2. Accessing the microscopic parton dynamics underlying QGP properties.
3. Developing a unified picture of particle production from small (pp) to larger (p–A and A–A) systems.
4. Probing parton densities in nuclei in a broad $(x,\, Q^2)$ kinematic range and searching for the possible onset of parton saturation.

In the following, we summarize how the four general goals are addressed by the measurements discussed in this report. As the density and temperature attained in hadronic collisions changes mildly but distinctly with the centre-of-mass energy, the physics opportunities listed below can be further enhanced by a combined interpretation of future measurements at the LHC and at RHIC. In particular, new or upgraded experiments at RHIC aim at providing measurements of highly-improved quality and precision in the sectors of hard probes (jets and jet correlations, heavy flavour, quarkonia) and electromagnetic observables.

1.1 Macroscopic QGP properties

At sufficiently long wavelength, essentially all forms of matter can be described by fluid dynamics. The observation of flow-like behaviour in nucleus–nucleus collisions and in smaller collision systems demonstrates that this universal long-wavelength limit of hot and dense QCD matter can be accessed experimentally at the LHC. This provides an experimental inroad to fundamental questions about QCD thermodynamics and hydrodynamics since i) the QGP properties entering a fluid dynamic description are calculable from first principles in quantum field theory, and ii) hydrodynamic long wavelength properties depend on the effective physical degrees of freedom in the plasma and they are thus sensitive to the microscopic dynamics that governs their interactions. The following properties of the QCD matter produced in TeV-scale collisions are accessible via future measurements at the LHC

1. *Temperature*
   Within the programme of determining the QCD equation of state, QCD lattice simulations at finite temperature have established since long a precise relation between the QCD energy density and pressure that determine the fluid dynamic expansion, and the temperature of QCD matter. While energy density and pressure can be constrained experimentally by many measurements, an independent determination of temperature is of great value for testing the idea of local equilibration in heavy-ion collisions or for establishing deviations thereof. Future LHC experiments will constrain the temperature and its time evolution with unprecedented precision, in particular via thermal radiation of real and virtual (dileptons) photons (Chapter 8).
2. *QCD phase transition at* $\mu_B \simeq 0$
   Collisions at the LHC realize systems of close-to-zero baryo-chemical potential. QCD calculations on the lattice predict in this regime a smooth cross-over transition from a hot partonic plasma

to a cold hadron gas. Fluctuation measures of conserved charges are sensitive to the characteristics of the phase transition. In future LHC experiments, they are accessible with unprecedented precision and completeness (Chapter 3). Future measurements of low-mass dileptons will also be, for the first time at the TeV-scale, sensitive to in-medium modifications of the ρ-spectral function (Chapter 8). This provides unique access to the transition between phases with restored and broken chiral symmetry that is predicted by lattice QCD.

3. *Viscosity and further QCD transport coefficients*
   Existing flow measurements provide tight upper bounds on the value of η/s and they have been a cornerstone in supporting the perfect-fluid paradigm. In the future, measuring higher-order cross-correlations of flow coefficients will significantly extend this line of research. In addition, we note that the value of η/s can be related to the existence and size of the mean free path (isotropization length scale), which in turn results from the existence of (quasi-)particle-like excitations in the produced matter. This motivates increasing the precision on η/s with the aim of establishing the tightest lower bound on this quantity (Chapter 4), and it motivates detailed studies of flow in smaller systems with the idea of identifying the scale at which the system size becomes comparable to the mean free path (Chapter 9). Also, measurements of soft dileptons will give access to the electric conductivity of the strongly interacting medium (Chapter 8), and flow and correlation measurements may help to constrain the bulk viscous corrections (Chapter 4).

4. *Heavy-quark transport coefficients*
   Heavy quarks provide unique tools for testing collective phenomena in nuclear collisions. As they are produced in initial hard-scattering processes and flavour is conserved throughout the collective dynamical evolution, they are the best experimental proxy to the idea of putting coloured test charges of well-defined mass into the medium and testing how they participate in the evolution. Of particular interest are precision measurements of transverse-momentum anisotropies v_{n} and nuclear-modification factors of open heavy-flavoured mesons that are known to constrain e.g. the heavy-quark diffusion coefficient $2\pi T D_s$ and its dependence on the temperature T, that can be compared to first-principle calculations of QCD on the lattice (Chapter 5).

5. *Searching for transport phenomena related to the presence of strong electrodynamic fields.*
   Heavy-ion collisions produce the largest electromagnetic field of any system accessible to laboratory experiments. The field is largest in the early phase of the collision, thus the early-produced heavy quarks are expected to be the most sensitive to its strength (Chapter 5). As the maximal field strengths are estimated to be of the order of the pion mass ($e\,B^2 \sim m_\pi^2$), effects are also likely to be present for light-flavour charged hadrons (Chapter 4). Other measurements of interest include transport coefficients such as the electric conductivity with which the plasma responds to an electromagnetic field, and that are calculable within QCD. In addition, as a consequence of the chiral anomaly, QCD coupled to QED gives rise to *anomalous hydrodynamics* that displays various qualitatively novel phenomena, including for instance a component of the electromagnetic currents that flows parallel to the magnetic field. The existence of these anomalous phenomena follows from first principles in field theory and thermodynamics, but the size of potential experimental signatures is model-dependent. Beyond determining conventional QED transport phenomena, LHC allows to search with increased precision for these intriguing signatures of anomalous fluid dynamics (Chapter 4).

1.2 Accessing the inner workings of hot QCD matter

Previous experiments at the LHC and at lower centre-of-mass energy have established that the QCD matter produced in nucleus–nucleus collisions is subject to strong collective evolution. However, the

nature of the effective constituents of that matter, and its characteristic inner length scales (such as screening lengths or mean scattering times, if any) are not yet understood. The scale dependence of QCD implies that one must be able to resolve partonic constituents of hot QCD matter at sufficiently high resolution scale. This motivates the use of high-momentum transfer processes (hard probes) to study the inner workings of hot QCD matter. In addition, the current status of phenomenological modelling does not exclude the existence of a sizeable mean free path of hot QCD matter (which is assumed in transport model simulations of heavy-ion collisions, but which is not assumed in almost perfect fluid dynamic models). This motivates to learn about the inner workings at hot QCD matter also from particle production at intermediate transverse momentum (such as heavy quark transport at intermediate and low p_{T}). Here, we highlight the following opportunities for further experimentation.

1. *Constraining with jet quenching the colour field strength of the medium*
   In general, the fragments of jets produced in nucleus–nucleus collisions are medium-modified due to interactions with the hot QCD matter. These jet quenching effects depend on the inner structure of that matter. In particular, the average medium-induced colour field strength experienced by the escaping jet can be quantified e.g. with the quenching parameter $\hat{q}$, which measures the average exchanged transverse momentum squared per unit path length. Experiments at the LHC will provide improved constraints on this field strength measurement (Chapter 6). Qualitatively novel opportunities for testing the time evolution of the medium opacity to hard partons could arise if boosted tops could be studied in nuclear matter. A run at the LHC with lighter (than Pb) nuclei, like e.g. $^{40}\mathrm{Ar}$, would provide sufficient luminosity to this end, as well as largely enhanced kinematic and statistics reach for γ–jet and Z–jet recoil measurements (Chapter 11.1). The opportunities for boosted top measurements in Pb–Pb and lighter nuclei collisions at the HE-LHC are also discussed (Chapter 13).

2. *Investigating the quasi-particle structure of QCD matter with jet and heavy-quark measurements*
   Hard quarks and gluons with different energies can be used to investigate the constituents of the QCD matter at various resolution scales. On one side of the scale, high-energy quarks and gluons (leading to high-energy jets) address the smallest spatial scale. While $\hat{q}$ characterizes the effects of jet–medium interactions in the coherent regime in which individual constituents in the medium are not resolved, Z/γ–jet correlations and modern jet substructure measurements on the high-statistics samples of future LHC Runs are expected to access a regime of Rutherford-type large angle jet–medium scattering, in which the detection of recoil or of large angle deflections gives insight into the microscopic structure of the produced matter (Chapter 6). On the other side of the scale, the scattering of low-momentum heavy quarks, characterized using for example the diffusion coefficient, addresses the nature of the QCD constituents at long-wavelength scale (Chapter 5).

3. *Testing colour screening with bottomonium production*
   The family of bottomonium bound states gives access to a set of well-defined length scales that are embedded in the hot and dense QCD matter. As a consequence, the dissociation of the various bound states sensitively depends on the interplay of color screening and the coupling to the strongly interacting medium through dissociation reactions. This opens a unique window on the in-medium modifications of the fundamental QCD force that binds bottomonium. Increasingly-tight bound states are expected to melt with increasing temperature, providing a laboratory for in-medium spectroscopy. The increased precision of future measurements will allow to test for additional physics mechanisms in the production of bottomonium, such as regeneration processes that may affect the yield of $\Upsilon(2\mathrm{S})$ and $\Upsilon(3\mathrm{S})$. Also, the higher rates of future experiments will allow one to cross-correlate measurements of bottomonium suppression with other manifestations of collectivity, such as elliptic flow (Chapter 7).

4. *Testing colour screening and regeneration dynamics with charmonium production*
   In close similarity to bottomonium, the medium-modification of charmonium bound states is sensitive to colour screening and it is subject to the same QCD dissociation dynamics. However, since charm quarks and anti-quarks are produced abundantly in nucleus–nucleus collisions at the TeV scale, c and $\bar{\mathrm{c}}$ produced in different hard processes can form bound states. Indications of this qualitatively novel bound-state formation process are accessible at low and intermediate transverse momentum, and they motivate high-precision measurements of nuclear modification factor R_{AA} and elliptic flow v_2. In addition, future open heavy-flavour measurements reaching down to zero p_{T} with high precision will help to determine the total charm cross section which is a central input for the precise quantification of regeneration (Chapters 5 and 7).

5. *Formation of hadrons and light nuclei from a dense partonic system*
   The question of how a collective partonic system of many degrees of freedom evolves into the hadronic phase and produces colour singlet hadrons and light nuclei is essential for a complete dynamical understanding of nucleus–nucleus collisions. Recent LHC measurements in proton–proton and proton–nucleus collisions suggest that also in small-system hadronic collisions the hadronization process may be modified with respect to elementary $\mathrm{e}^+\mathrm{e}^-$ collisions. Future measurements at the LHC will enable comparative and multi-differential studies of these modifications with unprecedented precision, for both the heavy-flavour sector (D_s^+, B_s^0, charm and beauty baryons, see Chapter 5) and for light nuclei and hyper-nuclei (Chapter 3). For open heavy flavour, these measurements are also crucial to disentangle the role of mass-dependent radial flow and of recombination, as well as to constrain the parameters of hadronization in the models that are used to estimate QGP properties like the heavy-quark diffusion coefficients. For light nuclei, precise measurements of nuclei and hyper-nuclei with mass numbers 3 and 4 as well as possible observation of exotic baryonic states will address the question whether their production is dominated by coalescence of protons, neutrons and Λ baryons or by statistical hadronization of a partonic system. These measurements, in addition to that of high-momentum deuteron production, also have important astrophysical implications (dense compact stars as well as dark matter searches in the Cosmos).

1.3 Developing a unified picture of QCD collectivity across system size

As discussed at the beginning of this chapter, recent LHC discoveries of signatures of collectivity in proton–nucleus and in proton–proton collisions question common beliefs. For the smallest collision systems, these measurements indicate that more physics effects are at work in multi-particle production than traditionally assumed in the modelling of proton–proton collisions. For the larger collision systems (proton–nucleus and nucleus–nucleus collisions), they question whether the origin of signatures of collectivity is solely (perfect) fluid dynamical, given that these signatures persist in proton–proton collisions. This raises important qualitative questions like: What is the smallest length scale on which QCD displays fluid-dynamic behaviour? Is there a non-vanishing characteristic mean free path for the production of soft and intermediate p_{T} hadrons, and if so, is it smaller or larger than the proton diameter? What are the novel physics concepts with which underlying event simulations in proton–proton collisions need to be supplemented (e.g. in multi-purpose event generators) to account for the totality of observed phenomena? While some of these questions sound technical, it needs to be emphasized that the size of dissipative properties of QCD matter, such as its shear viscosity, are quantitatively related to the presence or absence of intrinsic length scales such as a mean free path. Any systematic experimental variation of the system size therefore relates directly to a search for intrinsic length scales that determine the dissipative properties of hot QCD matter. Within the present report, we identify in particular the following future opportunities for an improved understanding of the system-size dependence of collective phenomena (Chapter 9):

1. *Flow measurements in* pp *and* p–A *systems: Onset and higher-order correlations*
While flow signals have been established in smaller collision systems in recent years, their detailed characterization lacks behind the state of the art achieved in nucleus–nucleus collisions. Future measurements will allow for characterizing higher-order cumulants in largely non-flow suppressed multi-particle correlations, and test whether there is a system-size dependence in the characteristic correlations between different flow harmonics v_{n}, or the characteristic reaction plane correlations.

2. *Flow of heavy flavour and quarkonium in smaller systems*
Is there a minimal system size needed to transport heavy quarks within a common flow field? Given that the local hard production of heavy flavour is expected to be independent of any collective direction, precision measurements of heavy-flavour flow in pp and p–A collisions will provide decisive tests of heavy quark transport, thus experimentally addressing the question of how QCD flow field build up efficiently and on short length and time scales.

3. *Strangeness production as a function of system size*
One of the recent surprising LHC discoveries that is not accounted for in traditional models of minimum-bias pp collisions but that may be accounted for in a thermal picture is the smooth increase of strangeness with event multiplicity across system size. We discuss in detail how future measurement at the LHC, such as the study of strange D-mesons or baryons, can extend the systematics underlying this observation (Chapters 5 and Section 9.7).

4. *Searching for the onset/existence of energy-loss effects in small systems*
All dynamical models of collectivity involve final-state interactions. This implies the existence of jet–medium final-state interactions and, a fortiori, the existence of parton energy-loss effects. The latter have not been identified experimentally, yet. In this report, we discuss novel opportunities to test for their existence, including tests in future p–Pb collisions, as well as opportunities specific to O–O collisions.

5. *Searching for the onset/existence of thermal radiation in small systems*
If the collectivity observed in smaller collision systems is due to final-state isotropization and equilibration phenomena, it must be accompanied by thermal radiation. The search for the corresponding conceptually clean electromagnetic signatures, such as thermal dilepton and photon production in p–Pb collisions, is an important part in developing a unified picture of QCD collectivity. This report discusses the experimental opportunities in light of experimental upgrades.

1.4 Nuclear parton densities and search for non-linear QCD evolution

Future experiments at the LHC offer a variety of opportunities for precision measurements with nuclear beams. Here, we highlight three opportunities that are clearly related to the main physics challenges of the heavy-ion programme (Chapter 10):

1. *Precise determination of nuclear PDFs at high* Q^2
As high-momentum transfer processes have a short space-time scale, they are not affected by the long-wavelength particle excitations of the QCD matter in nuclear collisions. This implies that the primary production rates of hard processes in nucleus–nucleus collisions are determined perturbatively, whereas their medium modifications arise from traversing a dense QCD matter of considerable spatial extent and considerable colour-field strength. For a dynamical understanding of jet quenching, control over primary-production rates is indispensable and this necessitates the knowledge of nuclear parton distribution functions. Global nPDF-fits that reflect the current state of the art of nuclear parton distributions could be improved at the LHC in the near future at high

Q^2 and $x \sim 10^{-3}$–10^{-2} in particular with high-precision W, Z and dijets measurements in p–Pb and Pb–Pb collisions (Sections 10.3 and 10.4). High-luminosity Ar–Ar collisions would enable for the first time using top quarks to constrain nuclear PDFs at very high Q^2 and large $x \sim 10^{-2}$–10^{-1} and would contribute to constraining experimentally the nuclear mass number A dependence of nuclear PDFs.

2. *Constraining nuclear PDFs at low Q^2*
   Drell-Yan and photon measurements (Section 10.3) in p–Pb collisions could provide significantly improved constraints on the nuclear parton distribution functions at low Q^2 and low $x \sim 10^{-5}$–10^{-3}, where nuclear effects are larger. In addition, although so far global PDFs do not use measurements from ultra-peripheral collisions (UPC), it is thought that quarkonia and dijet production in UPC can constrain nuclear PDFs in the future. This report identifies opportunities for the corresponding measurements (Section 10.2).

3. *Access to non-linear QCD evolution at small-x*
   The scale-dependence of parton distribution functions is known to obey linear QCD evolution equations within a logarithmically wide range in Q^2 and $\ln x$. However, where partonic density in the incoming hadronic wave function are not perturbatively small, qualitatively novel non-linear density effects are expected to affect the QCD evolution. For Q^2 smaller than a characteristic saturation scale $Q_s^2(x)$, these effects are dominant, and as the saturation scale $Q_s^2(x)$ increases with decreasing x, one expects on general grounds at sufficiently small $\ln x$ a qualitatively novel saturation regime in which non-linear QCD evolution occurs at perturbatively large Q^2. Future measurements at LHC will provide novel test for these saturation effects with previously unexplored measurements (Section 10.3). The larger centre-of-mass energy of the HE-LHC would extend the small-x coverage by an additional factor two. Measurements of relevance include in p–Pb collisions dilepton and photon production at small-x and forward measurements of dihadron and dijet correlations. The perspectives for such measurements are discussed in Chapter 13.

1.5 Physics performance studies by ALICE, ATLAS, CMS and LHCb

The performance results presented in this report were obtained by experimental groups within the four Collaborations and they are described in more detail in these documents: ALICE [1–4], ATLAS [5–7], CMS [8–12], LHCb [13]. Two types of results are included: *simulation* studies used full or fast simulations of the detector setups for Run 3 and/or Run 4; *projection* studies are based on existing measurements where their uncertainties have been reduced as expected with the future detectors and data samples. The impact of the detector upgrades on the various observables is discussed in the corresponding chapters and in more detail in the referenced documents by the Collaborations. The integrated luminosities used for the physics studies are summarised in Chapter 12.

2 Heavy-ion performance of LHC, HL-LHC and HE-LHC

Coordinator: John M. Jowett (CERN)

Contributors: R. Bruce (CERN), M. Schaumann (CERN), M.A. Jebramcik (Johann-Wolfgang-Goethe Universität, Frankfurt & CERN)

2.1 Heavy-ion performance of LHC in Runs 1 and 2

The 2018 Pb–Pb run of the LHC brought Run 2 to an end and launched the hardware upgrades to the collider, and to the ALICE experiment, that should allow the full "HL-LHC" heavy-ion performance to be delivered from 2021 onward. Beyond pp collisions, the 2004 LHC Design Report [14], specified only Pb–Pb collisions with a peak Pb–Pb luminosity of $L = 1 \times 10^{27}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$. Now, much of the upgraded performance is already in hand. Not only has that peak Pb–Pb luminosity goal been exceeded by a factor of more than 6, but the p–Pb collision mode—an upgrade beyond the initial design whose feasibility was widely doubted—has yielded similarly high luminosity in multiple operating conditions (see Ref. [15] and references therein). Table 1 summarises the main parameters of the runs to date. Additionally, in 2017, the LHC has collided beams of Xe nuclei [16], providing many new results and demonstrating the potential for colliding lighter species. The goal for 2018 was to complete the accumulation of an integrated Pb–Pb luminosity of $1\,\mathrm{nb}^{-1}$ to each of the ALICE, ATLAS and CMS experiments and this was substantially exceeded. The LHCb experiment also received over $0.26\,\mathrm{nb}^{-1}$.

2.2 Pb–Pb luminosity in Run 3 and Run 4 (HL-LHC)

The High Luminosity LHC (HL-LHC) is an upgrade of the LHC to achieve instantaneous pp luminosities a factor of five larger than the LHC nominal value. Its operational phase is scheduled to start in LHC Run 4, in the second half of the 2020s, for the pp physics programmes described in the other chapters of this report. The HL-LHC project also includes hardware upgrades of the present LHC that will allow the LHC to operate with potential peak Pb–Pb luminosities an order of magnitude larger than the nominal [14]. These upgrades will be completed during Long Shutdown 2 and can already be exploited in Run 3, starting in 2021. Upgrades to the heavy-ion injector chain, in the framework of the LHC Injectors Upgrade project will increase the total stored intensity of heavy-ion beams and will also be completed for Run 3. Finally, the ALICE experiment will be upgraded to accept higher peak luminosity.

The heavy-ion performance of the LHC will be similar in Run 3 and in Run 4. Therefore, the two Runs are discussed together in this report in terms of their contribution to the HL-LHC heavy-ion physics programme. Presently achieved performance of the injectors [18] and collider [19] indicate that the performance parameters given in the last column of Table 1 will be achieved the upgrades planned for the LHC's Long Shutdown 2. In a typical one-month Pb–Pb run, this will yield an integrated luminosity of $3.1\,\mathrm{nb}^{-1}$. The necessary single-bunch intensities have already been attained but an implementation of slip-stacking in the SPS will be required to obtain a basic bunch spacing of 50 ns and store over 1200 Pb bunches in each LHC ring. The necessary upgrades of the SPS RF system will be implemented during LS2 and it is planned to commission this new mode of operation in 2021.

2.2.1 Secondary beams from the IPs

Ultra-peripheral electromagnetic interactions of Pb nuclei lead to copious lepton-pair production. Most of this is innocuous except for the (single) bound-free pair production (BFPP1):

$$^{208}\mathrm{Pb}^{82+} + ^{208}\mathrm{Pb}^{82+} \longrightarrow ^{208}\mathrm{Pb}^{82+} + ^{208}\mathrm{Pb}^{81+} + e^{+}, \tag{1}$$

in which the electron is bound to one nucleus. As extensively discussed in e.g. Refs. [20–22] and elsewhere, the modified nuclei emerge from the collision point, as a narrow secondary beam with modified

Table 1: Representative simplified beam parameters at the start of the highest luminosity physics fills, in conditions that lasted for $> 5\,\mathrm{days}$, in each annual Pb–Pb run (Ref. [15] and references therein). The original design values for Pb–Pb [14] collisions and future upgrade Pb–Pb goals are also shown (in this column the integrated luminosity goal is to be attained over the 4 Pb–Pb runs in the 10-year periods before and after 2020). Peak luminosities are averages for ATLAS and CMS (ALICE being levelled). The smaller luminosities delivered to LHCb from 2013–2018 are not shown. Emittance and bunch length are RMS values. The series of runs with $\sqrt{s_{\mathrm{NN}}} = 5.02\,\mathrm{TeV}$ also included pp reference runs, not shown here. Design and record achieved nucleon-pair luminosities are boxed, and some key parameters related to p–Pb parameters in Table 2 are set in red type, for easy comparison. The upgrade peak luminosity is reduced by a factor $\simeq 3$ from its potential value by levelling.

magnetic rigidity, following a dispersive trajectory that impacts on the beam screen in a superconducting magnet in the dispersion suppressor (DS) downstream. These secondary beams emerge in both directions from every interaction point (IP) where ions collide. Each carries a power of

$$\mathrm{P}_{\mathrm{BFPP}} = L\sigma_{\mathrm{BFPP}}E_b, \tag{2}$$

where L is the luminosity and $\sigma_{\mathrm{BFPP}} \simeq 276\,\mathrm{b}$ is the cross-section at the 2015/18 run energy of $E_b = 6.37Z\,\mathrm{TeV}$. These losses carry much greater power than the luminosity debris (generated by the nuclear collision cross-section of 8 b) and can quench magnets and directly limit luminosity. With a peak luminosity of $L = 6.1 \times 10^{27}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$ each secondary beam carries $\mathrm{P}_{\mathrm{BFPP}} \lesssim 120\,\mathrm{W}$, which is more than enough to quench an LHC dipole as demonstrated in 2015 [23].

To reduce the risk of quenching these magnets, orbit bumps were implemented around the impact locations in IP1 and IP5 in order to move the losses out of the dipole and into the adjacent connection

Table 2: Representative simplified beam parameters at the start of the highest luminosity physics fills, in conditions that lasted for $> 5\,\mathrm{days}$, in the one-month p–Pb runs (Ref. [15] and references therein). The very short pilot run in 2012 is not shown. The original "design" values for p–Pb [17] collisions are also shown (in this column the integrated luminosity goal was supposed to be obtained over a few runs. Peak luminosities are averages for ATLAS and CMS (ALICE being levelled). The smaller luminosities delivered to LHCb from 2013–2016 and in the minimum-bias part of the run in 2016 are not shown. Emittance and bunch length are RMS values. Single bunch parameters for these p–Pb or Pb–p runs are generally those of the Pb beam. Design and record achieved nucleon-pair luminosities are boxed, and some key parameters related to p–Pb parameters in Table 1 are set in red type, for easy comparison.

cryostat ("missing dipole" in the DS) that does not contain a superconducting magnet coil and therefore is less likely to quench. This technique was first used in 2015. It was almost fully proved in 2018 when the ATLAS and CMS Pb–Pb luminosities were sustained at values very close to the nominal levelling values for Runs 3 and 4. Beam-loss monitor thresholds were set, based on the measured quench level in 2015 and it was clear that there was sufficient margin for still higher luminosity. In IP2, the method of orbit bumps alone is not applicable with present optics and layout. It is therefore foreseen to install an additional collimator in the connection cryostat on the outgoing beam on each side of IP2. In combination with this, orbit bumps will then be deployed to steer the BFPP beams onto the collimators. The installation will take place in LS2 in order to allow the HL-LHC design luminosity for ALICE (corresponding to a hadronic event rate of 50 kHz) in subsequent runs.

2.2.2 Collimation and intensity limit

While the LHC stores unprecedented beam energies, superconducting magnets are needed to bend and focus these beams, most of which are operated at 1.9 K. A loss of a tiny fraction of the beam is enough to induce a magnet quench, and it is therefore vital to avoid any uncontrolled beam losses. To safely intercept losses and provide protection of the magnets, the LHC uses a multi-stage collimation system [24–27]. During the first two runs of the LHC, this system has shown a very good performance with proton beams [28–31] and ion beams [32, 33].

LHC collimation is much less efficient with heavy-ion beams than with protons, since ions have a high cross section for undergoing nuclear fragmentation inside the primary collimators [34]. The angular offsets of the out-scattered fragments are frequently not large enough to reach the secondary collimators in the straight collimation insertion (IR7). At the same time these fragments have a magnetic rigidity different from the main beam, so that they risk being lost where the dispersion starts to rise in the first few dipoles of the DS. This was the most critical beam loss location during the Pb ion runs in Run 1 and Run 2, with a local cleaning inefficiency of about a factor 100 worse than for protons [32, 33]. Therefore, even though the total stored beam energy is about a factor 10 lower with Pb ions than with protons, collimation of heavy ions is critical. Still, ion collimation has worked well in the LHC and did not introduce operational bottlenecks so far. However, extrapolations of the losses in the DS from a 2015 experimental tests to Run 3 and HL-LHC show that, if nothing is done, the total stored Pb beam energy is limited to around 10 MJ, if drops of the instantaneous beam lifetime down to 12 minutes are assumed [35]. At the same time, it is foreseen to increase the stored Pb beam energy to about 24 MJ. To alleviate this limitation and safely intercept the losses, it is planned to install additional collimators, called TCLDs, in the dispersion suppressors [36–38]. On the other hand, the LHC was successfully operated with Pb beams containing over 13.5 MJ each in 2018 thanks to good control of beam lifetimes. In order to make space for the TCLDs, standard 8.3 T LHC dipoles will be replaced by an assembly consisting of two shorter higher-field 11 T dipoles with the TCLD in between [38]. The solution that gives the best simulated Pb cleaning efficiency uses two TCLDs per side of IR7. However, this is not possible within tight constraints of long shutdown 2 and the HL-LHC project, and the baseline is therefore to install one TCLD per side. If this turns out to be a real limitation, it could be considered at a later stage to install a second TCLD. As an alternative and complementary alleviation method, it is under study whether crystal collimation could help in reducing the losses in the DS. In this collimation scheme, bent crystals are used instead of the standard LHC primary collimators [39]. Incoming beam particles follow the curvature of the crystal planes, the so-called channelling, and exit with a significant angular kick. They can then be efficiently steered onto an absorber. Nuclear interactions inside the the channels of well-aligned crystals are significantly suppressed. Initial experiments using an LHC test installation [40] have shown very promising results with Xe and proton beams [41]. Channelling has very recently also been observed with Pb beams in 2018 and potential improvements of the collimation system are presently being assessed experimentally. Studies with Pb beams are not yet conclusive but it is hoped that this will be further clarified by analysis of data taken during the 2018 Pb ion run.

Collimation of lighter ion species has not yet been studied in detail, although some first simulations are presented in Ref. [32]. Results for Ar and Xe beams show that the amount of expected losses in the DS is similar to Pb but the longitudinal loss distribution changes. The fractional change in magnetic rigidity for every lost nucleon in the collimators is larger for light ions, and it is hence expected that out-scattered fragments have larger effective energy deviations and are lost more upstream. It is thus likely that the TCLD should help significantly also for lighter ions, although comparative studies on intensity limits for different ion species still remain to be done.

2.3 Proton-lead operation in Run 3 and HL-LHC

Within colliding nuclei, with charges Z_1, Z_2 and nucleon numbers A_1, A_2, in rings with magnetic field set for protons of momentum p_p[1], the colliding nucleon pairs will have an average centre-of-mass energy

$$\sqrt{s_{\mathrm{NN}}} \approx 2c\,p_p\sqrt{\frac{Z_1 Z_2}{A_1 A_2}} \approx 2c\,p_p \begin{cases} 1 & \mathrm{pp} \\ 0.628 & \mathrm{p\text{–}Pb} \\ 0.394 & \mathrm{Pb\text{–}Pb} \end{cases} \tag{3}$$

[1] Conditions imposed by the two-in-one magnet design of the LHC.

and a central rapidity shift in the direction of the (Z_1, A_1) beam

$$y_{\text{NN}} \approx \frac{1}{2}\log\left(\frac{Z_1 A_2}{A_1 Z_2}\right) \approx \begin{cases} 0 & \text{pp, Pb–Pb} \\ 0.465 & \text{p–Pb} \\ -0.465 & \text{Pb–p} \end{cases} . \tag{4}$$

We present parameters for operation at the nominal LHC momentum $p_p c = 7\,\text{TeV}$ extrapolating from the experience of the last p–Pb run in 2016.

The injection and ramp of protons and lead ions with equal magnetic rigidity leads to moving long-range beam-beam encounters in the four interaction regions of the LHC. These beam-beam encounters were one of the reasons why the feasibility of p–Pb operation in the LHC was initially questioned. This effect has been proven small in the LHC and calculations have this will remain true for the HL-LHC era despite larger bunch numbers and higher proton bunch intensities. The dynamic range of the interlock strip-line BPMs, common for the lead and proton beam, limited the proton intensity to $N_b < 5 \times 10^{10}$ protons per bunch during Run 1. Gating the stripline BPM read-out appropriately removed this constraint a few days before the end of the 2016 run. The higher proton intensity of $N_b = 2.8 \times 10^{10}$ protons per bunch resulted in increased luminosities at the IPs but also led to the substantial deposition of collision debris from the Pb beam in the dispersion suppressors at ATLAS and CMS risking a beam dump [42]. The collision debris collimators (TCLs), which could have intercepted emerging fragments from the IPs, were not commissioned at tighter settings for the 2016 p–Pb run. Appropriate TCL settings are expected to neutralise these fragments and should allow for higher peak luminosities in the future.

A potential p–Pb run during Run 3 and beyond will greatly benefit from the longitudinal slip stacking in the SPS and the small $\beta^* = 0.5\,\text{m}$ in three experiments. The proton intensity cannot be pushed to values much larger than the maximum achieved in 2016 as bunches colliding in multiple IPs and especially in ATLAS and CMS will approach the interlock BPM threshold of 2×10^9 charges per bunch too quickly if the luminosities of ATLAS and CMS are not levelled. This would lead to an undesirable early beam dumps while ALICE is still levelled. In order to predict the potential performance of a future p–Pb run, the expected Pb–Pb filling pattern [19] is used providing 1136 collisions in ATLAS/CMS, 1120 collisions in ALICE and 81 collisions in LHCb. This approximation is made since the proton injection should be flexible enough to reproduce most of the respective Pb pattern. This calculations assumes $N_b = 3 \times 10^{10}$ protons per bunch and ALICE being levelled to the instantaneous luminosity of $L_{\text{AA}} = 5 \times 10^{29}\,\text{cm}^{-2}\text{s}^{-1}$. $L_{\text{AA}} = 5 \times 10^{29}\,\text{cm}^{-2}\text{s}^{-1}$ ATLAS and CMS are not luminosity levelled in this scenario since the loss of integrated luminosity for ATLAS and CMS outweighs the marginal gain for ALICE. A simulation of the beam evolution based on ordinary differential equations including intra-beam scattering and radiation damping leads to a luminosity evolution in the different IPs as displayed in Fig. 1.

At around 6.1 h, the bunch intensity of the bunches colliding in ATLAS, ALICE and CMS drop below the interlock BPM threshold ultimately limiting the fill length, even though the potential levelling time for ALICE has not been reached. Detailed engineering of the filling scheme might avoid this. Key results from the beam evolution study are listed in Tab. 3. The expected peak luminosity in ATLAS and CMS is at around $L_{\text{AA}} = 17.4 \times 10^{29}\,\text{cm}^{-2}\text{s}^{-1}$, i.e., roughly a factor 2 larger than in 2016. The integrated luminosity in ATLAS and CMS are expected to approach $0.7\,\text{pb}^{-1}$ outperforming the 2016 integrated luminosity by a rough factor 3.5. Since the nominal HL-LHC normalised proton emittance of $\epsilon_N = 2.5\,\mu\text{m}$ is assumed, the actual performance may exceed these predictions since normalised proton emittances in the range of $\epsilon_N = 1.3\,\mu\text{m}$ have already been achieved.

2.4 Colliding lighter nuclei at HL-LHC

The bunch intensity limits in the injectors depend largely on the ion charge which changes at the various stripping stages which must be optimised for space-charge limits, intra-beam scattering, efficiency of

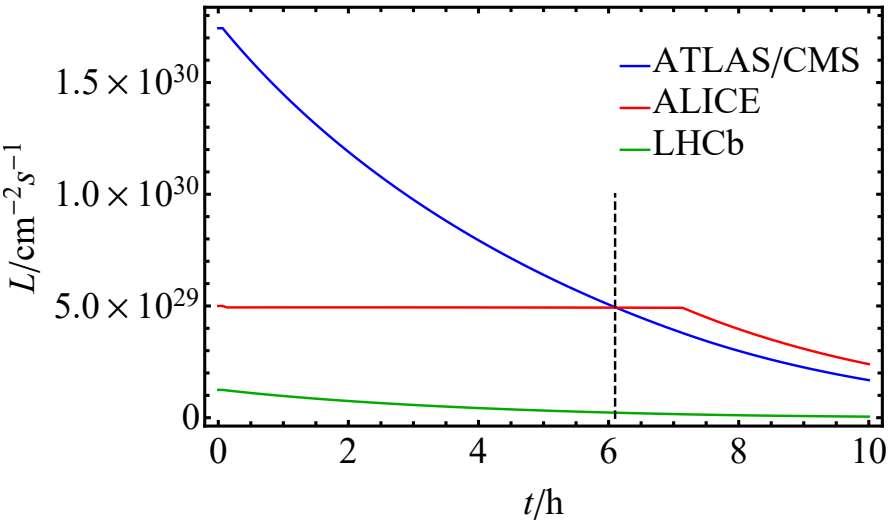

Fig. 1: Evolution of the instantaneous luminosity in the LHC experiments during a p-Pb fill. At around 6.1 h (dashed line), the interlock BPM threshold is reached for some bunches, limiting the fill length.

Table 3: Key parameters and results of the p–Pb beam evolution calculation. A turn-around time, i.e., the time between Beam Dump and Stable Beams, of 3 h and an operational efficiency factor of 0.5 is assumed. The final result was scaled down by additional 5 % to take potential deviations of the proton filling pattern into account. The time the first bunches need to reach the interlock BPM threshold is used as the fill time.

Species	p	Pb

electron-cooling, beam losses on residual gas and other effects in the ion source, Linac4, LEIR, the PS and SPS. Given the uncertainties, the deliverable intensity for other species can only be determined after sufficient time spend commissioning and empirically optimising the many parameters and operating modes of the whole injector chain. To simplify present considerations, we postulate a simple form relating the number of ions per bunch, N_b, to the well-established value (N_b(82,208)=1.9×10^8) for Pb beams

$$N_b(Z,A) = N_b(82,208)\left(\frac{Z}{82}\right)^{-p} \tag{5}$$

Fitting such an expression to the limited information [43] from the few species used for SPS fixed-target in recent years (since the commissioning of the present ECR ion source and LEIR) yields a value of the fit parameter $p = 1.9$. Beam quality requirements for fixed-target beams are, of course, less stringent than for injection into the collider. Fitting to the first commissioning of Xe beams for the LHC [16], on the other hand, gives a much less optimistic $p = 0.75$. Although this was the only occasion where any other species than Pb was delivered to the collider, only the simplest version of the injection scheme was used and it is clear that, given time, significantly higher intensities could be achieved. We consider that $1.5 \leq p \leq 1.9$ corresponds to a representative range of possibilities that could be realised in fully-prepared future operation.

In addition, we make a number of simplifying assumptions to allow a simplified, yet meaningful, comparison between species

- The *geometric* transverse beam emittances at the start of collisions will be equal to those of Pb beams [19]. This is justified, at least at the level of the LHC, since the scaling of intra-beam scattering with N_b, Z and A, given by the parameter f_{IBS}/(m Hz) is generally smaller than for Pb as long as $p \lesssim 1.9$. A similar scaling should hold in the injectors such as the SPS where intra-beam scattering may also blow up the emittances. This ignores possible space-charge limits in the injectors which should also be considered once the appropriate stripping schemes and charge states have been defined.
- Same filling scheme and number of bunches.
- No luminosity-levelling in any experiment.
- Fill length optimised for intensity evolution dominated by luminosity burn-off.
- Equal operational efficiency of 50%. Following conventional practice for HL-LHC, the integrated luminosity for a 1-month run is estimated assuming back-to-back ideal fills of optimal length and a turn-around time of 2.5 h between the end of one fill and the resumption of "Stable Beams" for collisions in the next. The operational efficiency factor is then applied as a way of taking into account the time needed for commissioning, intensity ramp-up, faults and other non-availability of LHC and injector systems.

The parameters are estimated using analytical approximations unlike the more elaborate simulations used in Section 2.2. Together with the assumption that there is no luminosity levelling, these lead to a higher estimate of integrated luminosity in a one-month run. Nevertheless they can be used as a guide to the relative gain factors in integrated nucleon-nucleon luminosity by changing from Pb to a lighter nucleus.

2.5 Short run for O–O and p–O

As discussed in Section 11.3, a short p–O collision run is of interest for cosmic-ray physics. If O beams were available from the injectors, this could be combined with a short, low-luminosity, O–O run, which would be of value for the main high-density QCD programme. Limiting the beams to low-intensities would allow a rapid set-up in LHC on the successful model of the 2012 p–Pb run which was later re-used in the 2017 Xe–Xe run [16]. Each of those runs took about 16 h of LHC operation time, including set-up and physics data-taking but a combination O–O/p–O run could take a few days.

Because oxygen is used as the carrier gas in the CERN heavy-ion source, the idea has been mooted that it may be possible to switch from Pb to $^{16}O^{8+}$ beams for the LHC, and back, somewhat more rapidly than other species. Commissioning of the O beam in the injectors for single-bunch injection into the LHC would need to be scheduled, in parallel with pp operation, and use of the injectors for other programmes, in the period preceding the O–O/p–O run. The possibilities are under study and include either inserting the run at the end of one of the annual Pb–Pb runs or scheduling it earlier in the year in order to provide time for the source to be switched back to Pb operation afterwards.

2.6 Heavy-ion performance of HE-LHC

Heavy-ion operation of HE-LHC awaits a fully detailed study. First results were presented in [44]. Since the HE-LHC would occupy the same tunnel as the LHC, one can, for the moment, assume the same injected beams as HL-LHC. Future possible upgrades to the injectors might improve this. The total integrated luminosity obtainable per fill, summed over all experiments, is bounded by the total intensity divided by the burn-off cross-section and will therefore be similar to the HL-LHC. The same can be said for time taken to inject a fill. Only a modest increase in integrated luminosity, given by somewhat shorter times spent in collision and, most likely, a reduction in the number of experiments, can be envisaged. For purposes of this report, we estimate that the integrated luminosity obtained by each of two experiments in a one-month run will be of order $6\,\mathrm{nb}^{-1}$. However, the BFPP power with Pb–Pb collisions will be very high and this could be a strong argument for running with somewhat lighter species. In that case, one can expect the luminosity to scale similarly to HL-LHC in Sect. 2.4.

3.1 Introduction

The analysis of the data collected at the LHC during Run 1 and Run 2 has consolidated our understanding of a standard model for the production of light-flavour hadrons (containing u, d and s quarks) in heavy-ion collisions: particle chemistry (described by integrated particle yields) is well described by the thermal-statistical model [45, 46] and kinetic equilibrium (reflected in the p_{T}-dependence of particle production) is well described by a common radial expansion governed by hydrodynamics [47, 48]. While the physics of light-flavour particles is often perceived as not statistics hungry, the unprecedented large integrated luminosities expected in Run 3 and Run 4 at the LHC offer a unique physics potential. Despite containing only u, d and s valence quarks, light (anti-)(hyper-)nuclei are very rarely produced because of their composite nature and very large mass. Their study will enormously profit from the significant increase in luminosity for heavy-ion collisions expected in the years 2021 until 2029. The same holds true for the study of event-by-event fluctuations of the produced particles, which is closely linked to the production of light (anti-)(hyper-)nuclei in the scenario of a common chemical freeze-out determining light-flavour hadrons and (hyper-)nuclei abundances. If, as indicated by the recent experimental findings [46], the thermal-statistical approach is the correct model to describe (anti-)(hyper-)nuclei production, the chemical freeze-out temperature is most precisely determined by measurements of light (anti-)(hyper-)nuclei as they are not subject to feed-down corrections from strong decays [45]. This is the same temperature at which event-by-event fluctuations of conserved quantities are compared to lattice QCD (lQCD). The physics of light (anti-)(hyper-)nuclei and exotic multi-quark states together with the related observables that will become experimentally accessible in Pb–Pb collisions at the LHC Runs 3 and 4 are discussed in Sec. 3.2. In Sec. 3.3, measurements of fluctuations of particle production and conserved charges are discussed as they give experimental access to fundamental properties of the QCD phase transition at μ_{B} and allow for direct comparison with lQCD calculations.
In small collision systems (pp, p–Pb), measurements of light-flavour hadrons provide fundamental input to the study of particle production mechanisms and collectivity across systems, as discussed in Ch. 9. At the same time, the physics programme with pp and p–Pb collisions in Runs 3 and 4 will open the possibility for system-size dependent studies of (anti-)nuclei production and for precision measurements of the hyperon-nucleon potentials. The physics case for these measurements in small colliding systems is motivated in this chapter in Sec. 3.2.6, as well as the implications of the findings at the LHC for astrophysics and searches for dark matter in space-based experiments.

3.2 (Anti-)(hyper-)nuclei production

3.2.1 Testing thermal production and nucleon coalescence models

The production of light (hyper-)nuclei and their anti-matter counterparts is modeled within the scenarios of thermal-statistical hadronisation and nucleon coalescence. In the thermal-statistical approach [45, 49], particles are produced from a fireball in thermal equilibrium with temperatures of the order of $T_{\rm chem} \approx 156$ MeV that are near the temperature of the QCD phase transition boundary, as predicted by lQCD calculations [50, 51]. The yields of the produced objects depend on the chemical freeze-out temperature $T_{\rm chem}$ (when inelastic collisions cease) and the mass m of the object, and approximately scale as $\mathrm{d}N/\mathrm{d}y \propto \exp(-m/T_{\rm chem})$. Thermal-statistical models have been successful in describing light-flavour particle production across a wide range of energies in nucleus-nucleus collisions [45, 46]. Due to their large mass, light (anti-)(hyper-)nuclei are particularly sensitive to $T_{\rm chem}$ and since they are not affected by feed-down from higher mass states [45], the measurement of their production constitutes a precision test for the thermal model.

In the coalescence scenario, composite objects are formed at kinetic freeze-out by coalescence of nucleons that are close in configuration and momentum space [52–57]. Calculations of the coalescence probability based on a density matrix approach [57] require the knowledge of the nucleus wave function and identify the volume of the particle source as the homogeneity volume that can be extracted via Hanbury-Brown–Twiss interferometry [58]. The size of the (hyper-)nucleus is identified with the size parameter of its wave-function, which is related to the (measurable) rms of the charge distribution by simple relations [55, 59].

While there are several theory groups working on the calculation of the expected coalescence [57, 60–63] and thermal production rates [49,64,65], predictions reported in Fig. 2 rely on the study presented in [59], which contrasts the two production scenarios. In order to distinguish them, a measurement of the coalescence parameter for (anti-)(hyper-)nuclei that differ by mass, spin and size as a function of source volume (or source radius) is proposed. The coalescence parameter $B_{\rm A}$ is defined as

$$E_A \frac{\mathrm{d}^3 N_A}{\mathrm{d}p_A^3} = B_A \left(E_{\rm p,n} \frac{\mathrm{d}^3 N_{\rm p,n}}{\mathrm{d}p_{\rm p,n}^3} \right)^A \Bigg|_{\vec{p}_{\rm p}=\vec{p}_{\rm n}=\frac{\vec{p}_A}{A}} , \tag{6}$$

where $p_{\rm p,n}$ are the momenta of the proton and neutron and $E_{p,n}$ their energies. In the coalescence model (black curves in top panels of Fig. 2), the coalescence parameter is determined analytically. The thermal model predicts $p_{\rm T}$-independent particle yields at a given $T_{\rm chem}$, therefore a Blast-Wave (BW) model is used in [59] to describe the $p_{\rm T}$-dependence of (hyper-)nuclei and nucleon production. With the $p_{\rm T}$ spectra of (hyper-)nuclei and protons obtained in this way, Eq. 6 is used to extract $B_{\rm A}$ (dashed blue curve in top panels of Fig. 2). Similarly, the coalescence parameter is obtained experimentally from Eq. 6 using the measured (hyper-)nucleus and proton $p_{\rm T}$ distributions as input. It is considered that for BW, little energy dependence of the fit parameters is observed in Pb–Pb collisions from $\sqrt{s_{\rm NN}}$ = 2.76 to 5.02 TeV. The thermal model yields only depend on temperature and no collision energy dependence of the temperature is expected in the LHC energy range. The size of the source can be sampled by means of multiplicity- and centrality-differential measurements.

The particle with the strongest sensitivity to the production mechanism appears to be the hypertriton (a pΛn bound state) with its large charge rms radius of about 10 fm, for which the coalescence and the thermal model predictions differ by up to three orders of magnitude as a function of the source radius. While the hypertriton seems to be largely suppressed with respect to ^{3}He (pnn), the $^4_\Lambda$H (ppΛn) is predicted to have only a slightly lower coalescence probability with respect to ^{4}He (ppnn). Moreover, for small R, i.e. in small systems as those formed in pp and p–Pb collisions, $^3_\Lambda$H is predicted by coalescence to be suppressed by about a factor of 100 with respect to ^{3}He. These considerations motivate systematic multi-differential measurements of A = 3 and A = 4 nuclei and hyper-nuclei as a function of

multiplicity and from small (pp, p–Pb) to large systems (Pb–Pb) to test the validity of the coalescence picture as opposed to thermal production.

With an integrated luminosity $L_{\rm int}$ = 10 $\rm nb^{-1}$ in Pb–Pb collisions in Runs 3 and 4, $B_{\rm A}$ for ^{3}He, $^3_\Lambda$H and ^{4}He can be measured in ALICE in up to ten centrality classes with a statistical precision lower than 5%, 10% and 20%, respectively. The projected relative statistical uncertainties on $B_{\rm A}$ ($\sigma_{\rm stat}/B_{\rm A}$) for (hyper-)nuclei with A > 2 are reported in the central row of panels of Fig. 2. These uncertainties have been estimated by scaling the significance of the nuclei and hyper-nuclei spectra measurements in Pb–Pb collisions at $\sqrt{s_{\rm NN}}$ = 5.02 TeV [66, 67] to the expected integrated luminosity of Runs 3 and 4 and assuming thermal production for the states with A = 4. The uncertainties on the proton spectra are negligible already in the existing measurements.

The experimental discrimination power between the models has been extracted as $(B_{\rm A}^{therm} - B_{\rm A}^{coal})/\sigma$, where $\sigma = \sqrt{\sigma_{\rm stat}^2 + \sigma_{\rm sys}^2}$, and is reported in the lower panels of Fig. 2. Relative systematic uncertainties $\sigma_{\rm sys}/B_{\rm A}$ = 10% and 20% have been considered, to be compared with a typical 15% uncertainty of the Run 1 and 2 measurements. Measurements of $^3_\Lambda$H allow for a 10σ discrimination between models, even in a pessimistic scenario in all centralities. The discrimination power rises above the 10σ level for ^{4}He in semi-central and peripheral collisions.

3.2.2 *Light (anti-)(hyper-)nuclei observables in Runs 3 and 4*

Measurements of (anti-)(hyper-)nuclei and exotic QCD bound states require large event samples collected with a minimum-bias trigger, as well as high tracking precision for the separation of secondary vertices and charged-hadron (light nucleus) identification. The upgraded ALICE detector after LS2 [3, 68–70] fulfills these requirements, developing further the potential already explored in Runs 1 and 2. The yields of (hyper-)nuclei (d, ^{3}He, ^{4}He, $^3_\Lambda$H, $^4_\Lambda$H, $^4_\Lambda$He) and their anti-particles in Pb–Pb collisions at the LHC in Runs 3 and 4 have been estimated for measurements with ALICE. The detectable yield and significance for (anti-)(hyper-)nuclei have been estimated for 0–10% central Pb–Pb collisions considering the acceptance and detection efficiency in the nominal magnetic field of the ALICE detector (B = 0.5 T). These projections are reported for anti-particles in Fig. 3 as a function of the minimum-bias integrated luminosity. The detectable particle and anti-particle yields are equivalent in the considered $p_{\rm T}$ range. All projections have been extracted in the $2 < p_{\rm T} < 10$ GeV/c range, where the lower limit is given by the $p_{\rm T}$ down to which nuclei with A $\geq$ 3 can be reconstructed without ambiguity in ALICE. In a scenario in which ALICE will take data with a central-barrel low-field configuration (B = 0.2 T), it will be possible to extend the low-$p_{\rm T}$ limit for (anti-)nuclei identification down to 1 GeV/c, increasing the expected number of detectable light (anti-)(hyper-)nuclei (by about 20% for ^{3}He). In Fig. 3, the bands indicate the uncertainty on the yield (significance) associated with different model predictions: the central line is obtained assuming statistical-thermal production with $T_{\rm chem}$ = 156 MeV [49], the upper line is the yield (significance) assuming thermal production at $T_{\rm chem}$ = 158 MeV, and the lower one using for the yields the expectation from coalescence (see Sec. 3.2.1). The arrow represents the recorded luminosity at the end of the LHC Run 2. It has to be noted that for this study, the geometry of the ALICE Inner Tracking System (ITS) in Run 2 has been considered. The new geometry and acceptance of the upgraded ITS system [3] are expected to increase the detection efficiency by up to 20%.

The expected yield per unit of rapidity at mid-rapidity are reported for $\overline{\rm d}$, $^3\overline{\rm He}$ and $^4\overline{\rm He}$ in left panel of Fig. 3. With $L_{\rm int}$ = 10 $\rm nb^{-1}$ recorded with the nominal magnetic field, a measurement of the elliptic flow (v_2) of ^{3}He and ^{3}H (and anti-nuclei) in Pb–Pb collisions will become feasible with ALICE with a statistical precision better than 5% in the 2–10 GeV/c transverse momentum range in at least eight centrality intervals. Elliptic flow measurements for anti-nuclei provide a powerful independent test of coalescence scenarios as already demonstrated with deuterons [71] and might provide an indirect assessment of the neutron flow comparing the ^{3}He and ^{3}H results. In addition, the large data sample

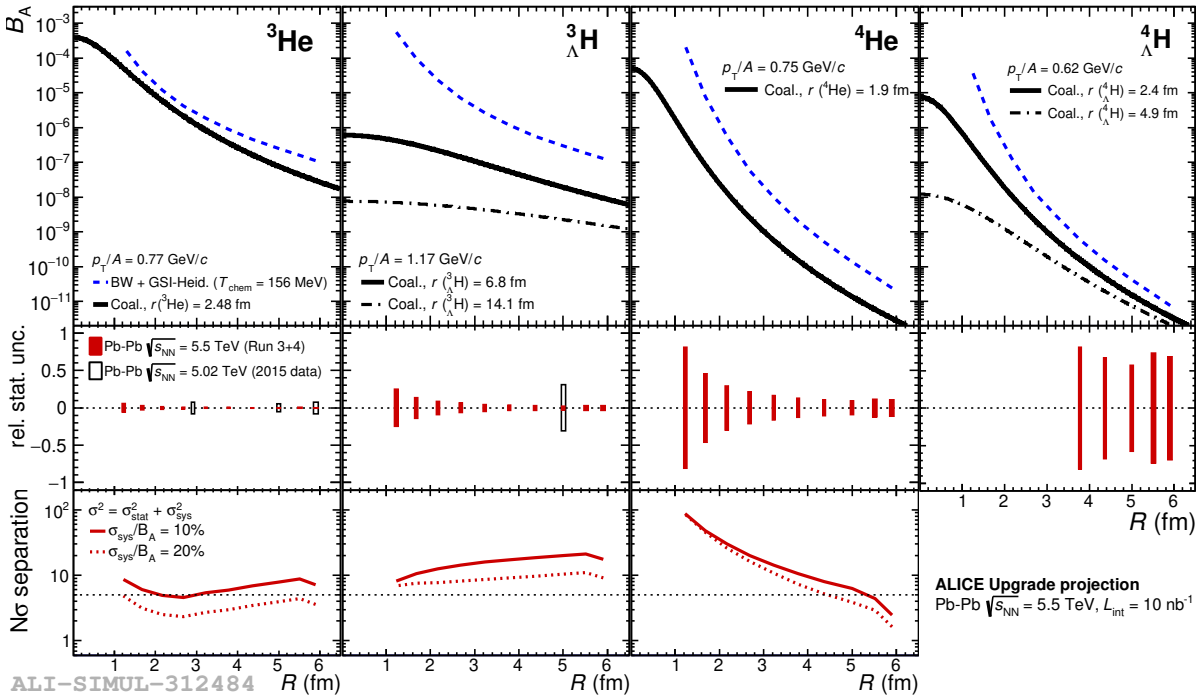

Fig. 2: Top: comparison of predictions for the coalescence parameters for (hyper-)nuclei with A = 3, 4 from the Blast-Wave + GSI-Heidelberg thermal statistical model and nucleon coalescence as a function of the radius (R) of the particle emitting source. For each (hyper-)nucleus, the radius r considered by the coalescence model is reported in the legend. For $^3_\Lambda$H ($^4_\Lambda$H), two values of the radius are considered: the lower value represents the average separation of the three (four) constituents, whereas the larger r corresponds to the average separation between the Λ and the deuteron (triton) core. See [59] for full details on the models. Middle: projection of the relative statistical uncertainty achievable with a minimum bias Pb–Pb integrated luminosity of $L_{\rm int}$= 10 nb^{-1} and the upgraded ALICE detector (in red) compared to the relative statistical uncertainty of the Run 2 measurements (in black). Bottom: significance in the discrimination between the two models, assuming 10% and 20% systematic uncertainty in addition to the statistical uncertainty expected with $L_{\rm int}$= 10 nb^{-1}. For $^3_\Lambda$H, the coalescence prediction considered is for r = 6.8 fm (corresponding to the black continuous lines in the top panel). Figure from Ref. [1].

that will be collected for light anti-nuclei will lead to the first precise measurements of the mass of light anti-nuclei with A = 3, by means of the Time-Of-Flight detector [72]. This measurement will make it possible to test Charge Symmetry Breaking (CSB) in the anti-nuclei sector due to the differences in the up and down quark masses and due to electromagnetic effects [73]. The differences in A = 3 systems are extensions of the neutron-proton difference. Although the mass difference for the lightest "mirror pair" with A = 3 (i.e. ^{3}H,^{3}He), is well known (at the level of O(eV) [74]), no measurement has been performed in the anti-matter sector and will be accessible with $L_{\rm int}$ = 10 nb^{-1}.

In the right panel of Fig. 3, the expected significance of anti-hyper-nuclei measurements in central Pb–Pb collisions is reported as a function of the minimum bias integrated luminosity. For each species, the decay channels with the minimum number of charged particles in the final state and with the highest detection efficiency in ALICE have been considered for this study, as reported in the legend of Fig. 3. The study of other decay channels, e.g. the three body decay of $^3_\Lambda$H that has larger theoretical branching ratio with respect to the 2-body decay [75], but lower detection efficiency in ALICE, will be also carried out profiting from the large integrated luminosity. Considering the thermal model predictions

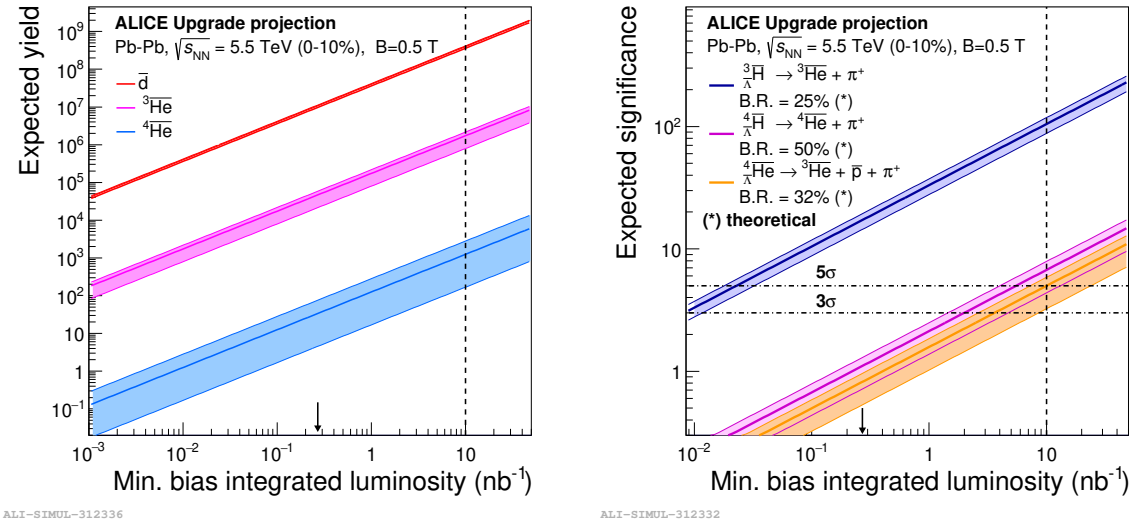

Fig. 3: Left: (raw) yield of anti-nuclei in the $2 < p_{\rm T} < 10$ GeV/c interval, detectable in 0–10% central Pb–Pb collisions with the ALICE detector as a function of the minimum bias luminosity. Right: Projected significance of anti-hyper-nuclei measurements in central Pb–Pb collisions in Runs 3 and 4 with ALICE as a function of the integrated minimum-bias luminosity. In both panels, the arrow represents the minimum bias Pb–Pb luminosity anticipated for the end of Run 2. The dashed vertical line marks the projections with $L_{\rm int} = 10\ {\rm nb}^{-1}$. The bands represents the uncertainty on model prediction for the yield (see text for details). Figures from Ref. [1].

at $T_{\rm chem}$ = 156 MeV, the expected significance of $^3_\Lambda\overline{\rm H}$, $^4_\Lambda\overline{\rm H}$ and $^4_\Lambda\overline{\rm He}$ at $L_{\rm int} = 10\ {\rm nb}^{-1}$ is 100, 7 and 5, respectively. The collected sample will enable very precise measurements of the production of $^3_\Lambda$H and $^3_\Lambda\overline{\rm H}$ and the first ever measurement of their elliptic flow as a function of $p_{\rm T}$. The discovery of $^4_\Lambda\overline{\rm H}$ and $^4_\Lambda\overline{\rm He}$ will be in reach with $L_{\rm int} = 10\ {\rm nb}^{-1}$ at the end of Run 4.

3.2.3 The hypertriton lifetime

The experimental measurement of the Λ separation energy of the $^3_\Lambda$H, $B_\Lambda = 0.13 \pm 0.05$ (stat.) $\pm$ 0.04 (syst.) MeV [76], led to the hypothesis that the lifetime of the hypertriton is equal to or only slightly below the free Λ lifetime $\tau(\Lambda) = 263.2 \pm 0.2$ ps [77]. Three different experimental techniques have been used to tackle this question: photographic emulsion, He bubble chambers, and counter experiments. The average for the emulsion experiments is 203^{+40}_{-31} ps [78], for the He bubble chambers is 193^{+15}_{-13} ps [78], and for the combination of both visualizing techniques is 193^{+14}_{-13} ps [78]. The most recent results, 181 $^{+54}_{-39}\pm$ 33 ps and 142 $^{+24}_{-21}\pm$ 29 ps, have been obtained with the counter technique in heavy-ion collisions by the ALICE [79] and STAR [80] experiments, respectively. This technique is currently the one with the highest precision (14-16%) and the weighted average of heavy-ion experiments results is 185^{+28}_{-23} ps [78]. However, the few existing theoretical calculations point in the direction of the hypothesis mentioned at the beginning of this section. The first theoretical determination of $\tau(^3_\Lambda{\rm H})$ (by Dalitz and Rayet, [81]) ranged from 239.3 to 255.5 ps. More recent calculations from Congleton [82] and Kamada [75] estimated values of 232 ps and 256 ps, respectively. The deviation of the experimental results from the theoretical calculations and the free Λ lifetime, by more than 2σ, is known as the "hypertriton lifetime puzzle".

With the expected integrated Pb–Pb luminosity at the end of the LHC Run 4, the statistical uncer-

tainty on the lifetime will be reduced down to 1%. In parallel, a reduction of the systematic uncertainty ($\sim$ 10% in the most recent ALICE measurements), will be achieved with the upgraded ALICE ITS that will allow for a reduction of the uncertainty due to tracking and material budget. To improve even further down the control on the systematic uncertainty, a better understanding of the corrections for the absorption in the material will be crucial.

3.2.4 Σ-hypernuclei

In addition to measurements of Λ-hypernuclei, also the search for Σ-hypernuclei is to be considered with the luminosities forseen for the LHC Runs 3 and 4. Theory calculations for the ΣNN system suggest the presence of a near-threshold narrow ($\sim$2 MeV wide) quasi-bound state in the I = 1 and J = 1/2 configuration, where the possible isospin and spin states are 0, 1, 2 and 1/2, 3/2, respectively [83]. Among Σ-hypernuclei, only the ${}^{4}_{\Sigma^0}\mathrm{He}$ bound state has been observed so far, using the ${}^{4}\mathrm{He}(K^-,\pi^-)$ reaction [84]. When the Σ^0 hyperon is bound inside a nucleus, the electromagnetic decay is dominated by the conversion reaction $\Sigma^0\mathrm{N} \rightarrow \Lambda\mathrm{N}$, thus the partial width of electromagnetic decay is expected to be reduced substantially. However, for the I = 2 state the conversion reaction is not allowed and the electromagnetic decay becomes prominent. Experimental searches for Σ-hypertriton bound states will also profit from the Pb–Pb data-taking programme of the LHC Runs 3 and 4 to exploit the strong decay ${}^{3}_{\Sigma^0}\mathrm{H}$ $({}^{3}_{\bar{\Sigma}^0}\overline{\mathrm{H}})$ $\rightarrow$ Λ $(\overline{\Lambda})$ + d and the decay ${}^{3}_{\Sigma^0}\mathrm{H}$ $({}^{3}_{\bar{\Sigma}^0}\overline{\mathrm{H}})$ $\rightarrow$ ${}^{3}_{\Lambda}\mathrm{H}$ $({}^{3}_{\bar{\Lambda}}\overline{\mathrm{H}})$ + γ following a similar strategy to the detected electromagnetic decay of Σ^0 $(\overline{\Sigma}^0)$ $\rightarrow$ Λ $(\overline{\Lambda})$ + γ [85]. The signal of hypertriton can be reconstructed in ALICE as discussed in Sec. 3.2.2. The soft photon can be identified by exploiting the conversion into electron pairs in the detector material of the ITS and Time Projection Chamber ($X/X_0 \approx 9\,\%$ considering the upgraded ITS and the TPC together), covering the pseudorapidity range $|\eta| < 0.8$, over the full azimuth ($\Delta\varphi = 2\pi$) [86]. Alternatively, the photon can be detected in the PHOS calorimeter, but with limited acceptance of $\Delta\varphi = 100^{\mathrm{o}}$ and $|\eta| < 0.12$ [86]. The search for Σ-hypernuclei via electromagnetic decay will be carried out in ALICE profiting from the expected detector performance and detection of about 10^5 hypertriton candidates (see Fig. 3) in 0–10% central Pb–Pb collisions at L_{int} = 10 nb^{-1}.

3.2.5 Exotic QCD bound states

At LHC energies, potential QCD bound states that have more complex structures such as pentaquarks, tetraquarks, hadron molecules or dibaryon states could be produced. In particular, the possibility to detect and measure f_0(980), N(1875), NΞ, NΩ and NΛ_c in heavy-ion collisions with the unprecedented statistics of the LHC Runs 3 and 4 programme has been investigated. The advanced capabilities of the ALICE experiment in terms of hadron identification, including topological reconstruction of weak decays, are particularly suited for these studies.

The per-event yields of these states $(\mathrm{d}N/\mathrm{d}y)_{\mathrm{th}}$ predicted by quark- and hadron-coalescence models [60] and the statistical-thermal model [45] are reported in Tab. 6.

The total number of signals ($\mathrm{S}_{\mathrm{raw}}$) detectable in ALICE with a minimum bias Pb–Pb integrated luminosity of 10 nb^{-1} have been estimated assuming the same detector performance as in Run 2 [87,88]. The significance is defined as $\frac{\mathrm{S}}{\sqrt{\mathrm{S+B}}}$, where S and B are the integrals of the signal and background distributions, respectively, in a $\pm$ 3 σ window centered at the nominal mass from [77]. σ is $\Gamma/2.35$, where Γ is the resonance width taken from [77]. The significance for f_0(980) and N(1835) was extracted assuming a combinatorial background in the invariant mass range under study. Such combinatorics was computed based on particle species that can populate the invariant mass distribution, making use of the corresponding momentum distribution as measured in ALICE in Run 2 (e.g. individual primary charged pions paired as candidates for the $\mathrm{f}_0(980) \rightarrow \pi^+ + \pi^-$ channel) and assuming a uniform distribution in φ

and η [2]. The resulting significance is reported in the last row of Tab. 6 for the most pessimistic scenario, in which production occurs via quark coalescence, and the most optimistic scenario, corresponding to thermal production.

Measurements of $f_0(980)$ and N(1875) will be feasible in Runs 3 and 4 and will shed light on the highly-debated nature of the states (hadrons or hadronic molecules). In particular, the N(1875) can be considered a molecular bound state and at the same time the strange partner of the recently discovered pentaquark P_c [90]. Because the structure of exotic states is related to the fundamental properties of Quantum Chromodynamics (QCD), their observation can provide new insights on the properties of QCD at finite temperature and density, for instance that tetraquark condensation may lead to a second chiral phase transition [60]. Several possible states have been studied and predictions are available on the expected yields at LHC energies [60]. Among the possible dibaryon bound states, the NΩ, NΞ and NΛ_c look promising in terms of detection feasibility. Their detection and baryon-baryon correlations will be useful for hyperon correlation studies, providing new insights into the baryon-baryon attractive potential as well as upper limits on the formation of such bound states in central heavy-ion collisions.

Very recently, a study was reported on the production of exotic charmonia, specifically the possible tetraquark state X(3872), in Pb-Pb and Kr-Kr collisions at LHC collision energies [91]. For X(3872) production in Pb-Pb collisions the authors predict, using the statistical hadronization model for charm, a transverse momentum distribution similar in shape to that for J/ψ mesons with a strong enhancement at low transverse momenta and a production yield of about 1% relative to that for J/ψ. It would be interesting and feasible to test this prediction in LHC Run 3 and especially Run 4.

[2] An additional factor is introduced if the decay particle is reconstructed via invariant mass, since the candidate may belong also to the background.

Table 6: Properties and yields of exotic states in 0–10% central Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.5$ TeV. Theoretical predictions of yields per event, $(\mathrm{d}N/\mathrm{d}y)_{\rm th}$, are given in three different scenarios: quark- and hadron-coalescence [60], and thermal model [49]. $S_{\rm raw}$ represents the total detectable yield at the Pb–Pb luminosity of 10 nb^{-1}, taking into account the branching ratios (B.R.) of the decay channels considered and assuming the ALICE detector performance as in Run 2 [87, 88]. For $f_0(980)$, a $\mathrm{K\overline{K}}$ state and a decay into $\mathrm{K\overline{K}}$ with B.R. = 10^{-3} is assumed for hadron coalescence †. A tetraquark state is assumed for quark coalescence and a decay into $\pi\pi$. The same decay channel is assumed for the thermal production case. Masses are from [89].

3.2.6 Implications of anti-nuclei measurements for cosmic-ray physics and dark-matter searches

The HL-LHC physics program with pp and p–Pb collisions will allow for precision measurements of anti-nuclei production and related observables that have implications for cosmic-ray physics and dark-matter searches. Cosmic-ray (CR) anti-nuclei $\overline{\mathrm{p}}$, $\overline{\mathrm{d}}$, and $^3\overline{\mathrm{He}}$ have long been considered as probes of new physics, such as dark matter annihilation [92–103]. Detecting these particles is one of the main goals of various CR experiments (e.g. AMS-02 [104, 105], GAPS [106, 107], BESS-Polar [108]).

The galaxy produces CR anti-nuclei as secondaries, due to collisions of CR protons and helium with interstellar matter. Information from accelerator experiments is essential for the theoretical description of the background constituted by these secondary anti-nuclei. The flux of secondary anti-nuclei can be calculated with only minor sensitivity to the details of CR astrophysics. The point is to use secondary-to-secondary flux ratios, where astrophysical uncertainties largely cancel. Secondary $\overline{\mathrm{p}}$, $\overline{\mathrm{d}}$, and $^3\overline{\mathrm{He}}$ are all formed dominantly by the same set of reactions. Using this basic fact, an explicit prediction for the locally observable flux of secondary $\overline{\mathrm{d}}$, relative to the flux of secondary $\overline{\mathrm{p}}$ can be derived [109–111]:

$$\frac{J_{\overline{\mathrm{d}}}(\mathcal{R})}{J_{\overline{\mathrm{p}}}(\mathcal{R})} = \frac{\int \mathrm{d}\epsilon\, J_{\mathrm{p}}(\epsilon)\, \frac{\mathrm{d}\sigma_{\mathrm{pp}\to\overline{\mathrm{d}}}(\epsilon,\epsilon_{\overline{\mathrm{d}}})}{\mathrm{d}\epsilon_{\overline{\mathrm{d}}}}}{\int \mathrm{d}\epsilon\, J_{\mathrm{p}}(\epsilon)\, \frac{\mathrm{d}\sigma_{\mathrm{pp}\to\overline{\mathrm{p}}}(\epsilon,\epsilon_{\overline{\mathrm{p}}})}{\mathrm{d}\epsilon_{\overline{\mathrm{p}}}} + \left(\sigma_{\overline{\mathrm{d}}}(\epsilon_{\overline{\mathrm{d}}}) - \sigma_{\overline{\mathrm{p}}}(\epsilon_{\overline{\mathrm{p}}})\right) J_{\overline{\mathrm{p}}}(\mathcal{R})}. \tag{7}$$

Here $J_{\overline{\mathrm{d}}}(\mathcal{R})$ is the predicted $\overline{\mathrm{d}}$ flux, given at magnetic rigidity $\mathcal{R} = p/Z$, where p is the momentum and Z is the electric charge. $J_{\overline{\mathrm{p}}}(\mathcal{R})$ is the (already well-measured [112]) $\overline{\mathrm{p}}$ flux at the same rigidity, and $J_{\mathrm{p}}(\epsilon)$ is the proton flux [113] at energy ϵ. $\frac{\mathrm{d}\sigma_{\mathrm{pp}\to\bar{x}}(\epsilon,\epsilon_{\bar{x}})}{\mathrm{d}\epsilon_{\bar{x}}}$ and $\sigma_{\bar{x}}(\epsilon_{\bar{x}})$ are the inclusive production and inelastic cross sections, respectively, with $x = \mathrm{d}, \mathrm{p}$. The particle energy $\epsilon_{\bar{x}}$ for a nucleus with mass number A is evaluated at $\mathcal{R}$: $\epsilon_{\overline{\mathrm{p}}} = \sqrt{\mathcal{R}^2 + \mathrm{A}^2 m_{\mathrm{p}}^2}$. To describe $^3\overline{\mathrm{He}}$ we use an analogous expression to Eq. (7), adding the production of $\overline{\mathrm{t}}$ which decays to $^3\overline{\mathrm{He}}$. More details, including the relation of the differential cross section appearing in Eq. (7) to the Lorentz-invariant differential cross section measurable at the LHC, can be found in [111].

The cross section for producing an anti-nucleus can be parameterized in terms of the anti-proton cross section, using the coalescence factor B_{A}: $(\epsilon_{\mathrm{A}}\mathrm{d}\sigma/\mathrm{d}^3p)_{\mathrm{pp}\to\mathrm{A}} = B_{\mathrm{A}}/\sigma_{\mathrm{pp}}^{\mathrm{A}-1}[(\epsilon_{\overline{\mathrm{p}}}\mathrm{d}\sigma/\mathrm{d}^3p)_{\mathrm{pp}\to\overline{\mathrm{p}}}]^{\mathrm{A}}$, where σ_{pp} is the total inelastic pp cross section. Here, for simplicity, threshold effects are omitted [111, 114, 115]. Using Eq. (7), and plugging in the coalescence factors experimentally obtained at the LHC [116], the predicted flux ratios can be obtained. Secondary CR production is dominated by the low p_{T} region. As a result, the impact on the CR flux, due to p_{T}-dependent B_{A}, can be factored out to good approximation, allowing us to derive simple approximate formulae [3] [111]:

$$\frac{J_{\overline{\mathrm{d}}}(\mathcal{R})}{J_{\overline{\mathrm{p}}}(\mathcal{R})}|_{\mathcal{R}=100\mathrm{GV}} \approx 4\times10^{-4}\left(\frac{B_2}{1.5\times10^{-2}\ \mathrm{GeV}^2}\right), \tag{8}$$

$$\frac{J_{^3\overline{\mathrm{He}}}(\mathcal{R})}{J_{\overline{\mathrm{p}}}(\mathcal{R})}|_{\mathcal{R}=100\mathrm{GV}} \approx 2\times10^{-7}\left(\frac{B_3}{1.5\times10^{-4}\ \mathrm{GeV}^4}\right), \tag{9}$$

where, for CR studies, the B_2 and B_3 values should be read from the average yield in the range $p_{\mathrm{T}}/\mathrm{A} = (0-0.5)\ \mathrm{GeV}/c$ in the accelerator analysis. The precision requirements (O(10%)) on the flux ratio determination for the astrophysical applications discussed here will be matched by measuring B_2 and B_3 in the lowest p_{T} bin with a relative systematic uncertainty of the order of 10% [116]. The latter largely dominates the statistical uncertainty that is expected to be of O(0.1%) already with $L_{\mathrm{int}} = 6\ \mathrm{pb}^{-1}$ in pp collisions at $\sqrt{s} = 5.5$ TeV. Moreover, a first measurement of B_4 in pp collisions will be achievable in the same sample. The statistical precision on B_4 can be lowered to the 10% level if a

[3] Note that the rigidity $\mathcal{R} = 100$ GV refers to the CR experiment rest frame, which is boosted w.r.t. the proton-proton collision centre of mass frame. In the proton-proton collision centre of mass frame, the anti-nuclei are formed close to threshold.

luminosity of 200 pb^{-1} in pp collisions at $\sqrt{s} = 14$ TeV can be inspected with a dedicated trigger for (anti-)nuclei.

It is important to note that the B_{A} measurement [116] performed by ALICE during the LHC Run 1 was confined to mid-rapidity, $|y| < 0.5$. Possible y dependence of the coalescence factor B_{A} at $y = \mathcal{O}(1)$, or variation of the $\overline{\mathrm{p}}$ differential cross section with respect to current parameterisations [117], would affect the prediction in Eqs. (8-9). It would be an important task of future LHC measurements to test these effects. Similarly important, albeit – possibly – beyond the reach of the LHC, would be to study the low $\sqrt{s} = \mathcal{O}(10)$ GeV behaviour of B_{A} [111].

3.2.7 Implications of anti-nuclei measurements and hyperon-nucleon correlations for neutron star physics

Although the neutron star crust is composed of neutrons, within the innermost core hyperons could be present [118]. Whether or not this scenario holds true depends on the two- and three-body hyperon nucleon interactions (YN and YNN) that are still only rather scarcely constrained experimentally.
At present the mass range for observed neutron stars is about (0.9 – 3.0)$M_{\odot}$ within errors [119], where $M_{\odot}$ stands for the solar mass. The equation of state (EoS) of neutron stars is constrained by the mass-radius relationship, in particular, the maximum mass (M_{max}). An EoS with "conventional" (N+π) degrees of freedom provides M_{max} invariably above $2M_{\odot}$ [120–122]. However, adding the Λ hyperon in the hadronic basis softens the EoS and, as a consequence, significantly reduces M_{max}. The solution of this so-called "hyperon puzzle" is non-trivial, and is presently the subject of very active research.

Thanks to the large yields of free hyperons and exotic (anti-)hyper-nuclei that can be produced in collider experiments and the excellent particle identification capabilities of the ALICE experiment, the upcoming experimental campaigns in Runs 3 and 4 at the LHC offer a unique opportunity to quantitatively characterise hypermatter under controlled (laboratory) conditions and infer on the equation of state of compact objects as neutron stars.

One of the crucial element to solve the “hyperon puzzle” is the determination of the ΛNN three-body forces. Calculations show that with a parameterization of these forces compatible with the hypernuclear binding energies, the admixture of Λ’s in neutron star matter gets strongly reduced such that the pressure to support a $2M_{\odot}$ neutron star can be maintained [123]. The observation of neutron-rich Λ hyper-nuclei like ${}^{4}_{\Lambda}\mathrm{H}$ etc. at colliders could be very promising for studying the effects of the three-body ΛNN forces in dense strongly interacting matter since a precise knowledge of light neutron-rich hypernuclei energy level structure could imply far-reaching consequences for dense strange stellar matter properties.

Another promising way to contribute to the understanding of the hyperon puzzle is to pin down the hyperon-nucleon two-body interaction for hyperons such as Σ^{-} and Ξ^{-}. These hyperons can also be produced within neutron rich matter (n + n $\rightarrow \Sigma^{-}+$ p, Λ + n $\rightarrow \Xi^{-}+$ p) depending on their interaction with the surrounding neutrons. Some models assume a repulsive pΣ interaction and postulate that Σ^{-} can appear in neutron rich matter only starting from baryon densities $\rho \simeq 4\rho_0$ (where ρ_0 is the density of standard nuclear matter) [124]. For Ξ, no reliable experimental information about the interaction is available. Recent studies [125] showed that the femtoscopy technique applied to pp and p–Pb collisions at LHC energies are particularly suited to study the final state interaction between nucleons and strange baryons (e.g.: Λ–p) and between two strange baryons (e.g.: Λ–Λ). Indeed, small colliding systems such as pp and p–Pb lead to hadron sources of rather small dimensions, of the order of 1 fm, in the range where the strong interaction is mostly evident. Also, the production mechanism of hadrons in minimum bias pp and p–Pb collisions is not affected by the intermediate creation of a QGP and its time-dependent evolution as in Pb–Pb collisions at LHC energies. This allows for a more precise study of the hadron-hadron interactions.

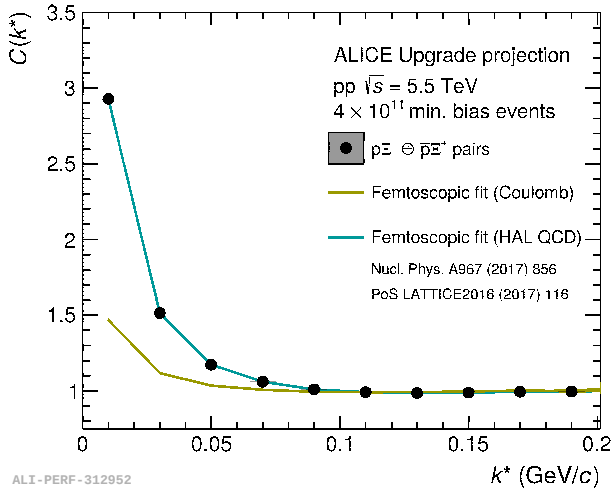

Fig. 4: Expected $\mathrm{p\Xi^-}$ + $\mathrm{\bar{p}\Xi^+}$ correlation for pp collisions at $\sqrt{s} = 5.5$ TeV and 4×10^{11} minimum bias events, corresponding to $L_{\mathrm{int}} = 6\ \mathrm{pb}^{-1}$. Only statistical errors have been estimated. Figure from Ref. [1].

Among the quantitative results obtained by ALICE in Run 2 at the LHC is the first observation of the attractive $\mathrm{p\Xi^-}$ interaction. Figure 4 shows the expected $\mathrm{p\Xi}$ correlation for the Run 3 pp sample as a function of the relative momentum $k*$. The projection is obtained on the basis of the current prediction by the HAL-QCD lQCD group [126,127] that is in agreement with the Run 2 results. The clear deviation from the Coulomb-only correlation function shows the effect of the strong attractive interaction and the expected statistics will allow for a quantitative determination of the scattering parameters and the test of different hadronic models [128, 129]. The investigation will also be extended to the Σ^0 hyperon, since in Run 3 and 4 we expect a total of 500,000 $\mathrm{p\Sigma^0}$ pairs to be used to study the femtoscopy correlation.

In summary, massive neutron stars with $M \sim 2M_{\odot}$ are very intriguing recent observations in relativistic astrophysics. An improved account of the two-body YN interaction, the three-body ΛNN forces, and the contribution of multi-strange hyperons in the EoS is crucially important for more realistic description of compact astrophysical objects, in particular neutron and hybrid stars. The measurement of hyper-nuclei and hyperon correlations with the HL-LHC project are suggested as a promising tool for astrophysical applications.

3.3 Fluctuations of conserved charges

3.3.1 Physics introduction and observables

In the phase diagram of strongly interacting matter at zero net baryon density, the presence of a chiral phase transition between hadronic matter and a QGP has been conjectured [130], and arguments have been presented [131, 132] in lQCD that the transition, for vanishing light quark masses, is of second order and belongs to the O(4) universality class. Due to the small but finite physical quark masses, in lQCD a rapid crossover is found [133–137] which, however, exhibits pseudo-critical features due to the smallness of the u- and d-quark masses and the proximity of the crossover region to the O(4) line [131, 138].

In general, fluctuations can be linked to critical behaviour associated with a phase transition, and it has been pointed out that fluctuations of conserved charges in heavy-ion collisions can provide an experimental observable to test for critical behaviour in the phase diagram of strongly interacting matter [139–142]. These fluctuations can be related to susceptibilities, specifically to the derivatives of the pressure with respect to the chemical potentials corresponding to the conserved charges. Here, the

relevant 'charges' are baryon number B, strangeness S, and electrical charge Q, and the corresponding chemical potentials are μ_B, μ_S, and μ_Q. The susceptibilities are defined (see e.g. [142, 143]) in terms of dimensionless normalized chemical potentials $\hat{\mu}_X \equiv \mu_X/T$ as

$$\chi^{BQS}_{ijk}(T) = \left.\frac{\partial P(T,\hat{\mu})/T^4}{\partial \hat{\mu}_B^i \partial \hat{\mu}_Q^j \partial \hat{\mu}_S^k}\right|_{\hat{\mu}=0} . \tag{10}$$

The generalized susceptibilities can be computed in lQCD at vanishing chemical potential, exactly the conditions probed by experiments at the LHC. Within the Grand Canonical Ensemble (GCE), these generalized susceptibilities can be related to experimental measurements of the fluctuations of particle multiplicities, such as the net number of baryons. For instance, a measurement of higher moments or cumulants of net baryon number in relativistic nuclear collisions can be directly related [144–149] to theoretical predictions from lQCD or from more phenomenological models of the chiral phase transition [150, 151] to shed light on the possible critical behaviour near the QCD phase boundary. For a distribution of the net baryon number, $\Delta N_B = N_B - N_{\overline{B}}$, with moments defined as

$$\mu_i = \langle (\Delta N_B - \langle \Delta N_B \rangle)^i \rangle, \tag{11}$$

the cumulants κ_i can be directly linked to the generalized susceptibilities such as

$$\kappa_2 = \mu_2 = VT^3\chi_2^B \tag{12}$$

$$\kappa_3 = \mu_3 = VT^3\chi_3^B \tag{13}$$

$$\kappa_4 = \mu_4 - 3\mu_2^2 = VT^3\chi_4^B . \tag{14}$$

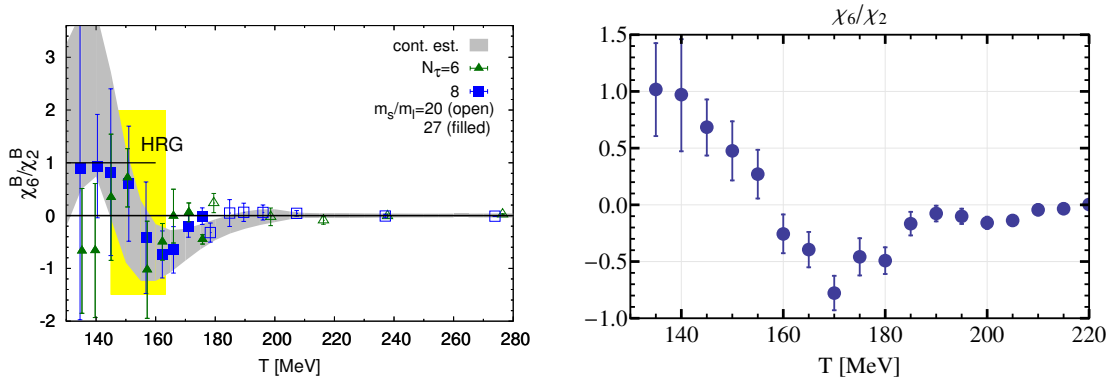

Fig. 5: Ratio of sixth to second-order baryon number susceptibilities from lQCD. The left-hand figure is from [140]. The right-hand figure is calculated from recent lQCD data on sixth and second order susceptibilities from [152].

In the O(4) universality class, a singular contribution to the pressure shows up for higher order moments. More specifically, at vanishing chemical potential, all odd susceptibilities of the net baryon number vanish. In addition, in the O(4) universality class, the second- and fourth-order susceptibilities remain finite at the phase transition temperature at $\mu_B = 0$ in the chiral limit, implying that only sixth- and higher-order susceptibilities diverge [139, 141]. Thus, for physical quark masses and at $\mu_B = 0$,

only higher order cumulants κ_n with $n \geq 6$ can exhibit O(4) criticality, whereas at finite μ_B this is already the case for κ_n with $n \geq 3$.

Sensitivity to chiral criticality due to the vicinity of the O(4) line at $\mu_B = 0$ is borne out in phenomenological models as is shown in [141, 150], and in lQCD predictions [140, 152], by strong deviations of χ_6^B/χ_2^B from unity as shown in Fig. 5.

We note that a convenient baseline for the cumulants of multiplicity distributions and fluctuations of produced particles in relativistic nuclear collisions can be obtained in the framework of the hadron resonance gas (HRG) [144, 152–155]. In this model, uncorrelated Poissonian fluctuations of baryon and anti-baryon multiplicities result in a Skellam distribution for the net baryon number, in which the higher moments and cumulants can all be related to the first moments in the following way [154, 156, 157]:

$$\kappa_n(N_B - N_{\overline{B}}) = \langle (N_B + (-1)^n N_{\overline{B}}) \rangle \tag{15}$$

For zero net baryon number then all odd cumulants vanish and all even cumulants are identical.

Measuring such cumulants with precision poses a formidable experimental challenge due to the requirement of very large data sets ($> 10^9$ events of a particular event or centrality class) with superb control of systematic uncertainties. As a first physics case to consider along this line, the impact of measuring the distribution of net protons as a proxy for net baryons needs to be studied further. We note that, at LHC energy and low transverse momentum, particle production near mid-rapidity takes place mostly in gluonic processes, implying that isospin asymmetries, as in the colliding nuclei, are absent. As a consequence, the production yields of protons and neutrons should be very close. For light nuclei this isospin symmetry has been checked experimentally, albeit with significant uncertainties. In addition, non-critical contributions to the cumulants from volume fluctuations and global baryon number conservation [145, 157, 158] need to be evaluated and the data corrected accordingly. Furthermore, in particular for comparison to lQCD predictions, care needs to be taken to keep experimental cuts such as in p_{T} to a minimum insofar as such cuts cannot be introduced in lQCD [159, 160].

Two-particle correlations with net baryons can also be used to explore transport properties of the hydrodynamic evolution. The baryon diffusion constant D is a fundamental transport property of the quark-gluon plasma, similar to shear viscosity η or bulk viscosity ζ. It characterizes the mobility of baryon number, and is predicted to be finite at the LHC despite the fact that $\mu_B \sim 0$. A two-particle correlation function as been proposed [161], which explores correlations of net-baryon fluctuations as a function of separations in azimuthal angle and rapidity, and can provide experimental constraints on the diffusion coefficient D. As $\mu_B \sim 0$ at the LHC, such an analysis has yet to be carried out in Run 1 and 2 data since it is statistically challenging, and will be greatly aided by the increase by about a factor 100 in the Pb–Pb integrated luminosity foreseen for Runs 3 and 4.

3.3.2 State of the art experimental measurements and present limitations

Net proton fluctuations measured by the ALICE experiment and in the STAR beam energy scan program provide interesting and stimulating results. The measurements at STAR [162] complement the corresponding measurements from ALICE, which will make it possible to pin down the global structure of the phase diagram of strongly interacting matter in a wide range of temperatures and net-baryon densities. However, before drawing firm conclusions by confronting theoretical calculations with data, non-dynamical contributions stemming from unavoidable fluctuations of participant nucleons and overall baryon number conservation have to be subtracted from the experimental measurements. Both of these non-dynamical contributions, which exist neither in lQCD nor in the HRG model, lead to deviations from the baseline as defined in Eq. 15. Indeed, the acceptance dependence of the second-order cumulants of net-protons measured by ALICE [163] exhibits deviations from the non-critical (Skellam) baseline. However, these deviations were explained by global baryon number conservation [157, 158, 163], which,

in accordance with the experimental findings, decreases the amount of fluctuations with the increasing acceptance. This is the first experimental verification of the lQCD predictions for the second-order cumulants of net-baryon distributions. This also serves as a strong support of the HRG model, in that experimental measurements of the second cumulants of net-protons do not show any evidence of criticality and actually coincide with the second cumulants of the Skellam distribution. In order to probe critical phenomena, higher cumulants beyond the second order have to be addressed.

As mentioned in the previous section, even at vanishing net-baryon densities, lQCD and other theoretical calculations such as Polyakov-loop extended Quark- Meson model (PQM) [150] predict critical fluctuations encoded in the deviations of net-baryon κ_4/κ_2 and κ_6/κ_2 from unity. Moreover, at the pseudo critical temperature of about 156 MeV the magnitudes of κ_4/κ_2 and κ_6/κ_2 are predicted in Ref. [150] to be 0.5 and -0.39, respectively. Similar values of κ_6/κ_2 are quoted in different lQCD calculations as presented in Fig 5. These numbers, shown in Fig. 6, do not take into account experimental artefacts such as global net-baryon number conservation and unavoidable fluctuations of participating nucleons from event to event. Also shown are the values of of κ_4/κ_2 and κ_6/κ_2 after accounting for these non-dynamical effects using the procedure in Refs. [157, 158, 164]. Even after accounting for participant fluctuations and global baryon number conservation we observe deviations in κ_4/κ_2 and κ_6/κ_2 from unity, although they are somewhat reduced. This motivates our experimental program of measuring higher moments of net-proton distributions at the LHC energies. Also, fluctuation measurements are underway in the strange baryon sector to approach measurements of net baryon number fluctuations. All this will be greatly helped by the anticipated dramatic increase in statistics in Runs 3 and 4.

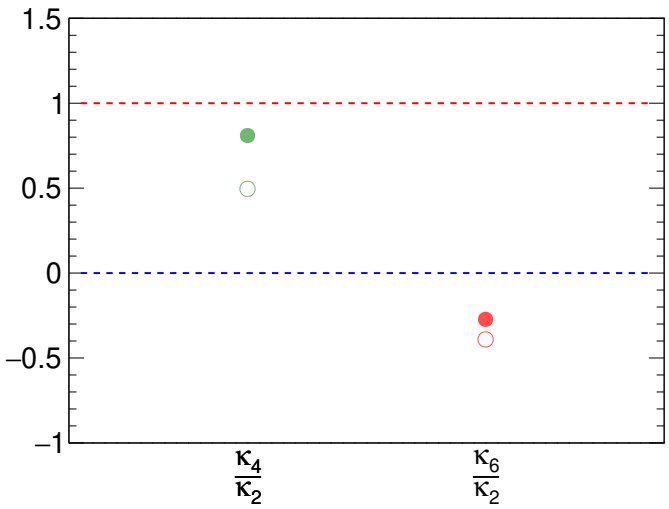

Fig. 6: κ_4/κ_2 and κ_6/κ_2 as calculated within PQM [150] model (open symbols). After taking into account contributions from participant nucleon fluctuations and global baryon number conservation [157, 158], the deviations from unity decrease (closed symbols).

3.3.3 Projections for HL-LHC

As discussed above, precise studies of the higher-order cumulants of particle multiplicity distributions are needed to verify theoretical predictions. In this section we estimate the statistics needed to address these measurements with the ALICE experiment. For this purpose two distinct Monte Carlo simulations

have been developed. In the first approach, following recent developments in [165], the probability distribution function of net-protons is approximated by a superposition of two Gaussian distributions which has four free parameters. Using the experimentally measured second cumulant of net-protons for 0-5 % most central Pb–Pb collisions [163] and the κ_4/κ_2 and κ_6/κ_2 ratios from the PQM model [150], absolute values for κ_4 and κ_6 were obtained first. These values were adjusted to account for fluctuations from participant nucleons in 0-5% most central Pb–Pb collisions and global baryon number conservation [157, 158]. Finally, the free parameters of the double Gaussian distribution were fixed using the expected values of κ_1 , κ_2 , κ_4 and κ_6 , where κ_1 equals zero by definition. The event-by-event net-proton number was sampled from the double Gaussian function thus generating the net-proton distribution for a given number of events. In the second approach the probability distribution functions of protons and anti-protons are calculated separately by exploiting the Pearson curve method [166]. This approach also needs four measurements as inputs, which are taken as the first four cumulants of the proton and anti-proton multiplicities measured by ALICE [167]. The net-proton distribution for a given number of events is constructed by sampling the obtained proton and anti-proton probability distribution functions. In each approach, the resulting statistical uncertainties are obtained using the subsample method.

The obtained results for κ_4/κ_2 and κ_6/κ_2 and their corresponding statistical uncertainties are shown in Fig. 7 as a function of the simulated event statistics. The dashed red lines correspond to the input values predicted by PQM calculations of critical fluctuations (CF) and assuming a double Gaussian net-proton distribution, while the green dashed lines come from the Pearson curve method based on the lower-order cumulants measured by ALICE. As expected, with increasing statistics both κ_4/κ_2 and κ_6/κ_2 approach their nominal values. The statistics necessary to measure these cumulants are presented in the bottom panels of Fig. 7, where the deviations of the expected values from unity are quantified in units of the magnitudes of the statistical uncertainty (σ). As seen from the left panel of Fig. 7, for κ_4/κ_2 already 10 million events are sufficient to distinguish the expected critical fluctuations signal from unity with a statistical significance of 4σ. Similar conclusions are obtained with the Pearson curve method. Several times this amount of data has already been recorded by ALICE, and the expected statistics in Runs 3 and 4 will make it possible to measure κ_4/κ_2 with unprecedented precision.

For κ_6/κ_2, however, significantly larger event sample is needed. As seen from the right panel of Fig. 7, more than 5 billion 0-5 % central events generated with the double Gaussian approach are needed in order to observe statistically significant deviations from unity in favor of the critical values indicated with the red dashed line. These would correspond to a minimum bias Pb–Pb integrated luminosity of 12.5 nb^{-1} in Runs 3 and 4. Results obtained with the Pearson curve method indicate that more than 200 million 0-5 % central events (corresponding to a minimum bias Pb–Pb integrated luminosity of 0.5 nb^{-1}) would be sufficient in order to claim a significant deviation from unity in favour of the corresponding expected value. This difference in the estimation of the required statistics for κ_6/κ_2 comes mainly from the different baseline values of -1.43 and -0.27 used in the Pearson and double-Gaussian methods, respectively. In addition, the value of κ_2 used in the Pearson method is about two times smaller than measured in the experiment and used in the double Gaussian method. Track reconstruction and particle identification efficiency in the fiducial acceptance in η and p_{T} efficiencies, which would increase the required number of events for a given statistical precision, are not included in the study presented here because they depend on the details of the analysis. Considering that these efficiencies are expected to range from 60% to 80%, we conclude that the Pb–Pb integrated luminosity of 13 nb^{-1} foreseen in Runs 3 and 4 (see Ch. 12) will be sufficient to probe the critical phenomena contained in κ_6/κ_2.

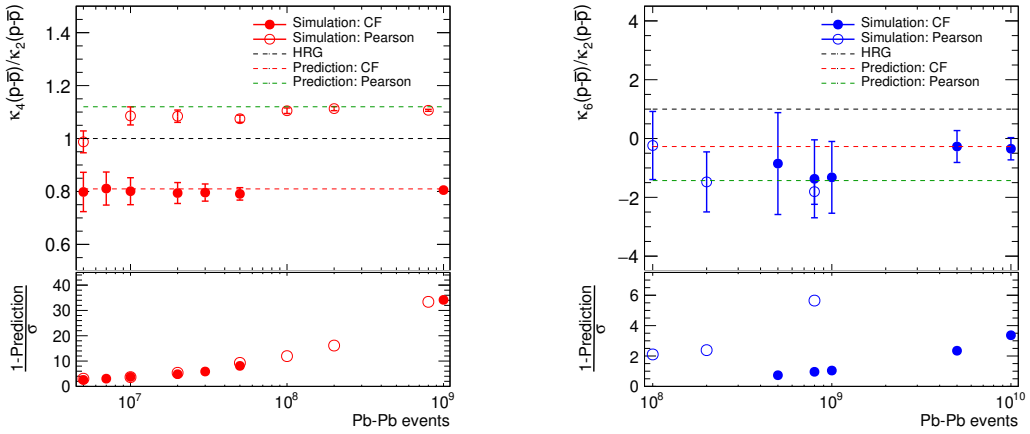

Fig. 7: Simulated values of κ_4/κ_2 (left panel) and κ_6/κ_2 (right panel) as functions of the generated number of events. Full symbols represent results obtained with the double Gaussian approach adjusted to reproduce critical fluctuations (CF) predicted in the PQM model [150]. Open symbols are obtained with the Pearson Curve Method [166].

4 Flow and Correlations

4.1 Introduction

It is particularly interesting to study the macroscopic properties of the QGP fluid because - at least conceptually - they are fully fixed by the microscopic properties of a renormalizable, fundamental quantum field theory, namely QCD. One key question is how macroscopic properties of QGP arise from its microscopic interactions. Many theoretical methods ranging from perturbative to non-perturbative techniques are being developed to understand this in detail and one can expect that the insights gained here will be valuable for many related problems in fields ranging from condensed matter theory to cosmology in the future. Many different fronts of research are being explored at the moment. This ranges from conceptual questions on how to consistently formulate relativistic fluid dynamics or how to solve quantum field theory in non-equilibrium situations to very concrete practical questions about the thermodynamic and transport properties (such as viscosities or conductivities) of the QGP. The description of the initial state – prior to QGP formation – and the mechanism by which the products of the collision rapidly thermalize are also under investigation. Besides the role of strong interactions, also electromagnetic interactions and in particular the role of magnetic fields are being explored. Other fronts of research concern the role of quantum anomalies, chirality and vorticity or the dependence of collective behavior on system size (nucleus-nucleus versus proton-nucleus and proton-proton collisions), on centrality and collision energy, the initial state directly after the collision, or various types of fluctuations. These challenges are discussed in more detail in this section.

4.2 Review of current status of theory on bulk and flow observables

4.2.1 QCD Equation of State

The QCD equation of state, accessible in high-energy collisions (and in the region around mid-rapidity) is one that has vanishing baryon chemical potential. It has been established for some time that it features a crossover transition to a chirally symmetric quark gluon plasma [133]. Most recent lattice calculations [168] have determined the cross-over temperature to be $T_c \simeq 156.5 \pm 1.5\,\mathrm{MeV}$. Recent efforts are also exploring the equation of state at finite μ_B, which at LHC would have relevance mainly at very forward rapidities. Here, because of the fermion sign problem in lattice QCD, methods like Taylor expansion [169–172] or imaginary chemical potentials [173–177] have to be used. To employ lattice QCD based equations of state in hydrodynamic calculations, they need to be matched to a hadron resonance gas model at low temperatures. Various equations of state [50, 178, 179], using different lattice data and different matching conditions have been used in simulations. A comparison of some of them can be found in [180], where the sensitivity of observables to the choice of equation of state was studied. For a recent theoretical proposal on how to gain experimental sensitivity on the equation of state, see ref. [181]. Currently available data are consistent with the lattice QCD equation of state, however with an $\sim 50\,\%$ error. To reduce the uncertainty, measurements of particle spectra over a wide range of colliding energies using a single detector with good particle identification, especially at low transverse momentum, would be needed. Another possibility to constrain the equation of state from experimental

data would be to extend state of the art Bayesian techniques [182] to include free parameters describing the equation of state and fit them along with other free parameters such as shear and bulk viscosities.

4.2.2 *Shear and bulk viscosities of hot nuclear matter*

Ideal fluid dynamics has been very successful in describing a variety of bulk observables in heavy ion collisions [183–185], indicating early on that the shear and bulk viscosities of the produced matter cannot be large. Calculations in the strong coupling limit using gauge gravity duality have found a value of $\eta/s = 1/4\pi$ for an $N = 4$ Supersymmetric Yang-Mills quantum system [186, 187]. This value was significantly smaller than the η/s obtained in perturbative QCD calculations, which were however, beset by significant uncertainties, mainly resulting from uncertainties in the relevant scales [188]. Recently, such perturbative calculations have been extended to include next-to-leading order corrections and a significant reduction compared to the leading order result was found [189]: At temperatures of the order of the QCD transition the η/s obtained using NLO corrections is smaller by a factor of 5 compared to the LO result, and reaches values of approximately $2/4\pi$. Extractions of transport coefficients from lattice QCD calculations [190–192] are extraordinarily hard, because a numerically difficult analytic continuation from imaginary to real times is necessary.

There are also several theoretical indications that bulk viscosity could play an important role in the QGP to hadron gas transition region (see [193] and references therein). Perturbative calculations have shown that the simple estimate $\zeta \approx 15\eta(1/3 - c_s^2)^2$ [194] is parametrically correct for QCD [195], where $(1/3 - c_s^2)$ is the deviation from conformal symmetry. Lattice calculations using the Kubo formula yield large values of ζ/s (~ 1) around T_c [196, 197] with large uncertainties [198]. The calculations also show a fast drop of ζ/s with increasing T. Parametrizations of the bulk viscosity over entropy density's temperature dependence were performed in [199] with input from [196] for the QGP phase and [200] for the hadronic phase. Similar to the case of shear viscosity, bulk viscosity over entropy density ratios have been determined also in holographic models that are supplemented with non-conformal features [201, 202]. In this approach, the ζ/s reaches a much lower peak value ~ 0.05 at temperatures slightly above T_c [202]. It remains to be understood to what extent this provides semi-quantitative guidance for the value in QCD.

Apart from theoretical calculations of the shear and bulk viscous properties, one may also constrain them by means of fluid dynamic simulations and comparison to experimental data [203, 204]. This method suffers mainly from uncertainties in the initial state (see also Section 4.2.3) and has an uncertainty of approximately a factor of 3 (for η/s) at this point. Some of the latest constraints come from simulations using the IP-Glasma initial state [205, 206], the EKRT model [207] and Bayesian analyses employing the Trento initial state model [182]. In terms of the Viscous corrections to the distribution function at freeze-out, the low-p_{T} range of the spectrum is more sensitive to the bulk viscosity than to the shear viscosity [208, 209]. Consequently, the uncertainties resulting from bulk viscous corrections are typically larger than for shear when studying p_{T} integrated observables. Precise measurements of the low-p_{T} spectra and mean-p_{T} in different collision systems will help in lowering the current uncertainties, specifically in the extraction of ζ/s. In order to disentangle features of the initial state and medium properties, it might be useful to study additional collision systems such as Ar–Ar or O–O and to perform a more detailed global analysis including refined data on harmonic flow coefficients for identified particles that become available during Run 3 and 4 (see Section 4.3.1).

4.2.3 *Initial conditions*

Modelling the exact geometry and initial conditions for a fluid dynamic description of heavy ion collisions is not a simple task, because it involves non-perturbative physics. The available descriptions for the initial state thus range from very simplistic models that assign deposited energy densities based on the wounded nucleons or binary collisions determined in a Monte-Carlo Glauber prescription, to classi-

cal effective theories of QCD that are valid in the high energy limit. The major ingredient that needs to be provided by an initial state model is the geometry of the interaction region in the plane transverse to the beam. It is entirely dominated by the positions of incoming nucleons whose fluctuations also play an important role.

Initial conditions for hydrodynamic simulations have to provide, in principle, all components of the energy momentum tensor as a function of spatial position (and initial conditions for other conserved charges, if considered). This includes, apart from the always included energy density distribution, the initial flow as well as initial viscous corrections. Initial flow is included in many recently developed models, that either assume free streaming [182], including Yang-Mills evolution, which is close to free streaming [210] or an initial flow distribution motivated by strong coupling calculations [211]. Initial viscous corrections are often set to zero. Only a few works [182,212,213] include the full viscous stress tensor provided by the initial state description.

Since the initial state models that provide the entire $T^{\mu\nu}$ all switch from essentially a freely streaming system to strongly interacting hydrodynamics at a fixed time τ, that transition is somewhat abrupt and unphysical. To improve over this situation an intermediate step using effective kinetic theory has been introduced [214, 215]. This procedure allows for a somewhat smoother matching but has yet to be used in full fledged hydrodynamic simulations. A first study that matches full kinetic theory to full viscous fluid dynamics indicates that the intermediate kinetic transport formulation becomes more important with decreasing system size [216].

As already discussed in Section 4.2.2, the choice of initial state has a significant effect on the extraction of transport coefficients. A more compact initial state and the presence of initial flow lead to a larger transverse flow, which requires a larger bulk viscosity to compensate for it and produce agreement with experimental data [213]. In addition the initial flow also affects the value of the extracted shear viscosity. Also, the models' eccentricities will affect the final momentum anisotropies, influencing the extracted shear viscosity to entropy density ratio. Two possible attempts to solve this problem have been pursued: the first is to perform a combined Bayesian analysis of all parameters [182], including those of the initial state, to find the best fit for all transport coefficients along with the initial state description. The second is to constrain an initial state description as well as possible using data from experiments other than heavy ion collisions e.g. e–p scattering data, which will hopefully be extended to e–A in a future electron ion collider facility. As mentioned above, at the moment the two approaches lead to some similar features of the initial state (product of thickness functions, presence of subnucleon structure), but also show discrepancies (size of the nucleon and sub-nucleon scales along with the size of the extracted bulk viscosity). In the near future, flow measurements in light ion collisions such as Ar–Ar, O–O etc. can also provide independent experimental constraints on initial conditions (see Section 4.3.2). Similarly, new flow observables can also help constrain the initial conditions. In particular the measurement of flow fluctuations has provided constraints on initial geometry models, in both the approaches discussed above. Analogously, the more recent studies of longitudinal flow fluctuations [217–219] and their extensions in Run 3 and 4 (see Section 4.3.3) can provide additional constraints.

4.2.4 Response functions

In a fluid dynamic description of heavy ion collisions, one can understand the azimuthal harmonic flow coefficients $v_{\rm n}$ as a response to deviations of the initial state from an azimuthally isotropic form. Mathematically, one can formulate this in terms of response functions that describe how the solution of the fluid dynamic evolution equations, as well as resulting experimental observables such as azimuthal particle distributions, get modified when the initial values of the fluid fields are changed [220–222]. In the simplest implementation, linear response functions describe the linear response of flow coefficients to eccentricities $v_n \sim \epsilon_n$, while the quadratic response functions describe terms like $v_n \sim \epsilon_a \epsilon_b$ where symmetry reasons imply $|n| = |a \pm b|$ [223,224]. Response functions can not only be used to study deviations

from azimuthal rotation symmetry but also for deviations from (approximate) Bjorken boost invariance, vanishing baryon number density, for electric fields and so on. Quite generally, response functions carry interesting information about fluid properties such as thermodynamic and transport properties. Where the response functions are known, one can infer properties of the initial state by reverse engineering. Experimentally, one can constrain properties of response functions indirectly via measurements of various particle correlation functions. It is particularly interesting to compare situations with strong deviations from a symmetry (such as peripheral collisions for the case of azimuthal rotation invariance) to situations with small deviations (such as central collisions) in order to differentiate between linear and non-linear response. For existing experimental work in this direction see [225–227] and for an example of a recent further going theoretical proposal see [228].

Detailed comparison of flow observables between experiment and theoretical calculations, especially regarding the dependence on external parameters like system size and collision energy as well as differential information such as on centrality, or particle identification will be helpful to make further progress in constraining response functions. Improvements in particle identification, transverse momentum and longitudinal coverage in Run 3 and 4 will be particularly valuable to this end.

4.3 Experimental constraints from Run 3 and 4

Since measurements of flow and correlations provide arguably the most direct manifestations of collectivity, they play naturally a central role in the scientific programme of exploring finite temperature QCD via collectivity. At the HL-LHC, much more stringent tests of the collective dynamics in nucleus–nucleus collisions will be possible. These will constrain QGP medium properties and initial conditions, as discussed in the previous section, in great detail. In the following, these newly arising opportunities are illustrated with a set of physics performance studies exploiting: 1) high-statistics particle-identified flow measurements, 2) system-size dependence of flow, and 3) longitudinal flow fluctuations.

4.3.1 Identified particle v_n

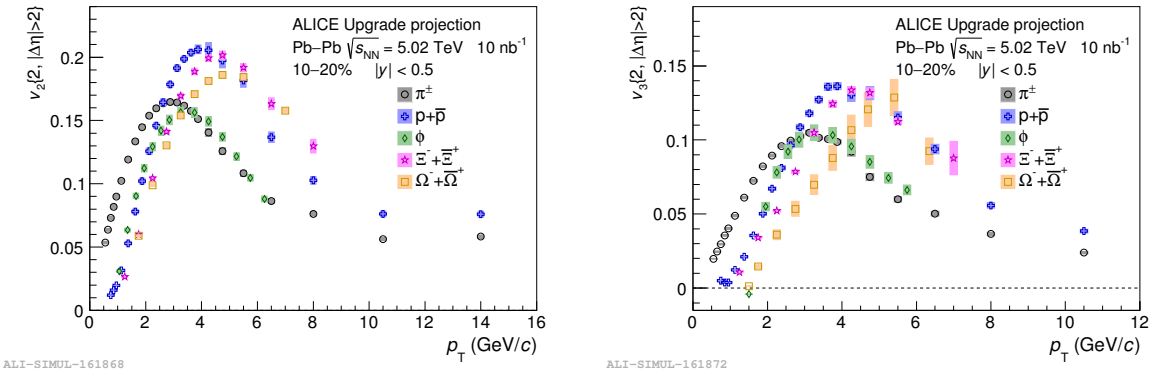

Fig. 8: ALICE projections for v_2 (left) and v_3 (right) of $\pi^{\pm}$, p+$\overline{\text{p}}$, Ξ+$\overline{\Xi}$, Ω+$\overline{\Omega}$, and the ϕ-meson in the 10–20% centrality interval for an integrated luminosity of 10 nb^{-1}. Error bars (shaded boxes) represent the projected statistical (systematic) uncertainties. Figures from Ref. [1].

In a fluid dynamic picture of A–A collisions, hadrons decouple from the fluid at late times, when the density of the system is sufficiently low and the mean-free path is sufficiently large so that a fluid dynamic description ceases to apply. Therefore, it is a direct consequence of this late time-scale, that the PID-dependence of v_n measurements tests a limitation of fluid dynamic behavior. Do all hadron

species emerge from the same common flow field? Or can one see at the higher accuracy of future v_n measurements particle specific differences in the decoupling which are related to the differences in hadronic cross sections? Quantitative questions of this kind will allow one to better constrain how significant the hadronic stage of A–A collisions contribute to v_n, and since the viscous properties of QCD change significantly in the hadronic stage, this is of direct relevance for extracting information about viscous transport coefficients with higher precision. The same class of improved PID-sensitive v_n measurements is also important for testing different dynamical pictures of hadronization. In particular since fragmentation is expected to be the dominant hadronization mechanism at high p_T while recombination becomes relevant at lower p_T, extending these PID measurements with precision over the largest possible transverse momentum range will be of interest. To this end, figure 8 shows projections from the ALICE collaboration for the v_2 and v_3 of several light-flavor species, that are expected for an integrated luminosity of 10 nb^{-1} expected in Run 3 and 4. The projected statistical uncertainties are typically negligible over the entire p_T range and in most cases the systematic uncertainties are quite small as well. These measurements will be much more precise compared to those in Run 1 and 2, and will allow for the recombination/fragmentation descriptions to be examined with unprecedented accuracy. Similar projections for heavy-flavor particles are discussed further in Chapter 5 together with their physics implications.

4.3.2 System size dependence

In Pb–Pb collisions, previous v_n measurements at the LHC have accessed the system size dependence of flow via the centrality dependence. However, this centrality dependence is biased by a strong variation of the spatial eccentricity of the nuclear overlap. While modelling allows one to control this eccentricity dependence to some extent, studying smaller collision systems at highest centrality (i.e. impact parameter close to zero) remains conceptually the cleanest way of establishing the system size dependence of flow. It also provides a way of disentangling the event-averaged spatial eccentricity from the event-by-event eccentricity fluctuations, and can thus contribute significantly to constraining the initial condition from which collective behaviour emerges. These are important motivations for studying soft multi-particle production and its transverse asymmetries in the collision of lighter nuclei.

Figure 9 shows ATLAS comparisons of the v_n in Xe–Xe and Pb–Pb collisions as a function of centrality (left panels) and their ratios (right panels). Also shown for comparison in the right panels are theoretical predictions for the ratios from Ref. [229]. It is seen that in most central collisions the ratio v_n (Xe–Xe)/v_n (Pb–Pb) is larger than unity for $n = 2$ and 3. With decreasing centrality the ratios for all harmonics show a decreasing trend. These trends can be explained as follows: Xe–Xe being a smaller system than Pb–Pb, the effect of fluctuations is more important. The fluctuations increase the initial eccentricities of the collision geometry and therefore enhance the v_n. However, because Xe–Xe is a smaller collision system the viscous effects (which suppress the v_n) are larger, and play a bigger role with decreasing centrality and increasing harmonic order. In most central events, the effect of the increased fluctuations wins for v_2. But with increasing harmonic order and/or decreasing centrality, eventually the viscous effects reduce the v_n compared to Pb–Pb. These observations indicate the ability of such cross-system v_n measurements to be very sensitive to initial conditions of the heavy ion collision as well as the transport coefficients of the QGP. The measured ratios for the v_n (Xe–Xe)/v_n (Pb–Pb) are qualitatively reproduced by the theory predictions from Ref. [229]. In order to illustrate the sensitivity of such models to the collision species, predictions are also presented for Ar–Ar and O–O collisions. The predictions show considerably larger variation of the centrality dependence of the v_n going from Xe–Xe to Ar–Ar to O–O, as compared to the variation going from Pb–Pb to Xe–Xe. Given such strong trends in the theory predictions, performing v_n measurements in light ion species such as Ar–Ar and O–O in Run 3 can provide strong constrains on the theoretical models.

Furthermore, there has been much work in studying long-range correlations observed in p–A,

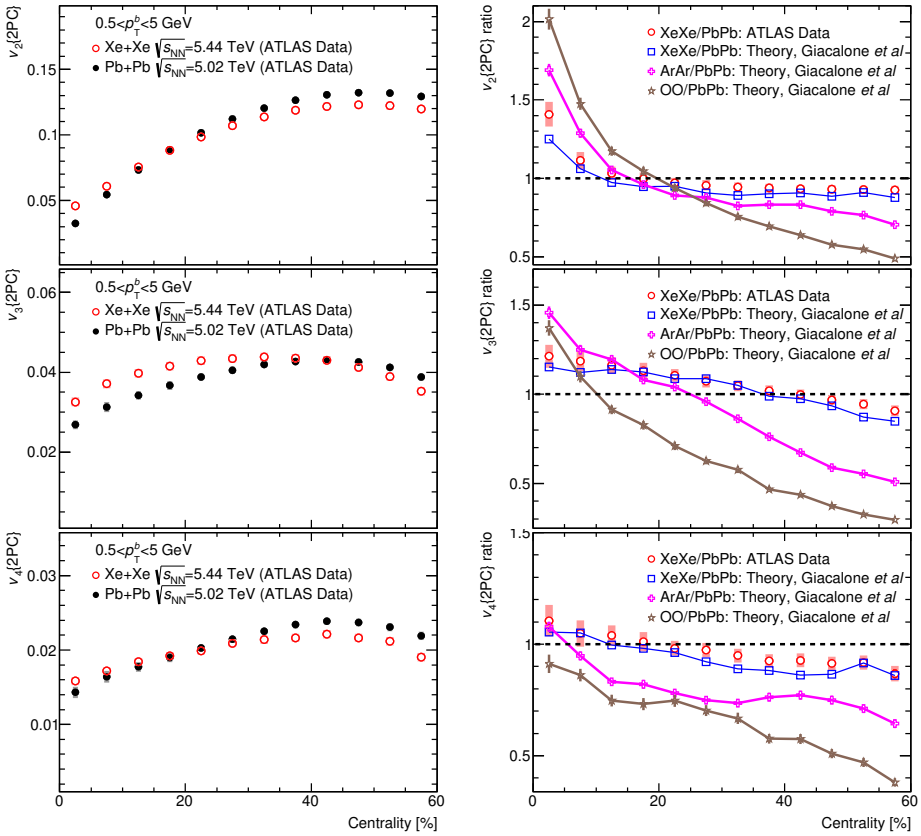

Fig. 9: Left panels: comparisons of the centrality dependence of the v_{n} measured in Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}}$=5.02 TeV to Xe–Xe measurements. The plots are for the 0.5–5 GeV/c p_{T} interval. From top to bottom each row corresponds to a different harmonic order n. The ratios are compared to theoretical predictions from Ref. [229]. Also shown are theory calculations of the ratios for Ar–Ar and O–O. ATLAS Data taken from Ref. [230].

d–A, ^{3}He–A, and more recently in pp collisions (see Chapter 9). Measuring flow in medium and light ions would allow for a continuous study of how collective phenomena vary from large (Pb–Pb) to small (p–A and pp) systems.

4.3.3 Longitudinal flow fluctuations

The characterization of how the longitudinal scales at which the symmetry planes Ψ_n associated to v_{n} decorrelate, and how this relates to the variation of the signal strength v_{n} with rapidity is still far from the state of the art reached in v_{n} measurements at mid-rapidity. However, any deviation from the simple picture of a rapidity-independent (Bjorken-like) longitudinal dynamics directly impacts our understanding of the time evolution of matter in all rapidity windows, including the well studied mid-rapidity one. Multiple recent measurements at the LHC indicate the presence of considerable longitudinal dynamics. These include measurements from CMS of event-plane decorrelation in p–Pb and Pb–Pb collisions [217, 218] and from ATLAS on flow-decorrelations [219] and forward-backward multiplicity fluctuations [231]. It is therefore important that experiments at the HL-LHC will parallel higher precision measurements at mid-rapidity with improved experimental control over the longitudinal evolution.

In the ATLAS measurements in Ref. [219], the flow decorrelation is quantified by constructing a

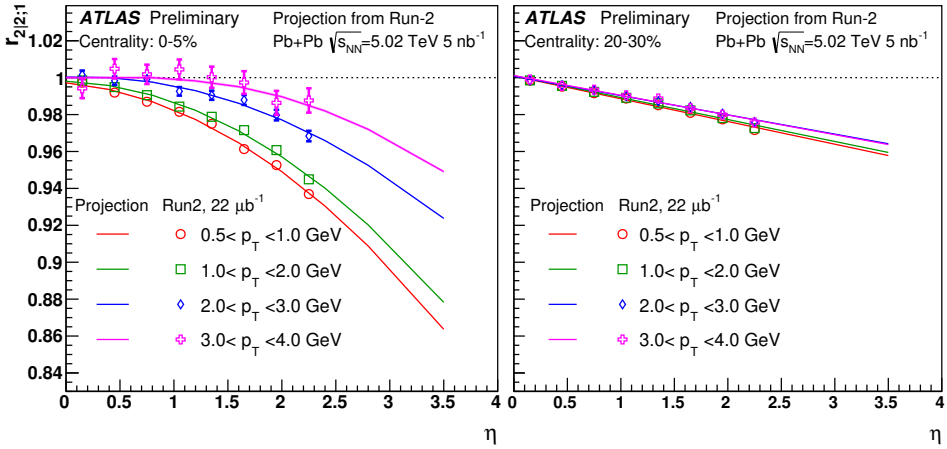

Fig. 10: ATLAS projections of the flow-decorrelation observable $r_{2|2;1}$ as a function of η (lines). The markers indicate the present measurements from Ref. [219]. The left and right panels show projections for the 0–5% and 20–30% centrality intervals, respectively. The width of the projection bands indicates the expected statistical uncertainty.

correlator $r_{n|n;1}$ defined as:

$$r_{n|n;1}(\eta) = \frac{\langle \mathbf{v}_n(-\eta)\mathbf{v}_n^*(\eta_{\rm ref})\rangle}{\langle \mathbf{v}_n(\eta)\mathbf{v}_n^*(\eta_{\rm ref})\rangle}, \tag{16}$$

where $\mathbf{v}_n$ is the normalized flow vector, and $\eta_{\rm ref}$ is the reference pseudo-rapidity [219]. The correlator, $r_{n|n;1}$, measures the relative difference between flow $v_n e^{in\Psi_n}$ at η and $-\eta$. If flow were boost-invariant, then $r_{n|n;1}$ would equal unity. However any difference in the η dependence of the flow magnitude $v_{\rm n}$ and the event plane angle Ψ_n will lead to $r_{n|n;1}$ become smaller than unity. The ATLAS measurements of $r_{2|2;1}$ over the 0–2.5 η range are shown in Figure 10 by the markers. It is observed that the $r_{2|2;1}$ is significantly smaller than unity in central collisions, which indicates stronger flow decorrelation. For a given centrality, $r_{2|2;1}$ decreases faster at low $p_{\rm T}$ that at higher-$p_{\rm T}$. In the 20–30% mid-central $r_{2|2;1}$ decreases linearly with η, however in the 0–5% most central collisions there are indications that the decorrelations are possibly quadratic.

Repeating this measurement in Run 4 will lead to significant improvements due to increased luminosity and especially due to increased tracking acceptance in η to ± 4 units. Figure 10 also shows the ATLAS projections for $r_{2|2;1}$ made for Run 4, indicated as dashed lines. The ATLAS tracking acceptance in Run 4 will extend the η range to ± 4 units, but the projected measurement is made to ± 3.5 units, in order to leave a gap between the ITk and the region of the forward calorimeter in which the reference measurement is made ($4.4 < |\eta| < 4.9$). The projections are made by fitting the existing data with a linear function for the 20–30% centrality range and with a quadratic function for the 0–5% centrality range. It is seen that with the increased η acceptance the non-linearity in the flow decorrelation can be studied in much more detail.

The longitudinal flow-decorrelation observables are sensitive to the event by event fluctuations of the initial energy density profile in the longitudinal direction. Thus precise measurement of these decorrelations should give a better understanding of the initial conditions along the longitudinal direction and in the development of full three-dimensional viscous hydrodynamic models. These would in turn result in a more accurate estimation of η/s.

4.4 Vorticity and polarization

An interesting open question for relativistic fluids is to what extent the spin degrees of freedom thermalize locally and to what extend spin polarization results as a consequence of the fluid motion. Intuitively, one might expect that spin aligns locally with the rotational motion of the fluid as measured by vorticity, corresponding to the curl of the fluid velocity.

The relativistic generalization of the non-relativistic fluid vorticity is not unambiguous, however. The vorticity of a fluid in local equilibrium is characterized by the so-called thermal vorticity tensor, corresponding to $\omega_{\mu\nu} = \frac{1}{2}(\nabla_\nu \beta_\mu - \nabla_\mu \beta_\nu)$ where $\beta_\mu = u_\mu/T$ is the ratio of fluid velocity to temperature [232]. This thermal vorticity includes contributions from global rotational motion, local fluid acceleration, and temperature gradients. It has been argued that this thermal vorticity should lead to local spin polarization. If this holds at chemical freeze-out, one should be able to find traces of the thermal vorticity in the spin polarization of particles and resonances, such as Λ ($\overline{\Lambda}$) particles.

Spin polarization is in this picture closely tied to angular momentum of the expanding fireball. For non-central events, the angular momentum of the produced matter is perpendicular to the event plane. Via the spin-vorticity coupling mechanism, this leads to a global polarization in the transverse plane aligning with the global angular momentum (also known as the "transverse polarization"). This global transverse polarization has recently been observed in the measurement of Λ spin polarization at RHIC [233]. For this global effect following global angular momentum, one expects a decreasing magnitude with increasing collision energy and the effect is expected to be relatively small at LHC energies.

Figure 11 shows the energy dependence of the global transverse polarization of Λ and $\overline{\Lambda}$ for semi-central heavy ion collisions. The RHIC results show the decrease of polarization with increasing $\sqrt{s_{\rm NN}}$. The preliminary ALICE data point at $\sqrt{s_{\rm NN}} = 2.76$ TeV is consistent with zero within 1σ statistical/systematic uncertainties. However it is also consistent with the predicted maximum value (blue line) within $\sim 2\sigma$ statistical/systematic uncertainties. But the ALICE upgrade projection at twice large collision energy, (assuming zero signal) shows that the polarization in Run 3 and 4 can be measured with very high precision. Therefore the study of global polarization of Λ and $\overline{\Lambda}$ within HL–LHC project allows the unambiguous conclusion with regard of the values of this physics quantity in the TeV-energy domain.

In addition to the transverse polarization, an azimuthal-dependent, longitudinal polarization (in the direction of the beam pipe) has also been predicted and recently observed at RHIC [236]. This is mainly a consequence of an azimuthal dependence of local acceleration and temperature gradient (e.g., the elliptic flow), which could lead to an elliptic modulation of longitudinal spin polarization in non-central collisions. Unlike the global transverse polarization, this longitudinal polarization effect has a much weaker dependence on collision energy from RHIC to the LHC [237], mainly because the anisotropic flow has a weak collision energy dependence. With increased data sample and upgraded detectors covering a wider rapidity range in the HL–LHC era, there will be exciting opportunities for precision study of the Λ polarization and to map out the dependence on variables such as azimuthal angle, rapidity, transverse momentum.

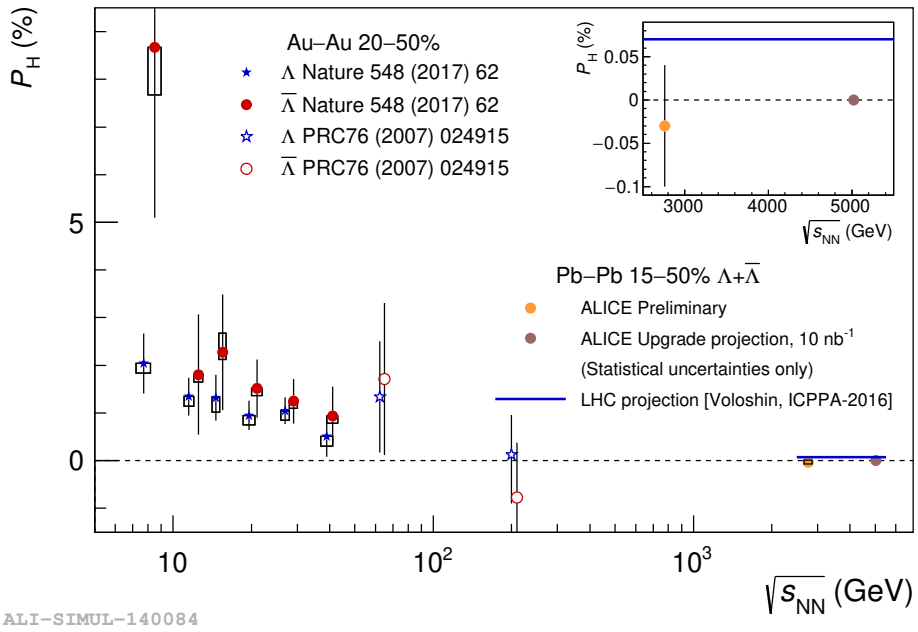

Fig. 11: ALICE projections for the Global hyperon polarization in Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 2.76$ TeV for an integrated luminosity of 10 nb^{-1} (blush symbol), together with the present measurements (orange symbol) compared to analogous measurements at various collision energies from the STAR collaboration [233, 234] (blue and red symbols). The blue line indicates the prediction for the maximum value at the LHC [235]. The inlay plot shows a zoomed in version of the plot around the ALICE measurement and Run 3 and 4 projection, together with the prediction for the maximum value at the LHC. The points for $\overline{\Lambda}$ are slightly shifted along the horizontal axis for visibility. Error bars (open boxes) represent the statistical (systematic) uncertainties. Figure from Ref. [1].

4.5 Chiral Magnetic Effect

An important property of the strong interaction which is potentially observable in heavy-ion collisions is parity violation. Although it is allowed by quantum chromodynamics (QCD), global parity violation is not observed in strong interaction. However, QCD predicts the existence of topologically non-trivial configurations of the gluonic field, instantons and sphalerons, which might be responsible for local parity violation in microscopic QCD domains at finite temperature [238–241]. The P- and CP-odd interactions between quarks and such fields with non-zero topological charge [242] change the quark chirality, breaking parity symmetry by creating an imbalance between the number of left- and right-handed quarks. Furthermore, an extremely strong magnetic field is expected to be produced in heavy-ion collisions [243, 244] (of the order of 10^{19} Gauss at the LHC) because the charges of initial ions add coherently. This strong magnetic field aligns the spins of the positively (negatively) charged quarks in the direction parallel (anti-parallel) to magnetic field orientation. Moreover, right-handed (left-handed) quarks have their direction of momentum parallel (anti-parallel) to the spin orientation. The spin alignment coupled with the local imbalance between the number of left- and right-handed quarks leads to the development of a quark current. The current moves the positively charged quarks along its direction and the negatively charged quarks in the opposite direction. This implies a charge separation along the direction of the magnetic field, which is on average perpendicular to the reaction plane, a phenomenon called Chiral Magnetic Effect (CME) [245–248].

The sign of the topological charge can give rise to a positive or negative current in the magnetic

field direction with equal probability. Therefore, the charge separation averaged over many events is zero. This makes the observation of the CME experimentally difficult and possible only via azimuthal particle correlations, which introduces a large flow related background into the measurements.

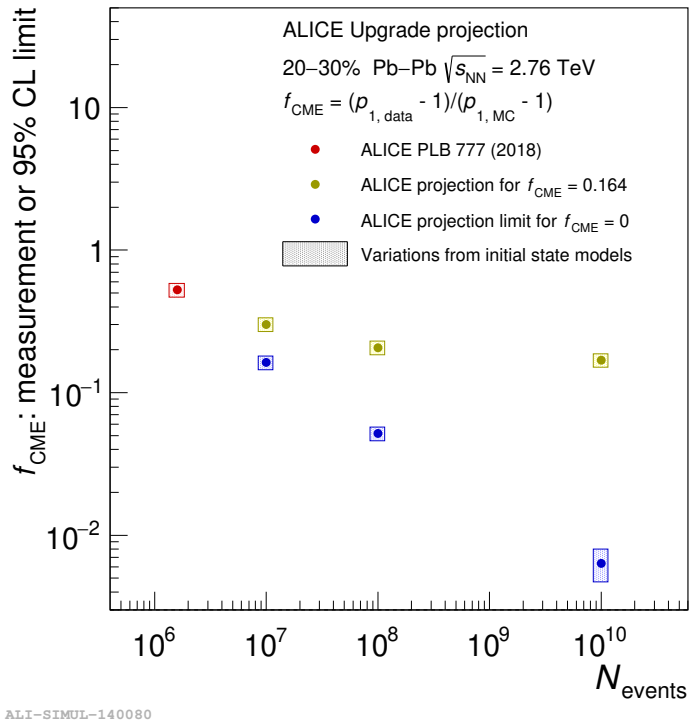

Fig. 12: ALICE projections for the upper limit on the CME fraction at 95% confidence level as a function of the number of events in the 20–30% centrality interval. The right-most projection point corresponds to an integrated luminosity of 10 nb^{-1}. The result reported by the ALICE collaboration [249] is shown together with expectations for $f_{\rm CME} = 0.164$ (current estimate) and $f_{\rm CME} = 0$ (null hypothesis). The shaded boxes denote variations from various initial state models (see text for details). Figure from Ref. [1].

The three-particle correlator $\gamma_{\alpha\beta} = \langle\cos(\varphi_\alpha + \varphi_\beta - 2\Psi_2)\rangle$ [250], where φ_α is the azimuthal angle of the particle of charge α and Ψ_2 is the second harmonic symmetry plane angle, was proposed to measure charge-dependent azimuthal correlations. This correlator eliminates correlations independent of symmetry plane orientation, suppressing background contributions at the level of $\sim v_2$. However, the interpretation of the experimental results is complicated by the remaining background (e.g. local charge conservation (LCC) coupled with elliptic flow [251,252]). Recent observation of similar charge-dependent azimuthal correlations in p–Pb (where the CME is not expected) and Pb–Pb collisions [253] indicates the $\gamma_{\alpha\beta}$ correlator be dominated, if not all, by the background effect. The ALICE [249] and CMS [254] collaborations have used the Event Shape Engineering (ESE) technique [255] to estimate the CME fraction to the charge dependence of $\gamma_{\alpha\beta}$, $f_{\rm CME}$, in Pb–Pb collisions. ALICE extracted $f_{\rm CME}$ by relating measurements of the charge dependence of $\gamma_{\alpha\beta}$ from the ESE analysis to CME signal expectations from various initial state model calculations including a magnetic field. It has been assumed that the CME signal is proportional to $\langle|B|^2\cos(2(\Psi_{\rm B} - \Psi_2))\rangle$, where $|B|$ and $\Psi_{\rm B}$ are the magnitude and direction of the magnetic field, respectively. Within current experimental uncertainties, the CME signal contribution to the $\gamma_{\alpha\beta}$ correlator is consistent with zero.

Figure 12 shows the upper limit on $f_{\rm CME}$ at 95% confidence level for the 20–30% centrality

interval reported by the ALICE collaboration together with expectations for $f_{\mathrm{CME}} = 0.164$ (current estimate) and $f_{\mathrm{CME}} = 0$ as a function of the number of events. The shaded boxes denote variations due to different estimates of the magnetic field from the investigated models. The ALICE upgrade projection indicates that stringent constraints for the CME contribution to the charge dependence of $\gamma_{\alpha\beta}$ can be achieved at a level of less than 1% with the expected HL–LHC statistics.

One key ingredient needed for the observation of the CME is the strong magnetic field in the QGP medium. It is important to establish direct evidence for this field and determine its strength, which will help significantly constrain theoretical predictions on the magnitude of the CME signal. Measurement of the pseudorapidity-odd component of directed flow, v_1^{odd}, separately for positive and negative charged particles has been proposed as a probe to the magnetic field [244]. Any difference will indicate the presence of induced electromagnetic currents and will allow to estimate the magnitude of the effect. It will also provide information on the electric conductivity of the QGP medium.

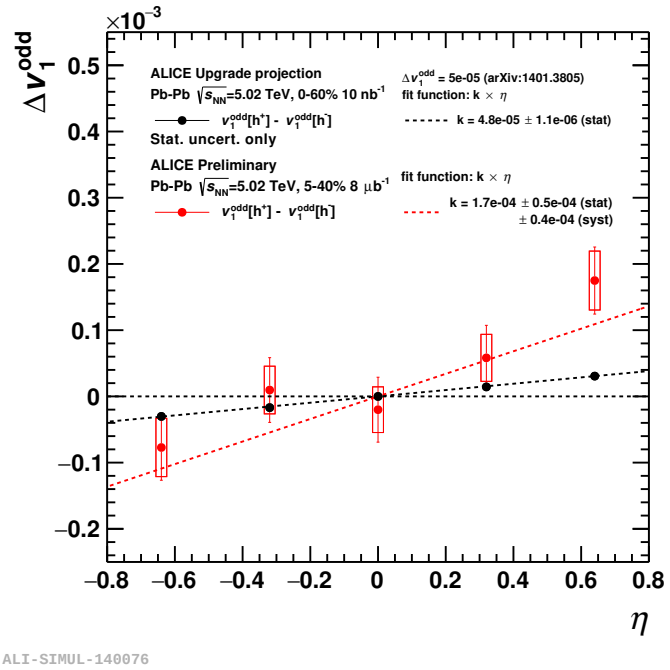

Fig. 13: Charge difference of v_1^{odd} as a function of pseudorapidity measured by the ALICE collaboration in Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV [256] (red symbols) and the projection for a 5×10^{-5} difference [244] from 10 nb^{-1} (black symbols) together with linear fits (dashed lines). Error bars (open boxes) represent the statistical (systematic) uncertainties. Figure from Ref. [1].

Figure 13 shows the charge difference of v_1^{odd}, $\Delta v_1^{\mathrm{odd}} = v_1^{\mathrm{odd}+} - v_1^{\mathrm{odd}-}$, as a function of pseudorapidity measured by the ALICE collaboration in Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV [256] together with a linear fit. A hint of a charge-dependent difference is observed and quantified by the slope k with a total significance of 2.6 σ. This difference, which differs both in magnitude and sign compared to predictions for $\pi^{\pm}$ at $\sqrt{s_{\mathrm{NN}}} = 2.76$ TeV and similar $\langle p_{\mathrm{T}} \rangle$ [244], needs to be measured with better precision. This will be achieved with the large data sample expected at the HL–LHC which will be sensitive to a difference as small as 5×10^{-5} (about three times smaller that the current measurement), as reported by the ALICE upgrade projection in Fig. 13. Furthermore, similar measurement can also be performed in the heavy flavor sector, e.g., for D^0 and $\overline{\mathrm{D}^0}$ meson directed flow [257], this is further discussed in Chapter 5. Heavy flavor quarks have the advantage of being produced at a very early stage, and thus

potentially have a better sensitivity to the magnetic field at its evolution at early time.

4.6 Summary

The measurements of inclusive hadron $v_{\rm n}$ by traditional methods such as two-particle correlations, event-plane/scalar-product methods, multi-particle cumulants etc. have been performed with high precision by the ALICE, ATLAS and CMS experiments at the LHC. These inclusive hadron $v_{\rm n}$ measurements are not statistically limited across most of the centrality-$p_{\rm T}$ phase space and further improvement in the measurements is not a high priority for Run 3 and 4. However, in the case of identified hadrons the increased statistics will lead to further improvement in the $v_{\rm n}$ measurements. This is true for both light hadrons such as pions, protons, ϕ-mesons as shown in Figure 8, as well as for heavy-flavor particles such as $\rm D^0$, $\rm D^{\pm}$, J/ψ, Υ which are discussed in Chapters 5 and 7, respectively. Significant improvements are expected in measurements of longitudinal flow fluctuations, which have only been briefly investigated in Run 1 and 2. These are largely driven by the increases η acceptance of the ATLAS and CMS tracking detectors in Run 4, the acceptance is planned to reach $\pm$5 units. The study of longitudinal flow fluctuations will allow comparisons to predictions of 3+1D hydro models. Flow measurements in light ions such as Ar–Ar and O–O, will lead to stronger constraints on theoretical models describing different stages of a heavy ion collision – initial conditions, equation of state, transport coefficients etc. This is difficult presently, as flow observables are dependent on all of these, so it becomes difficult to constrain any one of these without full knowledge of the others. Flow measurements across a variety of colliding species will provide independent data that will improve our understanding of the different stages of heavy ion collisions. Further physics motivations for colliding light ions are discussed in Chapter 11.1.

Other observables related to collective phenomena where current measurements are statistics limited and are expected to improve considerably are related to effects of vorticity and magnetic fields. The current measurements of Λ polarization from ALICE are statistics limited and consistent with both the null hypothesis as well as with the theoretically predicated value. The ALICE projections for Λ polarization in Run 3 and 4 show that the measurements will have significantly smaller statistical uncertainties and will differentiate between the null and predicted values. ALICE and CMS have measured the fraction of the three-particle correlator $\gamma_{\alpha\beta}$ that arises from CME effects: $f_{\rm CME}$. The measured $f_{\rm CME}$ by ALICE is consistent with zero but due to large uncertainties its upper limit at 95% CL can be as large as $\sim$0.5. ALICE projections for Run 3 and 4 show that the $f_{\rm CME}$ can be determined with a precision of better than 1%.

5.1 Perspectives for heavy-flavour observables in LHC Run 3 and 4

Charm and beauty quarks are produced in hard scattering processes occurring in the early stage of heavy-ion collisions. They subsequently traverse the QGP medium and interact with its constituents through inelastic (gluon radiation) and elastic (or collisional) processes. These interactions may lead to the thermalisation of low-momentum heavy quarks, which would thus take part in the expansion and hadronisation of the medium. For these reasons, heavy-flavour hadrons provide information on all stages of the system evolution and they uniquely probe the quark-mass dependence of the QGP inner workings (see Refs. [258–260] for recent reviews).

Many experimental observations from RHIC and LHC showed evidence that charm and beauty quarks interact strongly with the QGP and that beauty quarks lose less energy at low transverse momentum compared to charm quarks [261, 262]. While data are becoming more and more precise to start imposing constraints on theoretical calculations, there are still several unresolved questions: What are the microscopic mechanisms that drive heavy-flavour interaction and diffusion in the QGP, and what are their implications for the QCD matter structure? What is the relative relevance of collisional and radiative processes? Can the same QCD process can describe both the heavy-quark interaction with the strongly coupled plasma and the mechanisms of hadronisation?

The Run 3 and 4 of the LHC will open a new precision era for heavy-flavour measurements in heavy-ion collisions that will address the above questions. With the upgrades of the machine and of the tracking detectors, the higher accumulated statistics and higher precision will make it possible to quantify the properties of the QGP with heavy-flavour probes. This high-precision era will also make new and more differential observables accessible for the first time. The key measurements that are expected to have a strong impact on the characterisation of the QGP with heavy-flavour observables are discussed in this chapter and summarized below.

– Nuclear modification factor and flow harmonics: these measurements for particles with charm and beauty in the large kinematic range covered by combining the different LHC experiments will put the strongest constraints on the transport coefficients of the QGP, clarifying the microscopic

mechanisms governing the interactions of heavy quarks with the medium, and quantifying their degree of thermalisation.

– Strange D and B mesons, charm and beauty baryons: currently limited by statistics, these measurements will help to quantify not only the degree of thermalisation of heavy quarks, but also the contribution of recombination with lighter quarks to the hadronisation process. They are also sensitive to the mass scaling of the hyrodynamical flow in the heavy-flavour sector.
– Heavy-flavour correlations and jet observables: they will provide new insights on the parton mass effects in parton showers, on the redistribution of the radiated energy, and on the role of collisional and radiative energy loss.

5.2 Impact of detector upgrades on heavy-flavour measurements

The upgrades of the four large LHC experiments during LS2 and LS3 will strongly enhance their performance for open heavy-flavour measurements. The detector improvements that will have the largest impact are the new silicon trackers, with higher granularity and precision, as well as extended pseudo-rapidity coverage. Brief descriptions of these improvements are reported in the following.

– ALICE. The new Inner Tracking System [263], which will be installed during LS2, is composed of seven layers of pixel detectors with an intrinsic spatial precision of about 5×5 μm^2 and a material thickness of 0.3% of the radiation length in the innermost layers. The track pointing resolution will be improved by a factor 3 in the direction transverse to the beam line and by a factor 5 in the longitudinal direction, down to values of about 20 μm for tracks with $p_{\mathrm{T}} = 1$ GeV/c. A Muon Forward Tracker [4], composed of 5 disks of pixel detectors with the same spatial resolution as the Inner Tracking System, will instrument the region $2.5 < \eta < 3.6$, in front of the muon spectrometer, enabling the separation from the primary vertex of single and dimuons from D, B and J/ψ decays. The upgraded TPC with GEM-based readout chambers, together with readout upgrades of several other detectors and with a new Online-Offline computing system, will enable the full recording of Pb–Pb interactions with a minimum-bias trigger at a rate of 50 kHz, which is 50-fold larger than for the present apparatus.
– ATLAS. The Inner Tracker (ITk) [264] will be an all-silicon tracker composed of pixels and strips installed during LS3 for ATLAS phase II. The ITk will provide charged-particle tracking acceptance for $|\eta| < 4$. The performance of the ITk in Pb–Pb collisions is expected to be comparable to pp collisions. The High Granularity Timing Detector [265] has been proposed to complement the spatial information of the ITk with timing information. These detectors will improve jet reconstruction capabilities, and in particular tagging of heavy-flavour jets, as well as all studies using charged particles.
– CMS. The following upgrades scheduled for LS3 will largely enhance the performance for heavy-flavour measurements, in particular in the low-momentum region [266]. The upgraded inner tracker will cover a large acceptance up to $|\eta| < 4$ [267]. The improved L1 and DAQ rate (up to 60 GB/s) will allow more sophisticated triggers and to record a larger number of minimum-bias triggered events. In addition, the proposed MIP Timing Detector [268] with a radius of 1.16 m and a time resolution of ≈ 30 ps could provide, in conjunction with other detectors, proton, pion and kaon separation in the interval $0.7 < p_{\mathrm{T}} < 2$ GeV/c in $|\eta| < 1.5$.
– LHCb. The experiment is preparing to run at five times larger instantaneous luminosities in pp collisions, processing the full event rate with a software trigger and preserving or exceeding the present performance. All tracking detectors will be upgraded during LS2 [269,270]. Most notably for heavy-flavour observables, the active area of the upgraded Vertex Locator, the pixel detector replacing the present silicon strip detector, will move as close as 5.1 mm to the nominal beam spot. The larger granularity for the majority of phase space will improve the performance in Pb–Pb

collisions whereas proton-induced reactions will result in average in lower detector occupancies than the standard pp running.

5.3 Nuclear modification factor and collective flow

The standard observable used to study the medium effects on heavy-flavour meson production is the nuclear modification factor ($R_{\rm AA}$), defined as the ratio of the Pb–Pb yield to the pp cross-section scaled by the nuclear overlap function. In the view of the pQCD-based models, heavy quarks interact with the medium constituents via radiative and collisional processes. While radiative interactions only lead to energy loss, collisional ones can also result in an increase of the heavy-quark momentum. The dead-cone effect [271] is expected to reduce small-angle gluon radiation of heavy quarks when compared to both gluons and light quarks. At low $p_{\rm T}$, the production rate of heavy-flavour mesons in heavy-ion collisions is sensitive to the elastic energy loss of the heavy quark in medium, the nuclear shadowing effect in the initial state, and the recombination of the heavy quark with light quarks at the hadronization stage. At high $p_{\rm T}$, the nuclear modification factor is sensitive to the medium-induced radiative energy loss of heavy quarks. Precise measurements of the $R_{\rm AA}$ thus provide insights on the momentum dependence of heavy quark energy loss, and provide important tests of QCD predictions, in particular for the expected flavour and mass dependence of the energy loss processes.

Another interesting observable is the azimuthal anisotropy of open heavy flavour production, which can be characterized by the Fourier coefficients v_n in the azimuthal angle (φ) distribution of the heavy-flavour hadron yield with respect to the reaction plane in non-central Pb–Pb collisions. At low $p_{\rm T}$, the v_2 measurements can provide important insights into the mechanisms of interaction of heavy quarks with the medium and on their strength (as discussed in more details in Sec. 5.3.2). Heavy quarks are indeed expected to acquire a positive v_2 mostly as a consequence of their interaction with the light quarks of the medium. Measurements of elliptic flow of heavy hadrons are also sensitive to hadronisation processes. In particular, they can be used to study the relevance of heavy-flavour recombination (see Sect. 5.4.1) in which heavy-quarks can acquire additional v_2 by combining with light quarks at the hadronisation stage. At high $p_{\rm T}$, v_2 of heavy-flavour hadrons is sensitive to the path-length dependence of heavy quark energy loss. The simultaneous description of $R_{\rm AA}$ and v_2 for heavy-flavour hadrons is still challenging for most of the theoretical calculations, because it entails accurate modelling of the initial heavy-quark production and its modification in nuclei, of the medium and its expansion, of the various quark-medium interaction mechanisms and of the possible modification of hadronisation processes.

5.3.1 Experimental performance of the ALICE, ATLAS and CMS experiments

Figure 14 shows the projected performance for the $R_{\rm AA}$ of several heavy-flavour hadrons or decay channels with $L_{\rm int} = 10\ {\rm nb}^{-1}$. The left panel presents the projection of charged particles, $\rm D^0$, $\rm B^+$ and non-prompt J/ψ from b-hadron decay which can be measured by CMS. The right panel shows the ALICE simulation results for $\rm D^0$, non-prompt J/ψ, non-prompt $\rm D^0$, $\rm B^+$ ($\rightarrow$ $\rm D^0\pi^+$) —in addition, the $\rm B^0 \rightarrow D^{*+}\pi^-$ reconstruction was studied by ALICE and it provides an alternative channel for the study of the beauty meson $R_{\rm AA}$ with a significance of larger than $5\,\sigma$ at $p_{\rm T} > 3$ GeV/c. With the high luminosity and the Inner Tracking System Upgrade in ALICE, the $R_{\rm AA}$ of light hadrons, charm hadrons and beauty hadrons can be clearly separated in a wide kinematic range.

Figure 15 shows the projected performance for v_2 of charm hadrons with $L_{\rm int} = 10\ {\rm nb}^{-1}$. The left panel shows the projection for $\rm D^0$ in CMS, with the charged particle v_2 also shown for comparison. The right panel presents the projection for $\rm D^0$, $\rm D_s$ and Λ_c in ALICE [263]. Precise measurements of charm hadron v_2 will allow the study of the thermalization of heavy quarks and the wide kinematic range allows to get insights on different process, as coalescence hadronization and energy loss. Figure 16 (left) shows

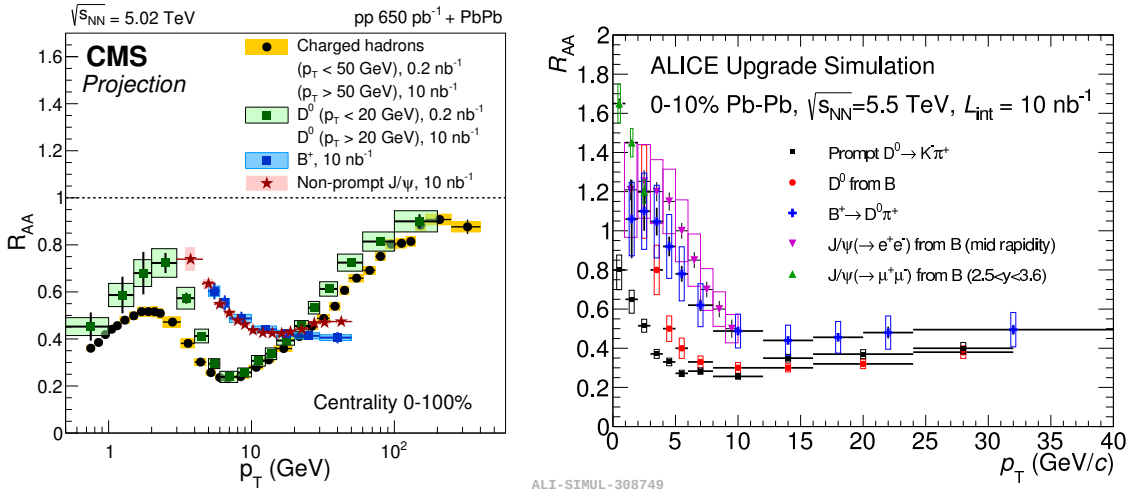

Fig. 14: Nuclear modification factors of charged particles, D^0, B^+ and non-prompt J/ψ in CMS [8] (left). R_{AA} of D^0, non-prompt J/ψ and non-prompt D^0 in ALICE in central Pb–Pb collisions for $L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$ [1, 263] (right).

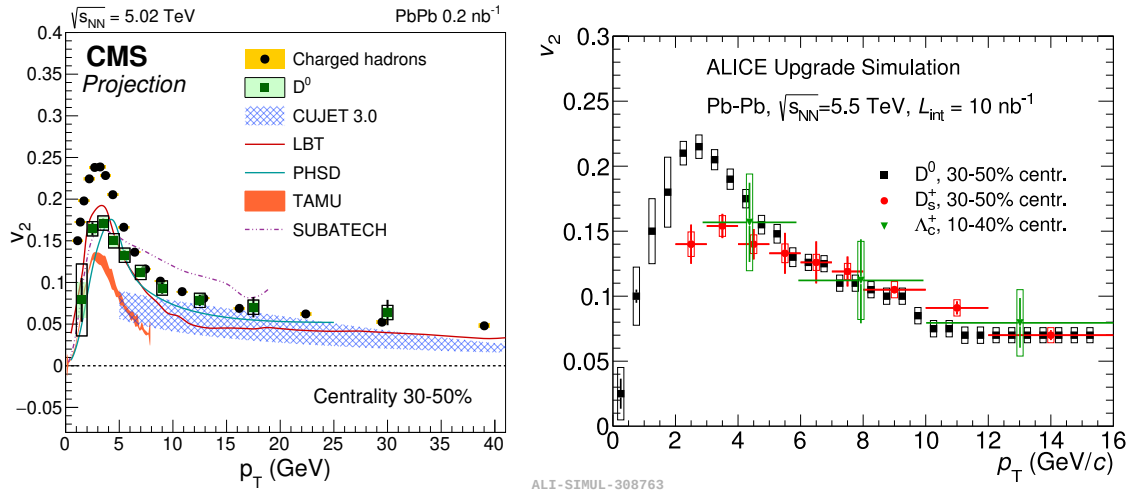

Fig. 15: v_2 of charged particles and D^0 in CMS [8] (left), charm hadrons (D^0, $\mathrm{D_s}$, Λ_c) in ALICE (right) in Pb–Pb collisions with $L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$ [1, 263].

the projected performance for v_2 of B^+ mesons, non-prompt D^0 and non-prompt J/ψ. These will be the first precise measurements of B meson elliptic flow at the LHC. Heavy-flavour flow will also be measured with high precision using decay electrons and muons. As an example the projection for the measurement with muons by ATLAS is shown in Fig. 16 (right) [6].

5.3.2 Constraining the heavy-quark diffusion coefficient $2\pi TD_\mathrm{s}$

Many theoretical efforts have been recently undertaken to understand the properties of the QGP medium and the interaction between heavy quarks and the medium constituents, see Refs. [258–260] for recent reviews. Although the interaction mechanism can widely vary among different theoretical models, the

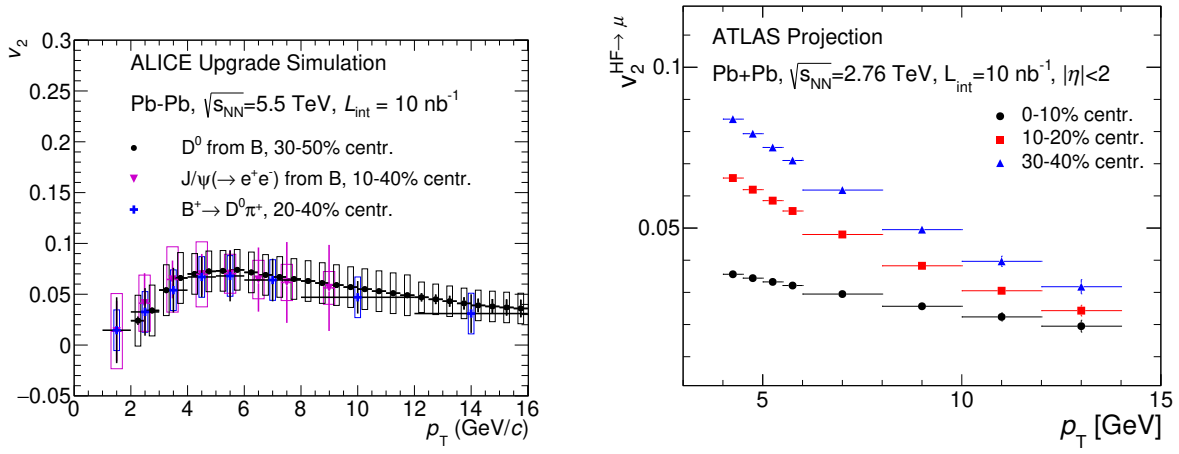

Fig. 16: v_2 of non-prompt D^0, non-prompt J/ψ and B^+ ($\rightarrow \mathrm{D}^0$) in ALICE (left) [1, 263] and of heavy-flavour decay muons in ATLAS (right) [6] in Pb–Pb collisions for $L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$.

reduction to a few transport coefficients allows one to compare these models and evaluate different microscopic pictures. Most of the present theoretical models explain the interactions of heavy quarks as dominated by collisional (elastic) processes in the low transverse momentum region (up to about 5–10 GeV/c) and by radiative energy loss (inelastic process with gluon radiation off the heavy quark) at higher p_{T}.

The extraction of the heavy-quark spatial diffusion coefficient, which is one of the main QGP properties regulating the strength of collisional processes, is considered here to illustrate the impact of the high-precision measurements in Run 3 and Run 4. In particular, the p_{T}-dependence of this coefficient provides important constraints on the weakening of the interaction strength with increasing p_{T}. For illustration, the extracted values of D_s is considered at a fixed p_{T} value. The heavy-quark spatial diffusion coefficient D_s in the QGP is related to the relaxation (equilibration) time of heavy quarks $\tau_{\mathrm{Q}} = \frac{m_{\mathrm{Q}}}{T} D_s$, where m_{Q} is the quark mass and T is the medium temperature [272].

Figure 17 shows the constraining power of future experimental measurements of R_{AA} and v_2 on the heavy quark diffusion coefficient ($2\pi T D_{\mathrm{s}}$) using two different transport models: Catania model with Fokker-Plank equation [273,274] on the left and a modified Langevin framework on the right [275]. The left figure presents a normalized χ^2 as a function of spatial diffusion coefficient by comparing the model calculation [273, 274] of D-meson R_{AA} in Pb–Pb collisions at 5.02 TeV in a single centrality class (0–10%). The cases of the present experimental uncertainties (2015 Pb–Pb sample) and of these uncertainties reduced factors of two or five are considered for illustration. In the projections for $L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$ shown in the previous section, the D-meson R_{AA} uncertainties are reduced by a factor between two and five, depending on p_{T}, with respect to the present measurements. Considering the $2\pi T D_{\mathrm{s}}$ range with $\chi^2_{R_{\mathrm{AA}}}/\mathrm{n.d.f} < 1.5$ (corresponding to 85% confidence), it is found that by reducing the present experimental uncertainty by a factor two or five, the uncertainty on the estimation $2\pi T D_{\mathrm{s}}$ would be also reduced almost to 50% or 20%, respectively. The right panel presents the diffusion coefficient as a function of temperature, which is estimated using a Bayesian calibration on D-meson R_{AA} and v_2 in Pb–Pb collisions at 5.02 TeV for different centralities. The $2\pi T D_{\mathrm{s}}$ shows a positive temperature dependence with the minimum value around T_{c}. Such behaviour is consistent with the Bayesian estimation for shear viscosity η/s. The potential improvement with Run 3 and Run 4 measurements is estimated using the R_{AA} and v_2 projections by ALICE and CMS shown in the previous section and it is shown by the red band. With these future experimental measurements, the diffusion coefficient around T_{c} could be

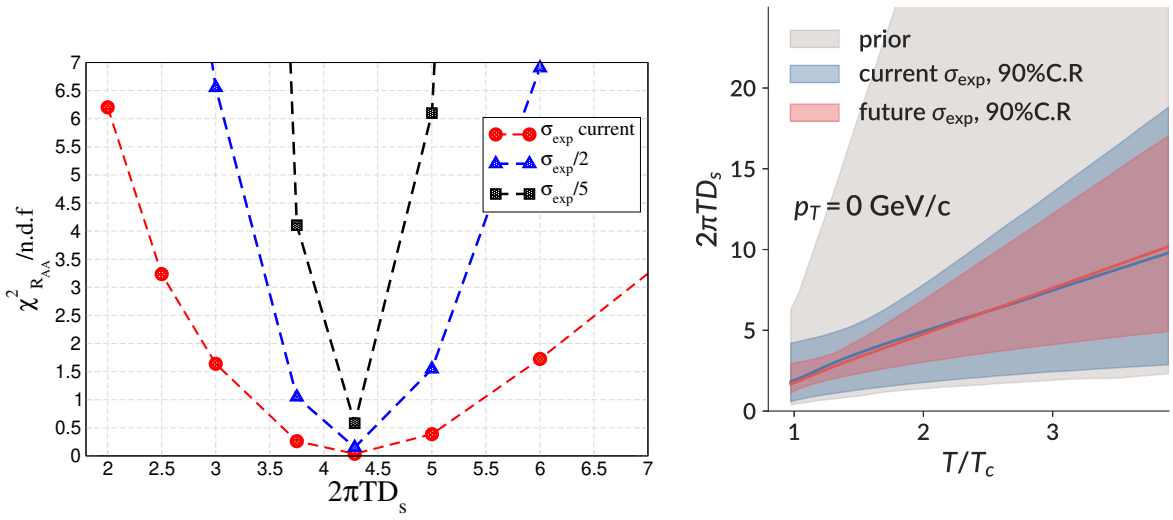

Fig. 17: Left: Normalized χ^2 as a function of spatial diffusion coefficient ($2\pi TD_{\rm s}$) for different experimental precision levels from the Catania Fokker-Plank transport model [273, 274]. Right: Coefficient range (90% credibility region) for $2\pi TD_{\rm s}$ as a function of $T/T_{\rm c}$ for different experimental precision levels, estimated by a model-to-data Bayesian analysis using a modified Langevin framework [275].

constrained with an uncertainty of about 30–50% of the present one.

5.3.3 D-meson analyses with Event Shape Engineering

Further insight into the dynamics of heavy quarks in the medium can be obtained from measurements of the yield and elliptic flow of heavy-flavour particles with the Event Shape Engineering (ESE) technique [255]. This technique consists of selecting events with the same centrality but different magnitude of the average bulk elliptic flow and therefore initial-state geometry eccentricity. The analyses with ESE will allow us to investigate the correlation between the flow coefficients of heavy-flavour hadrons and soft hadrons, to study the interplay between elliptic and radial flow, and to further constrain the path-length dependence of the energy loss suffered by the heavy quarks in the QGP. A first analysis was published by ALICE using 2015 Pb–Pb data [278]. In the left-hand panel of Fig. 18, the prospects for the measurement of the $\rm D^0$-meson v_2 with the ESE technique in the 30–50% centrality class with $L_{\rm int} = 10\ \rm nb^{-1}$ are shown. In particular, the ratio between the v_2 of D mesons in the 10% of the events with larger (smaller) elliptic flow of the bulk (quantified through the magnitude of the so-called reduced flow vector q_2) and the v_2 in all the collisions in the considered centrality class is reported as a function of $p_{\rm T}$. It is compared to the current measurement of the same ratio for charged particles, which is dominated by light-flavour hadrons. The expected statistical uncertainties for the $\rm D^0$-meson v_2 in the 0–10% of events with larger (smaller) q_2 are of the order of about 1–2% in the interval $1 < p_{\rm T} < 8$ GeV/c. This will allow us to resolve a possible difference of a few percent in the response of the v_2 to the ESE selection between the $\rm D^0$ mesons and the light hadrons, providing new insight on the coupling of the charm quark with the medium constituents and on its degree of thermalisation. The performance for the measurements of $\rm D^0$-meson $p_{\rm T}$-differential yield in event-shape classes is displayed in the right-hand panel of Fig. 18. The expected performance will provide a sensitivity of a few percent for the modification of the D-meson $p_{\rm T}$ spectra in events with small (large) initial geometrical anisotropy. This will open the way for precise studies on the interplay between the initial geometrical anisotropy (the collective flow of the bulk) and the heavy-flavour radial flow and energy loss.

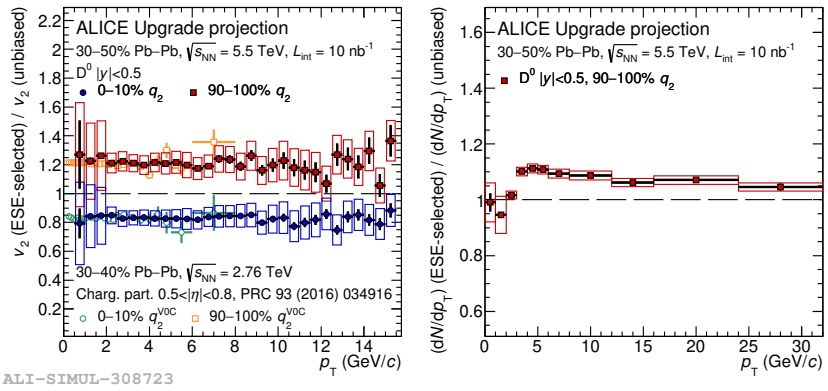

Fig. 18: Left: projection of the expected ratio of D^0-meson v_2 in the 10% events with larger (smaller) q_2 with respect to the unbiased one as a function of p_T for the 30–50% centrality class. The modification of the D^0-meson v_2 was assumed to be equal to that measured for the charged particles in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV in the the 30–40% centrality class (superimposed for comparison) [276]. Right: projection of the expected ratio of D^0-meson p_T-differential yield in the 10% events with larger q_2 with respect to the unbiased one, estimated considering the prediction provided by the POWLANG model [277]. Figure from Ref. [1].

5.4 Studies of heavy-quark hadronisation

5.4.1 Hadronisation mechanisms for c and b quarks

The hadronisation mechanisms belong to the non-perturbative domain of QCD and a first-principle description of these processes is still missing, for both light and heavy flavours. However, from the study of charm dynamics in nucleus–nucleus collisions in the last decade there is a general consensus that the details of hadronisation have a large effect on both the heavy-flavour observables R_{AA} and v_2 [260, 279, 280]. This section introduces the two main microscopic hadronisation mechanisms for the production of heavy-flavour hadrons: fragmentation and coalescence (also denoted as recombination). Fragmentation is one of the most common approaches for the calculation of inclusive hadron production and it is appropriate for high-momentum partons emerging from initial hard processes, where high-momentum quarks fragment directly and independently into high-momentum hadrons. Independent fragmentation has also been widely applied at low momentum in e^+e^-, ep and pp collisions. On the other hand, coalescence is expected to dominate in the low-momentum regime in nucleus–nucleus collisions, where partons are abundant and heavy quarks can hadronise by recombination with light quarks [281–283]. Recent measurements at the LHC indicate that fragmentation may not be sufficient to describe charm quark hadronisation at low momentum in pp and p–Pb collisions, at least for what concerns baryon production [284, 285].

The hadron momentum spectra produced by heavy-quark fragmentation are given by:

$$\frac{\mathrm{d}N_{\mathrm{had}}}{\mathrm{d}^2p_{\mathrm{T}}\,\mathrm{d}y} = \sum \int \mathrm{d}z \frac{\mathrm{d}N_{\mathrm{fragm}}}{\mathrm{d}^2p_{\mathrm{T}}\,\mathrm{d}y} \frac{D_{\mathrm{had/Q}}(z, Q^2)}{z^2} \tag{17}$$

where $z = p_{\mathrm{had}}/p_{\mathrm{Q}}$ is the fraction of quark momentum carried by the hadron, $Q^2 = (p_{\mathrm{had}}/2z)^2$ is the momentum scale for the fragmentation process and $D_{\mathrm{had/Q}}$ is the fragmentation function.

In the basic coalescence model developed in Refs. [286–292] and used here for illustration, the

spectrum of heavy-flavour hadrons formed by coalescence of heavy-light quarks can be written as

$$\frac{\mathrm{d}^2N_{\mathrm{had}}}{\mathrm{d}p_{\mathrm{T}}^2} = g_{\mathrm{had}} \int \prod_{i=1}^{n} \frac{\mathrm{d}^3p_i}{(2\pi)^3E_i} p_i \cdot \mathrm{d}\sigma_i \cdot f_{q_i}(x_i,p_i) f_{\mathrm{had}}(x_1...x_n,p_1...p_n)\, \delta^{(2)}\left(p_{\mathrm{T,had}} - \sum_{i=1}^{n} p_{\mathrm{T},i}\right) \tag{18}$$

where $\mathrm{d}\sigma_i$ denotes an element of a space-like hypersurface and f_{q_i} are the quark (antiquark) phase-space distribution functions for i-th quark (antiquark), while g_{had} is the statistical factor to form a colourless hadron from quarks and antiquarks with spin 1/2. An alternative approach proposes resonance formation in quark-antiquark scatterings as the main production channel of D mesons through coalescence. In this approach, the same QCD process is responsible for both the interaction of charm quarks with the strongly-coupled medium and for the process of D-meson formation through recombination [293, 294].

Hadronisation via coalescence leads to a modification of the relative abundance of the various heavy-flavour hadron species produced. The most striking effect is an enhancement of the baryon-to-meson ratios for heavy-flavour hadrons. First studies of these ratios [290, 292] indicated a significant change in the relative abundances of the heavy-flavour hadron species, and in particular a ratio of $\Lambda_{\mathrm{c}}/\mathrm{D}^0$ close to unity, which is nearly an order of magnitude larger than what predicted by the fragmentation process implemented in the PYTHIA event generator. This value is also much larger than the prediction of the statistical hadronisation model [295], in which the hadronisation occurs by recombination of an equilibrated system of quarks and the hadron abundances are mainly determined by their masses. In addition, hadronisation via coalescence in a strangeness-rich Quark-Gluon Plasma is predicted to lead to a large enhancement in the production of strange heavy-flavour hadrons, like $\mathrm{D_s}$ and $\mathrm{B_s}$ [296–298]. Hints of an enhancement of the $\mathrm{D_s}/\mathrm{D}^0$ and $\Lambda_{\mathrm{c}}/\mathrm{D}^0$ ratios in nucleus–nucleus collisions have recently been reported by ALICE at the LHC [299, 300] and by STAR at RHIC [301].

The hadronisation by coalescence plus fragmentation also affects the p_{T} distribution of heavy-flavour hadrons. For D mesons the effect can be roughly seen as a shift in p_{T} of about 1.0–1.5 GeV/c in the region of p_{T} of 1.5–6 GeV/c, resulting in a significant enhancement of $R_{\mathrm{AA}}(p_{\mathrm{T}})$. The degree of these enhancements for D mesons, however, is significantly different among the different implementations of the hadronisation by coalescence and it is nearly unknown for heavy-flavour baryons, like Λ_{b} and Λ_{c}.

Finally, the coalescence process leads to a significant enhancement of the $v_2(p_{\mathrm{T}})$ in the intermediate p_{T} region that, for D mesons, amounts to about 20–40% depending on the specific modelling. The Λ_{c} is expected to acquire instead a much larger enhancement of at least a factor of two for the v_2. Therefore, a combined measurement of the $\Lambda_{\mathrm{c}}/\mathrm{D}$ and $\Lambda_{\mathrm{b}}/\mathrm{B}$ ratios and of the baryon elliptic flow would impose strong constraints on the hadronisation mechanism and lead to a better determination of the diffusion transport coefficient of heavy quarks (see Section 5.4.3).

5.4.2 Measurement performance studies (ALICE and CMS)

Simulation studies for the measurement of the $\mathrm{D_s}$, Λ_{c} and Λ_{b} production were carried out by the ALICE Collaboration [263] and are updated in the present document. A projection of the performance for the $\mathrm{B_s^0}$ meson by the CMS Collaboration is also reported [8]. The $\mathrm{D_s}$, Λ_{c} and Λ_{b} ($\rightarrow \Lambda_c\pi$) reconstruction strongly benefits from the improved track spatial resolution of the ALICE Inner Tracking System Upgrade, because they have small mean proper decay lengths (e.g. about 60 μm for Λ_{c}) and large combinatorial backgrounds. The Λ_{c}, Λ_{b} and $\mathrm{B_s^0}$, in particular, require very large integrated luminosities, because the decay branching ratios are very small (e.g. about 3×10^{-4} for $\Lambda_{\mathrm{b}} \rightarrow \Lambda_{\mathrm{c}}(\rightarrow \mathrm{pK}\pi)\pi$) and the combinatorial background is very large, in case for the Λ_{c}, which has a small separation from the interaction vertex and lower invariant-mass than the b-hadrons. In [8] it has been shown that the statistical uncertainty in the lowest accessible p_{T} intervals for these hadrons would increase above 20–30% with integrated luminosity significantly lower than 10 nb^{-1}.

Figure 19 shows the performance for the R_{AA} of $\mathrm{D_s}$ (left) and $\mathrm{B_s^0}$ (right), compared with the cor-

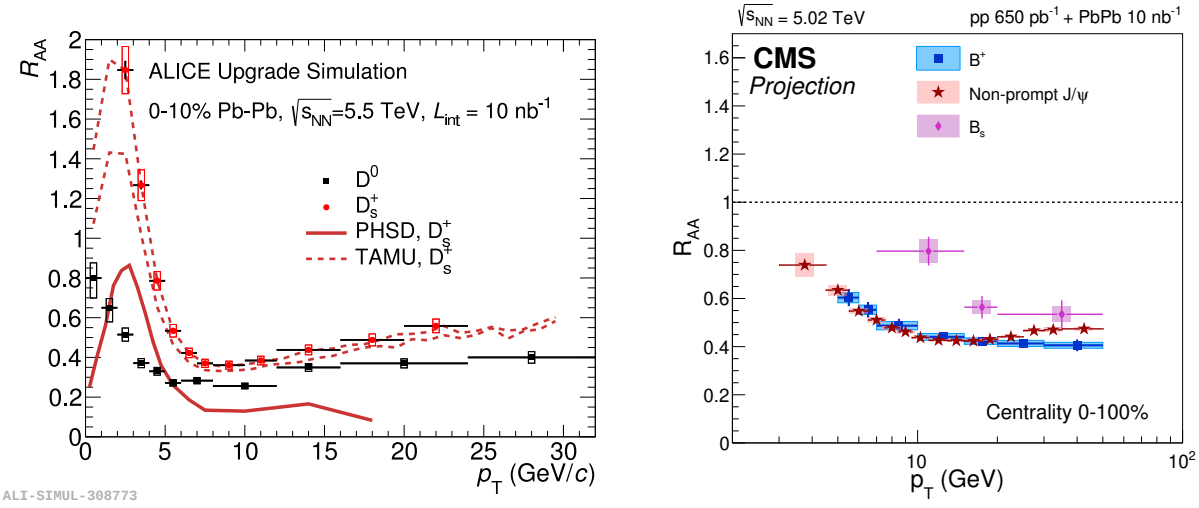

Fig. 19: Measurement performance projections for the nuclear modification factor R_{AA} of $\mathrm{D_s}$ (left) and $\mathrm{B_s^0}$ (right) mesons in Pb–Pb collisions ($L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$). The ALICE study for $\mathrm{D_s}$ is based on full simulation [1, 263]. The CMS projection is based on scaling of uncertainties from existing measurements [8, 9].

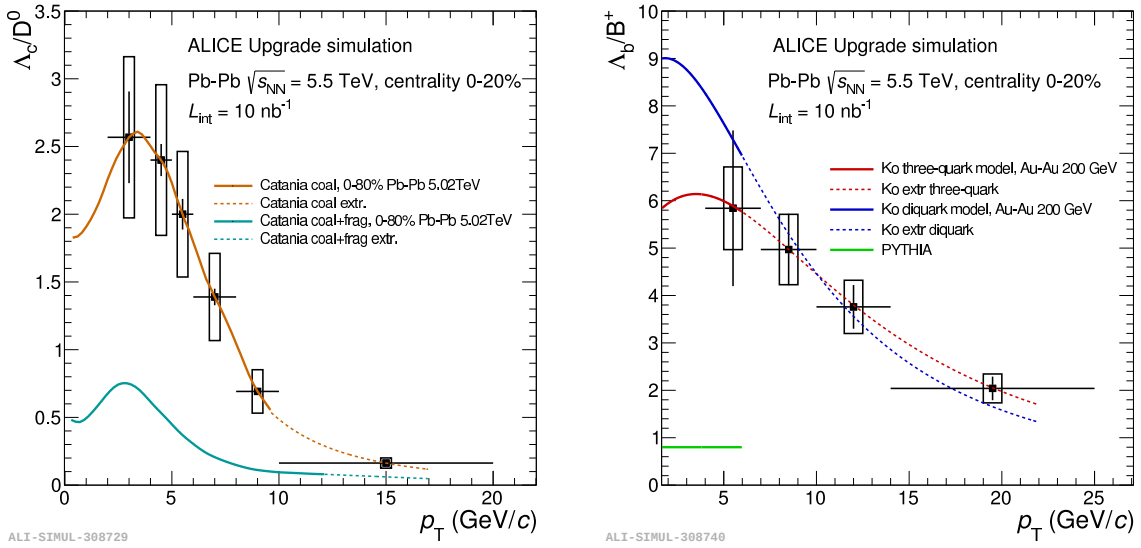

Fig. 20: ALICE measurement performance for the Λ_c/D^0 (left) and Λ_b/B^+ ratios in central Pb–Pb collisions ($L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$), based on studies from [263]. Figures from Ref. [1].

responding non-strange mesons. The predicted difference between the D^0 and $\mathrm{D_s}$ R_{AA} will be measured very precisely and the difference in the beauty sector could be observed with a significance of about $3\,\sigma$. The measurements were studied only for $p_{\mathrm{T}} > 2$ and 8 GeV/c, respectively, but an extension to lower p_{T} is considered within reach.

Figure 20 shows the performance for the charm and beauty baryon-to-meson ratios as they can be measured by ALICE with $L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$ [263]. The measurements are compared with predictions based on various mechanisms for heavy-quark recombination in the medium [290, 292]. Figure 15 (right) shows the performance for the elliptic flow coefficient v_2 of D^0, $\mathrm{D_s}$ and Λ_{c} in semi-central Pb–Pb

collisions [263]. The precision of the D_s v_2 should be sufficient to enable a significant comparison with D^0 and with model calculations, in which the observable is found to be sensitive to the interactions of D mesons in the hadronic phase that characterises the late stages of the collision [297]. Both measurements cannot be extended to the very-low-momentum region, where the separation of the heavy-flavour secondary vertex from the primary vertex is small. This limitation motivates studies for a further improvement of the ALICE inner tracker during LS3 [302]. A more precise measurement would open the possibility to test in the charm sector some features at present only observed for the v_2 of light-flavour hadrons: the mass scaling at low p_{T} and the baryon–meson grouping at high p_{T}. Finally, the detection of baryons with multiple-heavy-flavour content, like e.g. the Ω_{cc} and Ω_{ccc} states that are predicted to have enhancements of several orders of magnitude if heavy quarks recombine in the QGP [303–305], is one of the main physics goals driving the concept for a possible new heavy-ion experiment at the LHC [306]. This experiment, which could be a follow-up of the ALICE experiment in the 2030s, would be mainly based on ultra-thin and granular silicon pixel detectors.

5.4.3 *Impact of hadronisation models on QGP characterisation*

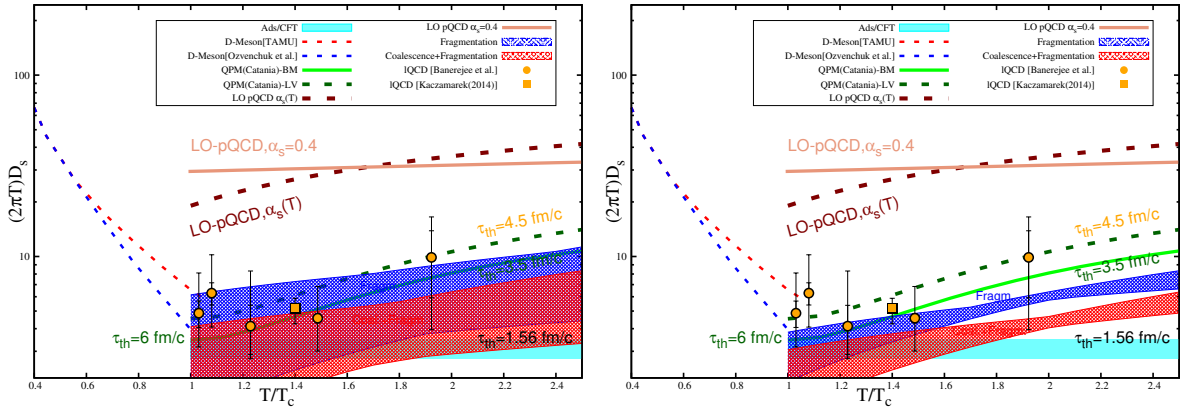

Fig. 21: Illustration of charm diffusion coefficient $2\pi T D_s(T)$ estimate from D meson $R_A A$ data using different hadronisation assumptions in the Catania model [273, 274] as a function of temperature. The blue band refers to fit with fragmentation only, the red band to the fit with coalescence plus fragmentation. In the left panel the D_s estimation obtained with the current experimental uncertainties is shown, while in the right panel the estimation considering the case with more precise measurements as expected with $L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$ is shown.

The hadronisation mechanism of heavy quarks is important for the description of the measured heavy-flavour R_{AA} and v_2 at RHIC and LHC energies. In particular, it has been recognized that recombination play a dominant role in describing simultaneously both D meson R_{AA} and v_2 [280, 307–309]. Moreover, as discussed in Section 5.4.1, the charm baryon-to-meson ratio Λ_c/D^0 measured at RHIC and LHC is not consistent with a fragmentation only scenario [290, 292]. Therefore, a combined study including also the heavy baryon-to-meson ratio provides further information to solve the ambiguity on the recombination fraction. In the following, the sensitivity of the QGP characterisation to the recombination fractions described in Section 5.4.1 is illustrated. To estimate how different model implementations of the hadronisation mechanisms can affect the extraction of the charm quark diffusion coefficient $2\pi T D_s$, a global quantitative χ^2 analysis was carried out by comparing experimental data on the D meson R_{AA} with theoretical results obtained using the Fokker-Planck equation under a standard bulk medium evolving hydrodynamically with $\eta/s = 0.1$ [310, 311]. The model developed in [273, 274] with diffusion and drag coefficients related by the fluctuation-dissipation theorem was used, considering two differ-

ent implementations of the hadronisation process: one using only fragmentation of charm quarks to D mesons (with the Peterson function) and another one including a hybrid hadronisation by coalescence plus fragmentation [280, 292]. For the estimate of the temperature dependence of $2\pi TD_s$, a schematic model in which the drag coefficient is parametrized as $\gamma = \gamma_0(T/T_c)^{\beta}$ was used. The two parameters γ_0 and β were determined by minimizing the $\chi^2/\mathrm{n.d.f.}$ of the model with respect to the measured D meson R_{AA}. The exercise could in principle be repeated using both R_{AA} and v_2. The spatial diffusion coefficient is directly related to the drag coefficient by $D_s = T/(M \cdot \gamma(p=0))$, where M is the charm quark mass. The left panel of Fig. 21 shows the spatial diffusion coefficient $2\pi TD_s(T)$ estimated from the fit to the present data with $\chi^2/\mathrm{n.d.f} < 2.5$. The blue band corresponds to the fragmentation only results and the red band to the coalescence plus fragmentation result. The right panel shows the same calculations obtained with experimental data with smaller error bars on the D-meson R_{AA} as expected with $L_{\mathrm{int}} = 10\ \mathrm{nb}^{-1}$. The comparison between the two cases highlights the difference in the estimation of the D_s coefficient obtained with the two different hadronisation mechanism. Clearly, an optimal estimate of the diffusion coefficient requires an accurate description of the hadronisation mechanisms in the model.

5.5 Heavy-flavour correlations and jets

5.5.1 Heavy-flavour correlations

Although heavy quarks at the LHC energies are mostly produced in primary hard scatterings between the incoming partons in hadronic collisions, a non negligible fraction of c and b quarks are originated from processes of gluon splitting. At the leading order, $\mathrm{c\overline{c}}$ pairs are produced with an azimuthal opening angle of 180°. At the next to leading order, gluon splitting and flavour excitation processes can generate $\mathrm{c\overline{c}}$ pairs typically at small opening angles. The role of next-to-leading order production is currently poorly understood even in proton-proton collisions [312, 313] and introduces sizeable uncertainties in the models for Pb–Pb collisions. As a result, heavy-ion calculations which use proton-proton generators as baseline can be biased because of the different energy loss of quarks and gluons. Correlations between D and $\overline{\mathrm{D}}$ represent a promising way to study the relevance of these mechanisms in different kinematic ranges of the charm quarks. In p–Pb collisions, the study of open heavy-flavour correlations at forward and backward rapidity provides information to test modifications of parton distribution functions in nuclei (see Sect. 10.3.3).

Figure 22 shows the LHCb projections for the azimuthal $\mathrm{D\overline{D}}$ correlations at forward rapidity in pp and p–Pb collisions at the same collision energy per nucleon-nucleon-pair of 8.8 TeV. The figure shows only statistical uncertainties (dominant with respect to the systematic uncertainties) as expected with the Run 3 and 4 integrated luminosity. The measurement of the $\mathrm{D\overline{D}}$ correlation can be performed in intervals of D meson p_{T}, providing differential information to test theoretical models with precision. The experimental projections are compared with predictions obtained with EPOS3-HQ event generator for two different kinematic selections in case of pPb collisions. In particular, the two selected p_{T} ranges, 2-3 GeV/c and 3-12 GeV/c, yield to significantly different correlation shapes in the calculation. This dynamic change of shape demonstrates the necessity to provide precise quantitative tests of the importance of different production mechanism at the partonic level, the hadronisation and potential medium effects in pp and in p–Pb collisions across different kinematic configurations.

In nucleus-nucleus collisions, $\mathrm{D\overline{D}}$ correlations are sensitive observables to discriminate among different mechanisms of in-medium energy loss of heavy-quarks, like radiative and collisional processes. Such measurements, presently challenged by statistical limitations, will greatly benefit from future high-luminosity heavy-ions runs.

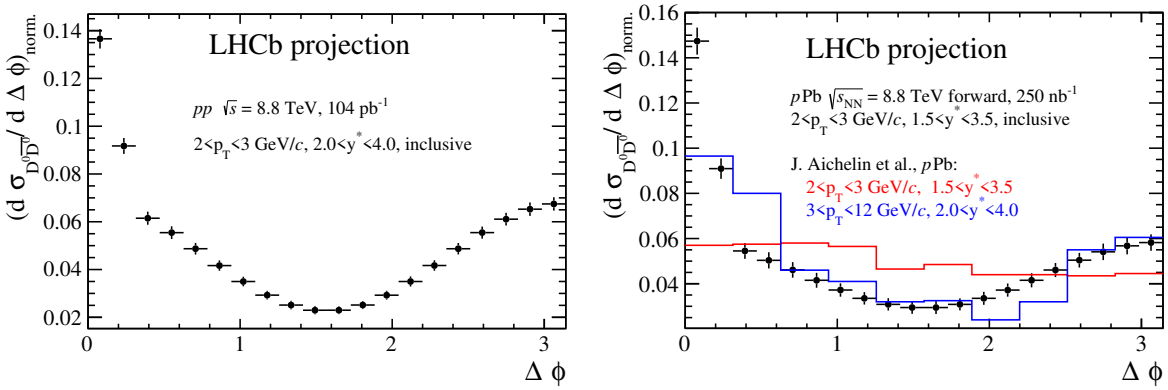

Fig. 22: LHCb projection of the azimuthal $\mathrm{D\overline{D}}$ correlations in p–Pb and in pp collisions at $\sqrt{s} = 8.8$ TeV for the integrated Run 3 and Run 4 luminosity. The p–Pb panel shows a calculation for two different kinematic selection in p–Pb collisions within the EPOS3-HQ generator. A detailed description of the experimental estimates can be found in Ref. [13].

5.5.2 Heavy-flavour jet measurements

Further insights into the mechanism of parton energy loss in the QGP can be provided by the study of reconstructed heavy-flavour jets. These measurements provide complementary information to the studies of D and B mesons since they enable to better determine the energy of the initial heavy quark and give access to the jet energy profile. By comparing the production of heavy-flavour jets with light jets one can test the expected flavour dependence of the in-medium energy loss in a wide transverse momentum range and study the different energy loss mechanism of quarks and gluons. The study of more differential observables related to the production of heavy-flavour particles in jets, like the fragmentation function and the angular correlations, provides additional constraints into the mechanisms of redistribution of the energy lost by the parton inside the medium.

Figure 23 (left) shows the projections for the nuclear modification factor of D^0-meson tagged jets in Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV with ALICE. The measurement will provide a precise estimation of the suppression of D^0-tagged jets down to low p_{T}, opening the way to study possible modifications of charm fragmentation. Future measurements of the fragmentation functions of charmed hadrons in pp collisions will also help to reduce the uncertainties on the charm fragmentation mechanisms, which are currently among the main sources of uncertainties for theoretical calculations that describe heavy-quark production at the LHC.

Figure 23 (right) shows the CMS projection for the distribution of D mesons as a function of the distance from the jet axis for jets of $p_{\mathrm{T}} > 60$ GeV/c in Pb–Pb collisions divided by the distribution in pp collisions. With the precision achievable with the high-luminosity data, one would be able to measure precisely the effect of heavy-quark in-medium energy loss and the redistribution of the energy at large angle with respect to the jet axis. This is expected to provide new constraints on in-medium energy loss calculations. By comparing the ratio measured for D mesons with the one obtained for charged particles, it will be possible to assess the relevance of medium response phenomena, which can induce modification of the jet shape at large angles and are expected to be less relevant for heavy quarks due to their large masses.

Another area of research where the LHC experiments can make key contributions is the study of heavy-flavour jet substructure. New experimental observables related to the inner structure of heavy-flavour jets, like the splitting functions, can provide insights into the mass dependence of the parton shower in new kinematic regimes. A precise measurement of these observables at the LHC down to low p_{T} would also provide a unique opportunity to further investigate the dead cone effect [271], currently

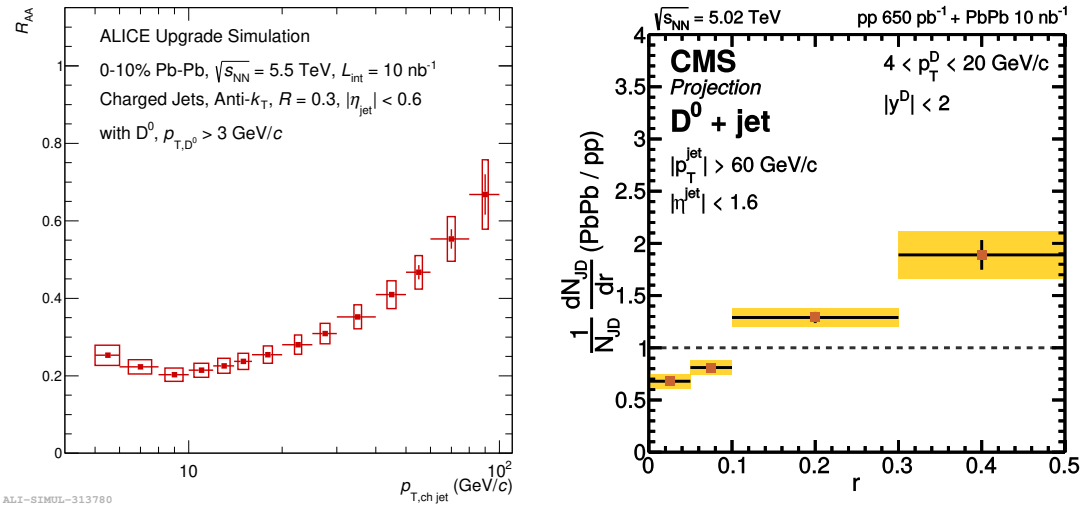

Fig. 23: (Left) ALICE simulation results for the nuclear modification factor of D^0-meson tagged jets in central Pb–Pb collisions [1]. (Right) CMS projection for the distribution of D mesons in jets as a function of the distance from the jet axis for jets of $p_{\mathrm{T}} > 60\,\mathrm{GeV}/c$ in Pb–Pb collisions divided by the distribution in pp collisions.

not well understood and constrained.

5.6 Sensitivity to early magnetic fields and vorticity phenomena

Recently, it has been recognized that very strong electric and magnetic fields are created at early times of ultra-relativistic heavy-ion collisions. In Fig. 24 (left), the time dependence of the magnetic ($\mathrm{B_y}$) and electric ($\mathrm{E_x}$) fields in Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 2.76$ TeV with impact parameter b=9.5 fm is presented for a system with electric conductivity σ_{el} =0.023 fm^{-1}. The space-time evolution is obtained as solution of the Maxwell's equations as developed in [244]. The magnetic field produced in non-central heavy ion collisions is dominated by the $\mathrm{B_y}$ component which induces a current in the xz plane while the time dependence of $\mathrm{B_y}$ generates an electric field which is directed in the x direction. The combined effect of both fields is a current in the xz plane.

The presence of early magnetic fields produced in heavy-ion collisions is expected to have an effect on the charm directed flow [257, 314], resulting in a v_1 value larger than that of lighter particles (short charm formation time and therefore sensitive to the maximum magnetic field strength), and opposite for particles with charm and anti-charm (due to the Lorentz force). Also the initial vorticity of non-central collision is expected to affect the directed flow observable. The STAR collaboration recently presented the first measurements of the directed flow v_1 coefficient for mesons. This first observation of non-zero v_1 for charm mesons, larger than that of lighter particles, is in qualitative agreement with theoretical models including both electromagnetic and vorticity effects. The uncertainties on the difference between the v_1 of D^0 and $\overline{\mathrm{D}}^0$ from STAR are still too large to draw conclusions on the effects of the early magnetic fields. The LHC Run 3 and 4 will enable more precise measurements on the charm directed flow, which will give additional insights into the initial vorticity of the Quark Gluon Plasma and the strength of the electromagnetic fields. Figure 24 (right) shows the precision level for the difference of directed flow v_1 for D^0 and $\overline{\mathrm{D}}^0$ which ALICE can measure as a function of pseudorapidity in semi-central Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.5$ TeV.

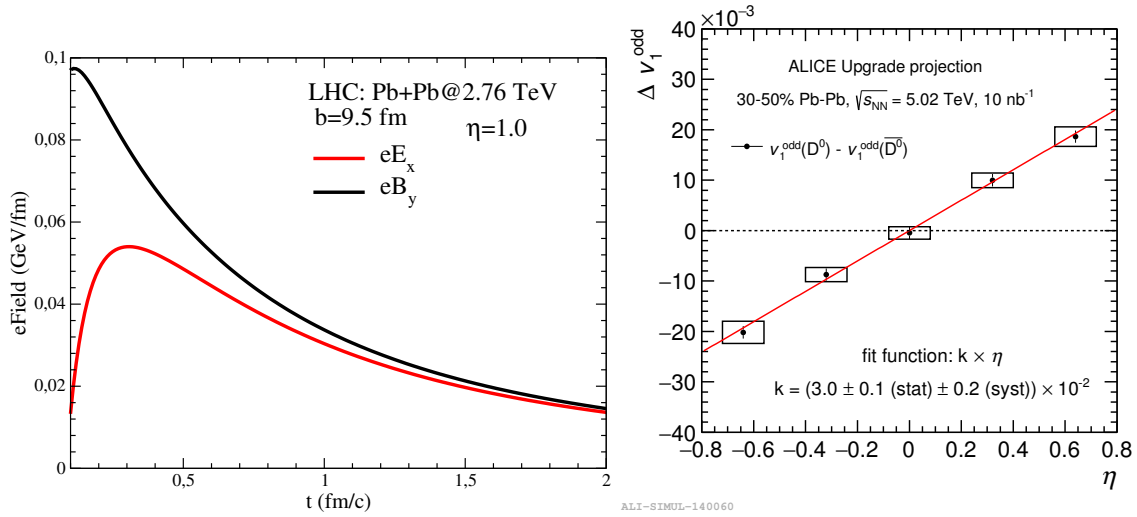

Fig. 24: Left: Time evolution in the forward rapidity region of the magnetic field $\mathrm{B_y}$ and electric field $\mathrm{E_x}$ in Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 2.76$ TeV with impact parameter $b = 9.5$ fm [257]. Right: ALICE projection of the difference of directed flow v_1 for $\mathrm{D^0}$ and $\overline{\mathrm{D}}^0$ as a function of pseudorapidity in semi-central Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.5$ TeV [1].

5.7 Heavy flavour measurements in small colliding systems

Traditionally, proton-nucleus collisions were considered just as a benchmark to investigate Cold-Nuclear-Matter (CNM) effects in the absence of a deconfined medium. As discussed in the devoted section, recent results suggest to partially reconsider such a paradigm. In particular, the study of soft observables in high-multiplicity p–Pb (and even pp) collisions led to the observation of signals traditionally attributed to the formation of a hot deconfined medium: long-range azimuthal 2-particle correlations [315–318], non-vanishing flow harmonics [319, 320], increasing baryon/meson ratio as a function of p_{T} [321], enhancement of strange-hadron production [322]. Many authors interpreted these observations as indications that the same strongly-interacting medium – with a collective hydrodynamic expansion driven by pressure gradients – supposed to be formed in nucleus-nucleus collisions is also produced in smaller systems. If the hydrodynamic scheme provides a consistent framework describing the above observations, its strong assumptions (e.g. a mean-free-path much smaller than the system size $\lambda_{\mathrm{mfp}} \ll L$) look challenging to satisfy for such small systems. Hence, some authors looked for alternative interpretation of the data in terms, for instance, of initial-state effects (Color-Glass-Condensate [323]), of the formation of a system with small parton-parton cross-sections [324], of the presence of anisotropic parton escape mechanisms [325] or of quantum-mechanical interference in the presence of multiple sources of particle production, entailing to reconsider the no-interaction baseline before looking for final-state collective effects [326] .

On the other hand, no signature of jet-quenching or suppression of high-p_{T} particle production was observed in high-multiplicity proton-nucleus collisions [327]. At first glance this appears in contradiction with the measurements involving soft observables. One should in any case consider that the quenching of jets due to parton energy-loss in the QGP has a strong dependence on the thickness of the crossed matter. On the contrary, if one accepts the hydrodynamic paradigm, the smaller size of the medium with respect to the nucleus-nucleus case would lead to even larger pressure gradients and hence to a larger acceleration of the fluid, compensating its shorter lifetime.

In light of the above findings, as an independent probe, it is clearly of interest to address the study of small systems also through heavy-flavour observables. Due to their large mass c and b quarks are in

fact produced in the very first instants in hard processes described by pQCD, at most affected by nuclear modifications of the Parton Distribution Functions (nPDFs) and by an initial transverse-momentum broadening acquired in CNM. It looks then natural to extend transport calculations, developed to describe heavy-flavour propagation through the plasma formed in nucleus-nucleus collisions, also to the case of small systems, assuming as a working hypothesis that also in this case a hot deconfined medium is formed. The theoretical modelling involves the same processes as in the heavy-ion case: the so-called CNM effects (nPDFs and initial k_{T}-broadening) modifying the hard $Q\overline{Q}$ production, the propagation of the heavy quarks throughout the fireball and finally their hadronization in the presence of a hot medium. The only difference is that, in the case of small systems, it is mandatory to include event-by-event fluctuations in the initial conditions.

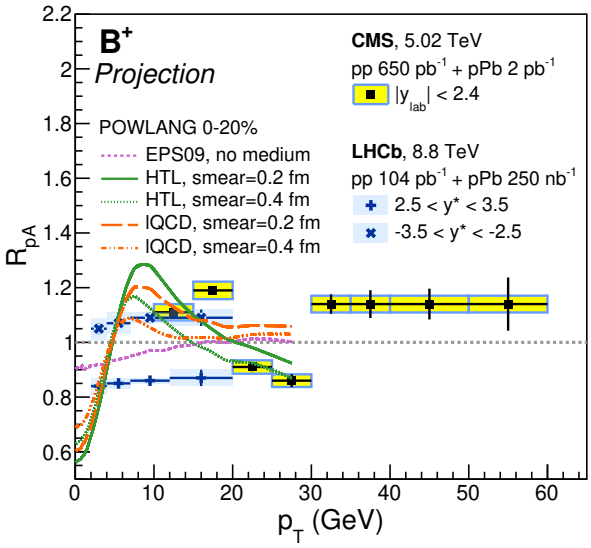

Fig. 25: Projection for the measurement of the nuclear modification factor of B mesons in p–Pb collisions achievable by CMS [9] and LHCb at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV and 8.8 TeV respectively. The predictions of the POWLANG model with different choices of the transport coefficients and of the smearing of the initial condition at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV are shown. Also reported, in magenta, the curve containing only Cold-Nuclear-Matter effects.

In order to illustrate the level of precision which future experimental measurements must reach to discriminate among different scenarios of initial and final-state effects, various sets of predictions based on the POWLANG model are reported in the following [328]. In Fig. 25 results of transport calculations for the nuclear modification factor of beauty hadrons in p–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV are displayed and compared to experimental projections by CMS for the B-meson R_{pPb} obtained from Run 2 data and projections of LHCb at lower transverse momentum for the B-meson R_{pPb} [13] obtained using as central points the calculations based on Ref. [329]. As can be seen, model predictions are sensitive to the different choices of the transport coefficients (see discussion in [328]) and of the initial conditions (each nucleon-nucleon collision is assumed to deposit some entropy with a Gaussian smearing). In order to answer the question about possible final-state hot-medium effects, experimental measurements should be extended to lower p_{T}, as planned for the different experiments (see ALICE plans to perform beauty measurements down to low p_{T} in nucleus-nucleus collisions in Sec. 5.3.1). In fact, for p_{T} larger than 10–15 GeV/c the curves accounting for the transport and hadronization of the heavy quarks in a hot medium (green curves) are very close to the (magenta) one which includes only the effect of the nPDF's and of the initial k_{T}-broadening acquired in CNM, all of them being very close to unity as the experimental projections by CMS. On the contrary, at lower p_{T} the radial flow of the beauty hadrons, acquired in part

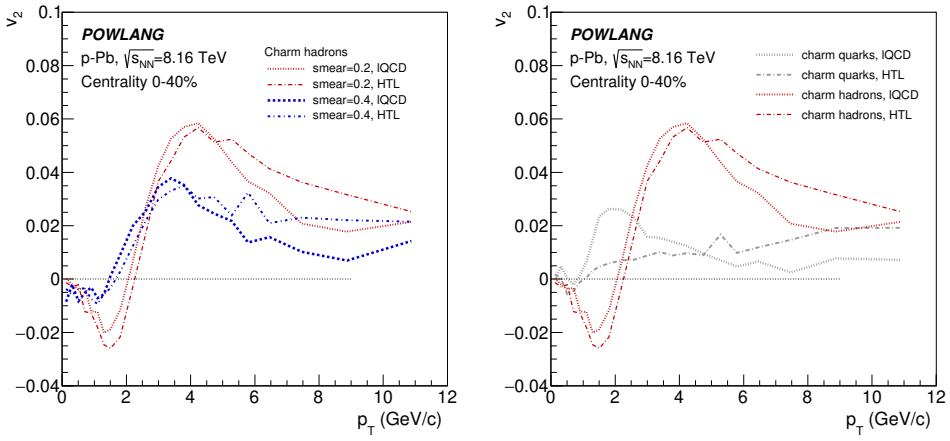

Fig. 26: Left: The elliptic flow of charmed hadrons in the 0-40% most central p–Pb collisions at $\sqrt{s_{\rm NN}} = 8.16$ TeV. Results of the POWLANG model with different choices of the transport coefficients and of the smearing of the initial condition are shown. Right: a comparison of the results at the level of charm quarks and hadrons. An important fraction of the flow is acquired at hadronization via recombination with light partons from the medium.

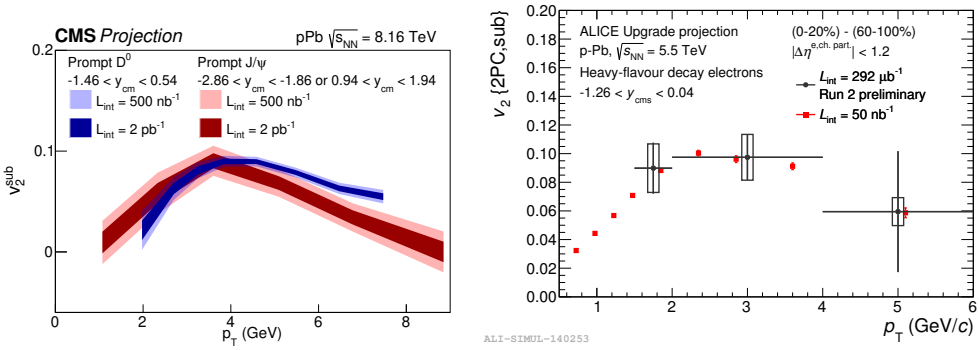

Fig. 27: Left: projection of prompt D-meson and prompt J/ψ elliptic flow as a function of $p_{\rm T}$ in high-multiplicity p–Pb collisions at $\sqrt{s_{\rm NN}} = 8.16$ TeV with CMS [11]. Right: projection of elliptic flow of electrons from heavy-flavour hadron decays as a function of $p_{\rm T}$ in 0–20% central p–Pb collisions at $\sqrt{s_{\rm NN}} = 5.02$ TeV with ALICE [1].

during the propagation through the hot medium and in part at hadronization via recombination, leads to a depletion of the spectrum at low $p_{\rm T}$ and to an enhancement at intermediate $p_{\rm T}$ which would allow one to distinguish this scenario from the case of pure CNM effects.

As displayed in Fig. 26 the possible production of a hot deconfined medium in proton-nucleus collisions would also leave its fingerprints in the azimuthal distribution of the final hadrons, leading in particular to a non-vanishing elliptic-flow coefficient. Notice how one gets a positive v_2 for charmed hadrons only starting from $p_T \approx 2$ GeV/c, in agreement with recent CMS data [330]. Differently from the heavy-ion case, in such small systems it is important how the initial entropy deposition is modelled with varying the smearing parameter (left panel). As displayed in the right panel of Fig. 26, within the framework of the model, an important role is played by hadronization via recombination with light partons from the fireball, whose collective flow enhances the azimuthal asymmetry of the charmed hadrons.

The projected precision with p–Pb integrated luminosities $L_{\rm int} \sim 2$ pb^{-1} (ATLAS and CMS)

and ~ 1 pb^{-1} (ALICE) has the potential to shed light on the different mechanisms behind the observed anisotropy (see Fig. 27 for D mesons and prompt J/ψ with CMS [11] and electrons from heavy-flavour hadron decays with ALICE).

Besides the analysis of kinematic distributions (in momentum and angle) of heavy-flavour particles, further interesting information on the onset of possible medium effects may come from the study of the yields of the various charm and beauty hadrons as a function of charged-particle multiplicity going from pp to p–Pb and Pb–Pb, as done in the past for the case of strangeness production. As an example, with high-multiplicity triggers in pp collisions at $\sqrt{s} = 14$ TeV ($L_{\rm int} = 200$ pb^{-1}), the ALICE experiment will have the potential to detect D mesons with a precision better than 10% in a wide kinematic range up to about 10–12 times the average charged-particle multiplicity.

6 Jets and parton energy loss

6.1 Introduction

The most direct way to measure the structure of matter is the controlled scattering of a beam of probe particles. This approach was used to discover the atomic nucleus, and quarks and gluons, and it is employed today to explore the partonic structure of nucleons and nuclei. However, the partonic phase of the QGP lives for $\sim 10^{-23}$ seconds before breaking up into its hadronic remnants, so that probing it by the scattering of an externally-generated beam is impossible in practical terms. As an alternative, energetic jets arising from high-Q^2 processes in the same nuclear collision that generates the QGP provide internally-generated probes that may be applied for this purpose [331–336].

Jets, observed as collimated sprays of energetic particles, were predicted by Quantum Chromo Dynamics (QCD) to form in high energy collisions. They constitute a substantial part of the background in beyond the Standard Model physics searches and were instrumental in the Higgs boson discovery. While jet evolution in vacuum is well understood, the question of how jets interact with a dense deconfined medium remains an active field of study, that is largely driven in the recent years by the unprecedented experimental capabilities of the RHIC and LHC accelerators and detectors. Understanding from first principles how a jet evolves as a multi-partonic system, spanning a large range of scales (from $\sim$1 GeV to $\sim$1 TeV) is crucial to quantitatively probe the Quark Gluon Plasma (QGP). The successful description of bulk observables by viscous hydrodynamic calculations with a small viscosity to entropy ratio have led to the standard picture of a strongly coupled plasma. However, due to the property of asymptotic freedom in QCD, the produced matter is expected to behave differently at smaller and smaller distances which can only be accessed with well calibrated probes, namely, QCD jets.

High-Q^2 processes between the partonic constituents of colliding nucleons occur early in the collision. Further interactions of the outgoing partons with the hot and dense QCD medium produced in heavy ion collisions are expected to modify the angular and momentum distributions of final-state jet fragments relative to those in proton-proton collisions. This process, known as jet quenching, can be used to probe the properties of the QGP [331–336]. Jet quenching was first observed at RHIC, BNL [337–347] and then at the CERN LHC [348–358] by studying the redistribution of energy radiated from the parton because of interactions with the QGP. More recent detailed analyses have focused on modifications to the distribution of final-state particles emitted in the parton's shower [359–365].

One of the main goals of the RHIC and LHC heavy ion physics programs is utilization of jets and their decay products, including high p_{T} hadrons formed by light and heavy quarks, to investigate the QGP properties. A milestone in this program is the extraction of the transport coefficient $\hat{q}$ by the JET Collaboration [366], based on inclusive hadron suppression measurements at RHIC and the LHC. However, this result has significant systematic uncertainties, due both to theoretical issues and to the limited view provided by inclusive hadron suppression measurements into the fundamental processes underlying jet quenching. A more complete picture requires measurements of reconstructed jets and their in-medium modification.

At the LHC, the collision energy is over an order of magnitude larger than at RHIC. Jet production cross-sections are correspondingly larger, enabling the study of hard processes over a wider kinematic range. Detectors at both facilities have extensive capabilities to study fully-reconstructed jets by grouping the detected particles within a given angular region into a jet, thereby capturing a significant fraction of the parton shower. Jets are a key diagnostic of the QGP, as their interactions with this new state of matter reveal its properties. The interaction with the medium can result in a broadening of the jet profile with respect to vacuum fragmentation. In this case, for a given jet size and a fixed initial parton energy, the energy of the jet reconstructed in heavy ion collisions will be smaller than in vacuum. In the case where the gluons are radiated inside the cone, the jet is expected to have a softer fragmentation and a modified density profile compared to jets in vacuum. Jets may also scatter coherently in the medium, and measurements of jet deflection may provide a direct probe of the micro-structure of the QGP. Fully reconstructed jets provide better theoretical control than high p_{T} hadrons because they are less sensitive to non-perturbative physics and therefore have the potential to provide a better characterization of the QGP. Furthermore, major theoretical and experimental advances were made recently in understanding the evolution of parton showers in a QCD medium with the development of novel jet substructure observables.

In the following sections the expected performance using a total integrated luminosity of 10 nb^{-1} of Pb–Pb data, which is expected for HL-LHC, for a selection of key jet observables will be discussed.

6.2 Out-of-cone radiation

One of the classic observables to measure the out-of-cone radiation due to jet quenching is the jet nuclear modification factor R_{AA} defined as:

$$R_{\mathrm{AA}} = \frac{\frac{1}{N_{\mathrm{evt}}} \frac{\mathrm{d}^2 N_{\mathrm{jet}}}{\mathrm{d}p_{\mathrm{T}}\mathrm{d}y}\Big|_{\mathrm{cent}}}{T_{\mathrm{AA}} \frac{\mathrm{d}^2 \sigma_{\mathrm{jet}}}{\mathrm{d}p_{\mathrm{T}}\mathrm{d}y}\Big|_{pp}}, \tag{19}$$

where N_{jet} and σ_{jet} are the jet yield in Pb–Pb collisions and the jet production cross-section in pp collisions, respectively, both measured as a function of transverse momentum, p_{T}, and rapidity, y, and where N_{evt} is the total number of Pb–Pb collisions within a chosen centrality interval. Measurements of the jet R_{AA} at the LHC have shown a suppression of a factor of two in central collisions over a wide range of jet transverse momentum [354, 355, 367]. Figure 28 shows the current precision obtained with 0.5 nb^{-1} and what can be achieved at the HL-LHC with a factor of 20 more data (10 nb^{-1}). Especially at high transverse momentum a strong reduction of the experimental uncertainties is expected, which will allow a detailed study of the momentum dependence of the out-of-cone radiation. The jet R_{AA} is sensitive to various physics mechanisms such as color coherence, flavor dependence of energy loss, and the medium response to the jet. Models incorporating these various physics effects can be confronted with the high precision data from HL-LHC with a goal of determining what the relative contribution of each of these phenomena is. The expected performance is compared with several recent model predictions: the Linear Boltzmann Transport model (LBT) [368], three calculations using Soft Collinear Effective Theory (SCET) [369–372], and the Effective Quenching model (EQ) [373]. The higher precision data will allow tighter constraints on or falsification of theoretical model predictions. In addition to the inclusive jet R_{AA} it is particularly interesting to study the mid- and forward rapidity region separately since it allows to study the interplay between flavor and spectral steepness, and the path-length dependence of jet quenching. The right panel of Fig. 28 shows the improvement in statistical precision in the forward rapidity region. The statistical precision should be sufficient to quantitatively assess the rapidity dependence of the R_{AA} up to a rapidity of $|y| = 2.8$. Both of these predictions

indicate that HL-LHC should bring a definitive understanding of the intriguing features of the jet R_{AA} as seen in the current data.

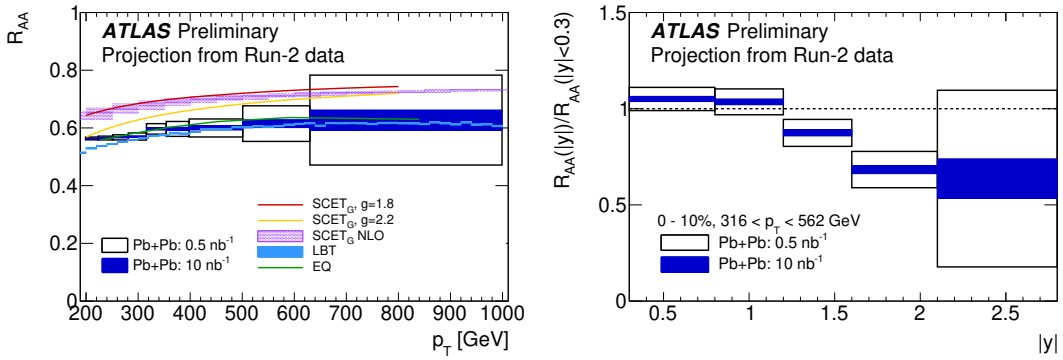

Fig. 28: Projection of the precision that can be reached for jet R_{AA} at the HL-LHC using calorimeter jets at ATLAS as function of p_{T} (left panel) and rapidity (right panel) [5]. See text for model details.

Parton energy loss can be studied more differentially using boson tagged jets. The bosons (photons or Z^0 bosons) escape the region of the hot dense medium unmodified. This has been confirmed through the absence of significant modification of both photon and Z^0 boson production rates in Pb–Pb collisions relative to expectations from measured cross section in pp collisions by both ATLAS and CMS collaborations [374–377]. However, the partons recoiling from the boson is modified in heavy ion collisions due to interactions with the QCD medium. Furthermore, jets produced opposite to the isolated boson are more likely to originate from quarks, while dijet and hadron+jet correlations usually involve significant gluon contributions. Comparing Z+jet and γ+jet observables to dijets [353, 378] (or hadron+jets [358]) allows to explore the difference between energy loss for quark and gluon initiated jets. Figures 29 and 30 show the expected performance at the HL-LHC for the transverse momentum balance between the jet and the boson. The central values are based on the smoothed data from the previous CMS publications [379, 380]. The systematic uncertainties are reduced by a factor of two with respect to the results with the 2015 Pb–Pb data due to improvements on the jet energy scale and jet energy resolution uncertainties available with the larger data sample at the HL-LHC. The collected number of γ+jet events will also be sufficient to study the path length dependence of jet quenching by performing measurements as a function of angle with the reaction plane for the first time. In addition to the smaller uncertainties due to the enhanced statistics at the HL-LHC, it will also be possible to utilize higher momentum photons and Z^0 bosons allowing the measurement of larger jet energy losses. The LHC experiments also envision extending the jet momentum reach to lower transverse momentum in certain analyses, allowing to recover those heavily quenched jets which are currently not selected for such measurements due to limitation arising from the fluctuating background. A distinct effect due to large backgrounds is that of limited jet energy resolution, which can be improved by using more sophisticated techniques for the background correction as was recently shown in Ref. [381].

6.3 Jet deflection

Angular deflection of the jet relative to its initial direction due to momentum transfer with the medium can be used as a direct probe of the QGP. Jet deflection can be measured by coincidence observables, in which an axis is determined by a hard reference object, and the deflection of the jet recoiling from hard object is measured relative to that axis. Such scattering measurements, carried out over a wide range in energy and resolution scale, can be used to explore the microscopic structure of the QGP. Modification of the rate of rare, large-angle jets with respect to the hard reference object in nuclear collisions compared

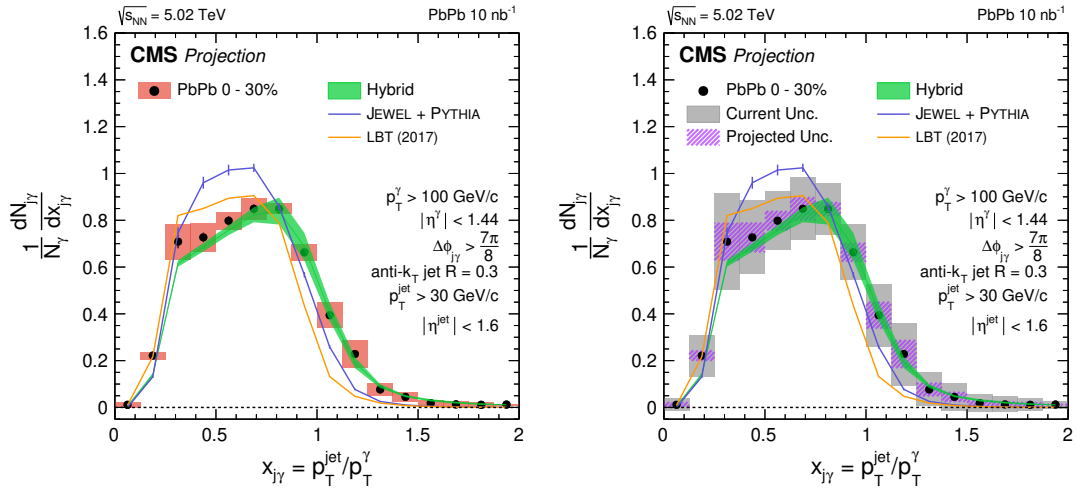

Fig. 29: (Left Panel) Photon-jet momentum balance $x_{j\gamma}$ distribution for isolated-photon+jets of $p_{\gamma} > 100$ GeV/c and $|\eta_{\gamma}| < 1.44$, $p_{\mathrm{jet}} > 30$ GeV/c and $|\eta_{\mathrm{jet}}| < 1.6$ in the HL-LHC data (Right Panel). Comparison between the current performance with 0.4 nb^{-1} of Pb–Pb data collected in 2015 and with HL-LHC data [8].

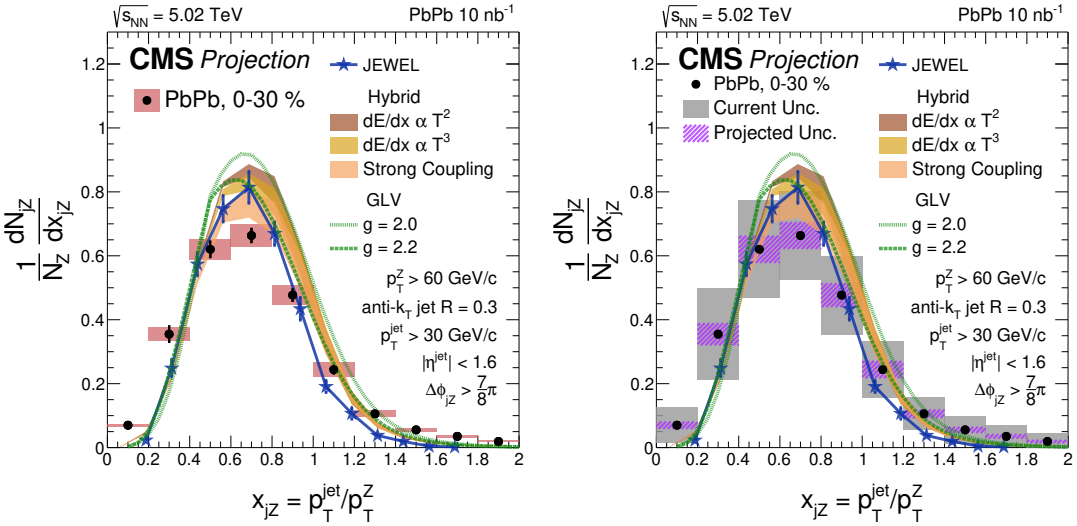

Fig. 30: (Left Panel) X_{jZ} distribution for Z boson-jet pairs with $p_{\mathrm{T}}^{Z} > 60$ GeV/c, $p_{\mathrm{jet}} > 30$ GeV/c and $|\eta_{\mathrm{jet}}| < 1.6$ in the HL-LHC data (Right Panel) Comparison between the current performance with 0.4 nb^{-1} of Pb–Pb data collected in 2015 and with HL-LHC data [8].

to the production rate in vacuum may arise from the scattering off quasi-particles (quarks and gluons or composite objects) of the QGP, thereby probing their nature [382]. In addition, the recoil jet distribution at small recoil angles relative to the reference axis (the axis of the hard object selected at the opposite hemisphere) may be modified by soft multiple scattering in the QGP, which can be used to extract the jet transport parameter $\hat{q}$ by comparison to models [383].

Measurements of the angular distribution of jets relative to a reference axis have been reported for either dijet, photon-jet, Z^0-jet and hadron-jet coincidences, at RHIC [347] and LHC [353,358,379,380,

384]. These current measurements exhibit no significant evidence of in-medium modification of angular distributions, both at small and large angles to the reference axis. While they impose constraints on the magnitude of in-medium scattering effects, their statistical precision is limited. Measurements during HL-LHC will either discover in-medium modification to the recoil jet angular distributions, or improve these constraints substantially.

There is an intensive ongoing effort to develop analysis tools and calculable approaches that discriminate the various contributions to in-medium jet deflection and shower modification, in both experiment and theory [385] (see Sec. 6.2 and 6.4). In this section we focus solely on jet-centroid deflection measurements, without consideration of the effects of shower broadening or other shower modification (see Sec. 6.4). Measurements of both classes of jet quenching observable must ultimately be interpretable in a single consistent picture, but such an approach is beyond current experimental and theoretical capabilities.

The most significant background to the measurement of medium-induced jet deflection is broadening of the angular difference between the two leading jets due to well-established vacuum QCD effects, in particular Sudakov radiation, which is radiation outside the jet cone that generates a broad peak in the recoil jet angular distribution relative to a reference axis (for example a high momentum hadron) [383, 386].

Low-energy jet measurements are expected to experience larger deflection for a given momentum transfer between the jet and medium [387, 388] and are therefore more likely to show large angle deflection. A recent calculation, that includes the effects of vacuum Sudakov radiation and jet-medium interactions based on the few-hard (GLV) or multiple-soft (BDMPS) scattering approaches to jet quenching, finds that the acoplanarity distributions for these different jet quenching pictures differ by a few percent in the range $20 < p_{\mathrm{T,jet}} < 40$ GeV/c [388]. This sets the precision required for the observation of medium-induced jet deflection during HL-LHC. Additional theoretical considerations of in-medium p_{T}-broadening can be found in [334, 389].

In light of such considerations, it is necessary to utilize analysis techniques that can attain few percent precision in the measurement of recoil jet angular distributions for low $p_{\mathrm{T,jet}}$ and large jet radius R, over the large and complex uncorrelated backgrounds in central Pb–Pb collisions at the LHC. This precision is achievable using the statistical approach to jet background correction [347, 358, 379, 380], in which the discrimination of correlated and uncorrelated recoil jet yield is carried out in a fully data-driven way, at the level of ensemble-averaged distributions. The statistical correction approach has been used to measure the azimuthal distribution for charged jets with $R = 0.5$ and $40 < p_{\mathrm{T,jet}}^{\mathrm{ch}} < 60$ GeV/c recoiling from a high-p_{T} hadron in central Pb–Pb collisions at the LHC [358], and for charged jets with $R = 0.5$ and $p_{\mathrm{T,jet}}^{\mathrm{ch}} \sim 10$ GeV/c in central Au–Au collisions at RHIC [347], as well as for photon-jet and Z-jet correlations [379, 380]. We expect that reaching as low as $p_{\mathrm{T,jet}} = 10$ GeV/c is likewise achievable at the LHC, with good systematic precision.

The required experimental approach is therefore in hand, and we explore here the statistical precision achievable using it for such measurements during HL-LHC. We utilize the JEWEL event generator [390] for these projections, which incorporates medium-induced interactions of partons propagating in the QGP. Calculations are carried out for central Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV with integrated luminosity of 10 nb^{-1} , and pp collisions at $\sqrt{s} = 5.02$ TeV with integrated luminosity of 6 pb^{-1}. The JEWEL calculations for central Pb–Pb collisions are carried out with the “Recoil off" configuration in which the partons from the medium response are neglected.

Figure 31 shows the recoil jet azimuthal angle, $\Delta\varphi$, defined with respect to the reference axis [358] as simulated by the JEWEL event generator. The background-corrected azimuthal distribution of recoil jets recoiling from a high-p_{T} hadron, with the statistics expected by ALICE for central Pb–Pb and pp collisions during the HL-LHC phase is shown. The distribution for central Pb–Pb collisions exhibits an overall yield suppression, corresponding to jet quenching, but also a slight narrowing of the main peak at

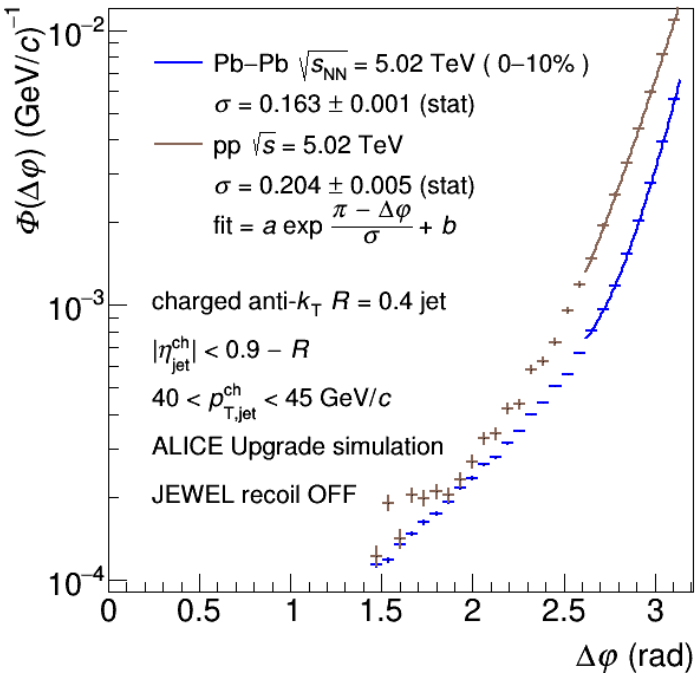

Fig. 31: JEWEL simulation of the angular distribution of charged jet yield in the ALICE acceptance for $40 < p_{\mathrm{T,jet}}^{\mathrm{ch}} < 45$ GeV/c and $R = 0.4$ recoiling from a high-p_{T} reference hadron ($20 < p_{\mathrm{T,trig}} < 50$ GeV/c), for central Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV with 10 nb^{-1} int. luminosity, and pp collisions at $\sqrt{s} = 5.02$ TeV with 6 pb^{-1} int. luminosity. The recoil jet azimuthal angle $\Delta\varphi$ is defined with respect to the reference axis. The observable shown is $\Phi(\Delta\varphi)$ which incorporates statistical suppression of uncorrelated background. Figure from Ref. [1].

$\Delta\varphi \sim \pi$ and an enhancement at large deflection angle. The narrowing is characterized by extracting the width of the $\Delta\varphi$distribution which is 0.204 ± 0.005 in the pp simulation and 0.163 ± 0.001 for the Pb–Pb simulation with JEWEL İn order to quantify the difference at large recoil jet deflection angle between pp and central Pb–Pb collisions, we integrate the $\Phi(\Delta\varphi)$ from $\pi/2$ to a threshold angle $\Delta\varphi_{\mathrm{thresh}}$ [358],

$$\Sigma(\Delta\varphi_{\mathrm{thresh}}) = \int_{\pi/2}^{\pi-\Delta\varphi_{\mathrm{thresh}}} \Phi(\Delta\varphi)\mathrm{d}\Delta\varphi. \tag{20}$$

Figure 32 shows $\Sigma(\Delta\varphi_{\mathrm{thresh}})$ for the $\Phi(\Delta\varphi)$ distributions in Fig. 31, together with their ratio. In this calculation, the value of Σ at $\Delta\varphi_{\mathrm{thresh}} = 0$ is around 0.5, which is the yield suppression averaged over the full recoil hemisphere. The ratio grows to $\Sigma \sim 1$ at $\Delta\varphi_{\mathrm{thresh}} = 1.2$, indicating a factor two enhancement in large-angle yield relative to the hemisphere average. The statistics of the measurement are clearly sufficient to measure the effect predicted by this calculation. However, the calculation in [388] predicts a difference of only a few percent in these distributions for GLV-like and BDMPS-like in-medium scattering, which is more difficult to discriminate. The statistical error in the ratio in Fig. 32 is

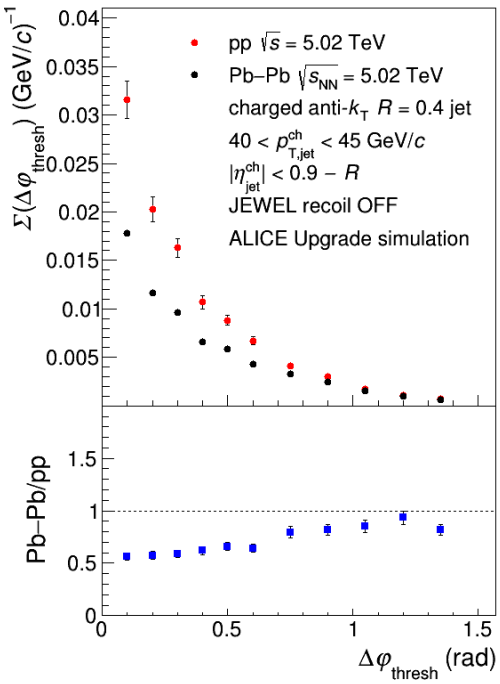

Fig. 32: Cumulative large-angle yield $\Sigma(\Delta\varphi_{\mathrm{thresh}})$ (Eq. 20) vs. $\Delta\varphi_{\mathrm{thresh}}$ for the pp and central Pb–Pb distributions $\Phi(\Delta\varphi)$ in Fig. 31. See text for details. Figure from Ref. [1].

around 5% at $\Delta\varphi_{\mathrm{thresh}} \sim 1$, due predominantly to the statistical precision of the pp distribution.

6.4 Jet internal structure

The first measurements of jet quenching through full jet reconstruction at the LHC revolutionized our understanding of parton energy loss in a hot and dense medium. Nevertheless, there remains a gap in our understanding of the jet quenching mechanism that could be resolved by measuring the exact properties of the parton evolution through the medium. High statistics of collected jets during HL-LHC will provide a prime opportunity to explore the details of the internal structure of high energy jets that undergo interactions with the QGP. Observables probing the internal structure of jets can be defined using all measured hadrons in a jet or by using subjet techniques selecting only a specific region of the radiation phase space. In the following sections both approaches and their potential will be discussed.

6.4.1 Substructure with hadrons

Inclusive measurements of the longitudinal and transverse momentum distribution of hadrons in inclusive jets have been performed with high accuracy at the LHC [391, 392]. The modification due to jet quenching is studied by comparing the results in pp and Pb–Pb collisions. For certain kinematic selections, for example at large z where the leading particle in the jet is carrying a large fraction of the total jet momentum, the current experimental uncertainties are however large (see left panel of Fig. 33) limiting the constraints on the jet quenching mechanism that can be extracted by comparing data to theoretical models. The expected statistical precision at HL-LHC for the ratio of fragmentation functions in Pb–Pb and pp collisions is shown in Fig. 33. This precision will allow detailed characterization of the excess in yield of hard (large z) and soft (small z) fragments and the suppression in the region between these two excesses providing strong constraints to theoretical models. Measurements of the rapidity dependence of jet observables are of great interest since the fraction of quark- and gluon-initiated jets

varies with rapidity. However, current measurements of the fragmentation function are statistics limited and no significant rapidity dependence is observed [391]. The right panel of Fig. 33 shows the ratio of fragmentation functions of high momentum jets for most central collisions with the expected accuracy at the HL-LHC. The projection are compared to the hybrid model [393, 394] which implements energy loss according to the strong coupling description of the radiation of low energy gluons associated with the hot QCD matter which predicts a rapidity-dependent suppression of particle yield at high z.

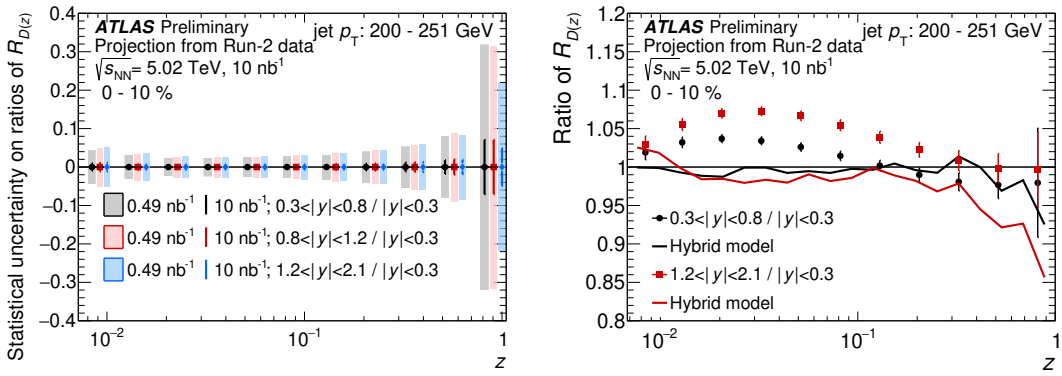

Fig. 33: Projection of the precision that can be reached for the modification of jet fragmentation function, $R_{D(z)}$, measured in jet p_{T} interval $200 - 251$ GeV/c. In the left panel the statistical uncertainty on the measurement with the shaded boxes corresponding to 0.49 nb^{-1} while the vertical bars are for 10 nb^{-1}. The right panel shows a comparison of $R_{D(z)}$ with a theory model (see text for more details) [5].

When interpreting the modification of inclusive jets one has to realize that by requiring a certain jet momentum range a different sample of partons initiating the jet is selected in pp and Pb–Pb collisions. Incorporation of this effect in model calculations introduces an additional uncertainty limiting the constraints that can be put on a model. This can be overcome by using the rare process of jets recoiling from photons. The expected performance of the radial p_{T} profile in jets recoiling from a high momentum photon at HL-LHC is shown in Fig.34. The central values of the extrapolated spectra are obtained by smoothing the results from [395] by a third order polynomial. The systematic uncertainties shown are obtained by reducing by a factor of two those from the 2015 Pb–Pb data results, considering the expected improvements on the jet energy scale and jet energy resolution uncertainties. The results show that the photon-tagged jet shape could be measured with high precision providing insights about the modification of the jet transverse structure of quark initiated jets in the strongly interacting medium. Figure 35 shows the expected statistical precision of the fragmentation function on photon-tagged events. The larger data sample will enable the measurement for finer centrality selections with respect to the current preliminary results [396] allowing an exploration of the temperature and path length dependence of jet quenching.

6.4.2 Substructure with subjets

Early hard splittings in a parton shower may result in two partons with high transverse momentum that are well separated in angle. Information about these leading partonic components can be obtained by removing the softer wide-angle radiation contributions. This is done through the use of a jet grooming algorithm called "soft drop", an extension of the modified mass drop tagger (mMDT), that attempt to split a single jet into two subjets, a process referred to as "declustering" [397–401]. For a parton shower in vacuum, these subjets provide access to the properties of the first splitting in the parton evolution [402, 403]. Figure 36 shows the expected performance for the momentum sharing fraction, z_{g} [403], in the

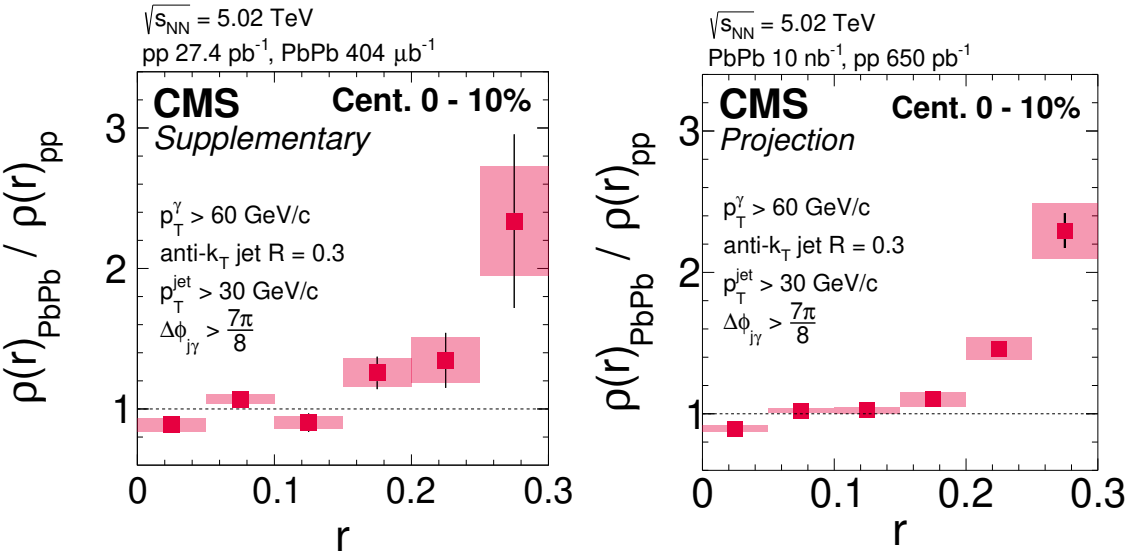

Fig. 34: (Left Panel:) The ratio of measured photon-tagged jet shape in Pb–Pb and pp collisions with the 2015 Pb–Pb data [395]. (Right Panel:) The expected performance of the jet shape ratio in the HL-LHC data, using a third-order polynomial for smoothing the data. [REF to be added when note is public]

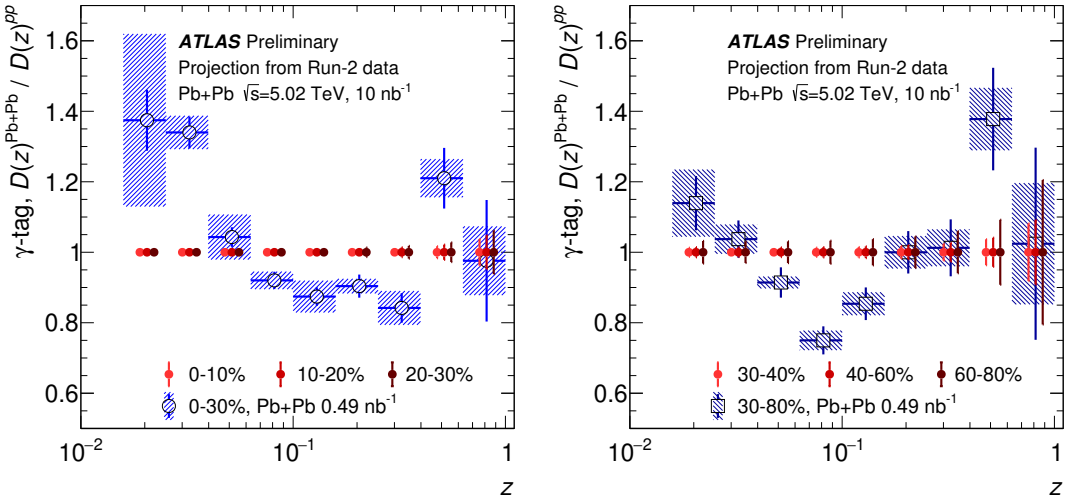

Fig. 35: Projection of the statistical precision that can be reached for the ratio of jet fragmentation functions in Pb–Pb and pp collisions, $R_{D(z)}$, of jets recoiling from a photon. The left panel shows the projection for the most central collisions while the right panel for the more peripheral events [5].

HL-LHC phase. The central values of z_g and jet mass are from previous CMS publications [364, 365]. The systematic uncertainties are reduced by a factor of two with respect to the results with 2015 Pb–Pb data due to the expected improvements on the jet energy scale and jet energy resolution uncertainties. While the current data is not precise enough to constrain the medium properties further, the expected luminosity at the HL-LHC will allow more detailed constraints as can be observed from the different results of the BDMPS [404] and SCETg [405] calculations when the medium density ($\hat{q}$ for BDMPS and g for SCETg) is varied. In addition, the expected precision will also provide the ability to distinguish

different physical mechanisms and scales relevant for jet quenching as is shown for the role of coherence in Fig. 36 in the HT theoretical calculations [406]. A measurement of the groomed jet mass with the 2015 LHC Pb–Pb data already showed that jet quenching might cause an increase of high mass jets [365]. Figure 37 shows the expected performance for the groomed jet mass at HL-LHC which will allow measuring the high mass region with higher precision.

6.4.3 Radiation phase space with Lund diagram

Recently, a theoretical representation of the radiation phase space within jets inspired by Lund diagrams [407] has been proposed [385] to study medium modification of the radiation pattern. The so-called Lund jet plane [408] - a portrayal of the internal structure of jets - was designed to build a conceptual connection between manually constructed observables and approaches that use Machine Learning techniques to study QCD jets and/or discriminate between signal and background jets. The diagram is constructed by mapping the available phase-space within a jet to a triangle in a two dimensional (logarithmic) plane that shows the transverse momentum and the angle of any given emission with respect to its emitter. Such a triangular diagram, a representation of the radiation within any given jet, can be created through repeated Cambridge/Aachen declustering.

To demonstrate the potential of future measurements at the LHC we constructed Lund diagrams using the JEWEL Monte Carlo event generator [390]. To study the differences in the Lund diagram due to medium effects the results are compared to a vacuum reference (jets produced in pp collisions). For the simulations the JEWEL generator with the default settings is used without the optional calculation of the so-called medium response retaining the partons / scattering centres that interacted with the jet was not used (i.e. *recoils off* setting of the MC generator was used). The substructure of jets was analysed

by reclustering the constituents of the jet with the Cambridge/Aachen (C/A) algorithm as implemented in the FASTJET package [409, 410] for two selections of jet p_{T} 80–120 GeV/c and 200–250 GeV/c.

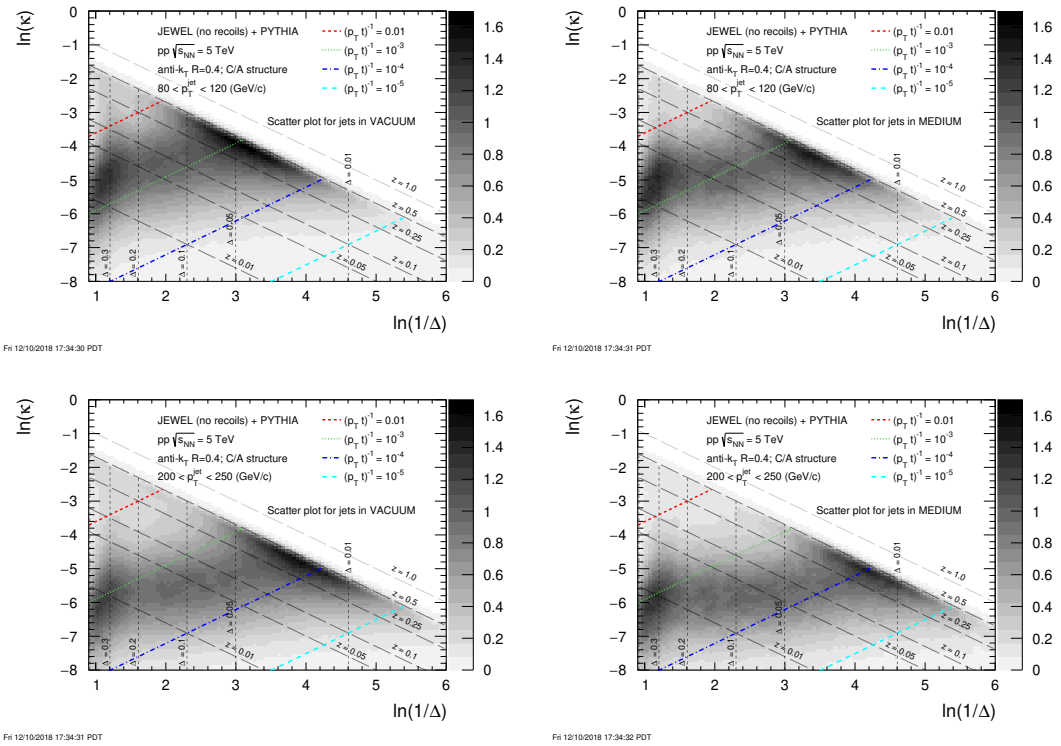

Fig. 38: The density of points of a Lund diagram for anti-k_{T} $R = 0.4$ jets for two p_{T} selections: $80 < p_{\mathrm{T}} < 120$ GeV/c in the upper row and $200 < p_{\mathrm{T}} < 250$ GeV/c in the lower row. Result of the JEWEL Monte Carlo generator with left column: jets in pp collisions; Right column: jets from Pb–Pb collisions - some with in-medium modifications. Each of the density plots shows curves of the average quantities of the densities over the other axis.

The Lund diagram density can be constructed experimentally and compared to analytic predictions and parton-shower Monte-Carlo simulations, such as JEWEL. For this purpose a density map of points (emissions) is defined following formulations in [408]:

$$\bar{\rho}(\Delta,\kappa) = \frac{1}{N_{\mathrm{jet}}} \frac{\mathrm{d}n_{\mathrm{emission}}}{\mathrm{d}\ln\kappa\,\mathrm{d}\ln 1/\Delta}, \tag{21}$$

where for two clusters 1 and 2 labeled such that $p_{\mathrm{T},1} > p_{\mathrm{T},2}$, $\Delta^2 = (y_1 - y_2)^2 + (\varphi_1 - \varphi_2)^2$ with φ being the azimuthal angle and y the rapidity of a cluster, and $\kappa = \frac{p_{T,2}}{p_{\mathrm{T},1}+p_{\mathrm{T},2}}\Delta$. Figure 38 shows the density $\bar{\rho}$ from the JEWEL simulation without (left panels) and with (right panels) medium effects. The z_g variable which was defined in [403] and studied in heavy-ion collisions [364] is related to the variables in the Lund plane in the following way: $z_{\mathrm{g}} = \kappa/\Delta$ from the first of the entries $(1...i...N)$ in the primary declustering sequence that satisfies $z^{(i)} \geq z_{\mathrm{cut}}(\Delta^{(i)})^{\beta}$ [408] resulting in diagonal lines with negative slope in the Lund diagram for a constant value of z_{g}.

The effect of jet quenching on the Lund diagram is quantified by taking the difference between the diagram with and without medium effects as shown in Fig. 39 for the two transverse momentum ranges considered in this study. The average density integrated over $\ln\kappa$ calculated for Pb–Pb (MEDIUM) case shows little deviation from the pp (VACUUM) reference. The most pronounced differences between

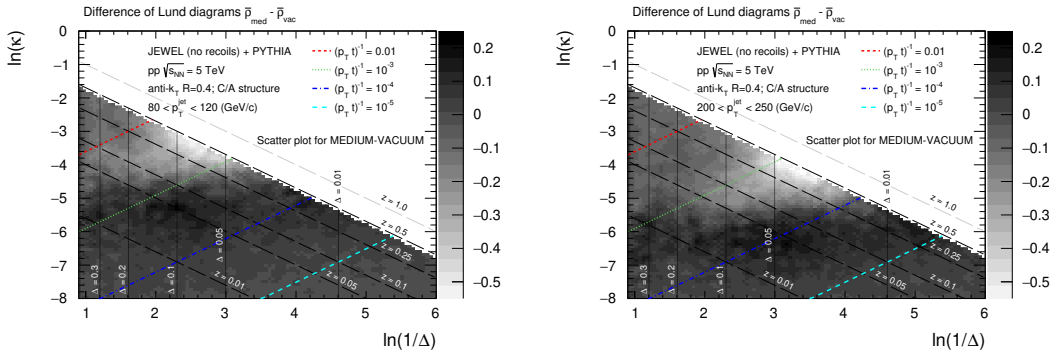

Fig. 39: Result of the JEWEL+PYTHIA MC simulation: MEDIUM-VACUUM difference of the calculations shown in Fig. 38 for two jet p_{T} selections.

VACUUM and MEDIUM calculations are visible for the region of $-3 < \ln\kappa < -3$ and large $\ln 1\Delta$ which correspond to the hard-collinear splittings (Region-A), and a band along $\ln 1/\Delta$ for small $\ln\kappa$ (Region-B): $-5 < \ln\kappa < -6$ for the lower p_{T} selection and $-5.5 < \ln\kappa < -7$ for higher p_{T} jets; that corresponds to an enhancement of soft (moderate $\ln 1/\Delta$) and hard collinear splittings (large $\ln 1/\Delta$). These observations are consistent with soft and hard collinear splittings being modified by the medium.

To illustrate the different modifications of the Lund diagram density for the two regions identified in Fig. 39, projections along $\ln 1/\Delta$ are shown in Fig. 40. For Region-A we observe 30%-40% depletion of splittings for the MEDIUM case whereas in Region-B a moderate increase of splittings induced by the medium is visible. The depletion in Region-A is consistent a sample of more collimated jets consistent with previous measurements in heavy-ion collisions [363, 392]. The increase seen in Region-B is consistent with a small in-medium enhancement of splittings with moderate dependency on the angle of the splitting but favoring the soft collinear medium-induced radiation (moderate $ln1/\Delta$).

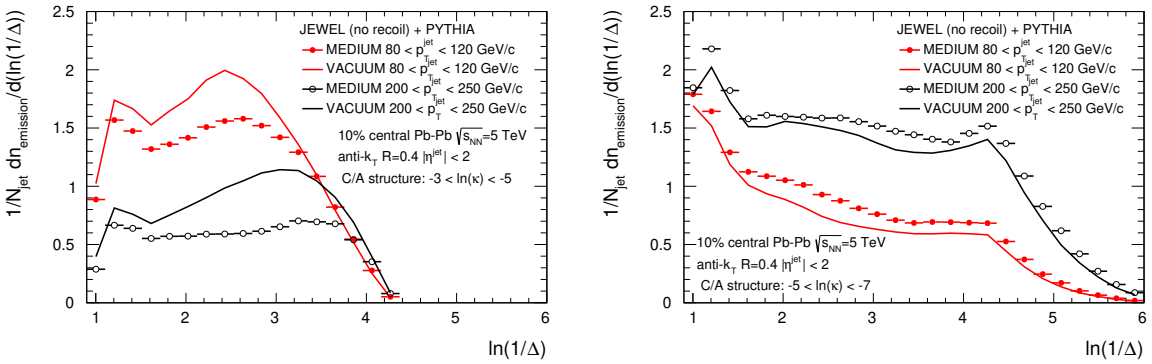

Fig. 40: Projections of the lund diagram along the angular separation $\ln 1/\Delta$ of the splittings for the two selections of jet p_{T}. In-medium suppression of splittings for moderate $\ln\kappa$ according to JEWEL (left). Enhancement for small $\ln\kappa$ (right).

As discussed in Ref. [385] specific regions in the Lund plane are sensitive to different type of parton splittings. These regions can be identified by selecting the desired area using linear functions $\ln\kappa = \ln 1/\Delta + \ln\frac{1}{p_{\mathrm{T}}t}$, where t is related to the decoherence time (thus formation time). Depending on the selection, different formation times are probed and splittings will occur within or outside the medium. Several arbitrary regions selected by the diagonal lines for constant $\frac{1}{p_{\mathrm{T}}t}$ are indicated in Fig. 38.

To illustrate the in-medium effects and their dependence on the jet momentum, the p_{T} and the formation (decoherence) time the density of the splittings can be projected along the momentum imbalance $z = p_{\mathrm{T},2}/(p_{\mathrm{T},1} + p_{\mathrm{T},2})$. In the left panel of Fig. 41 we show the relative difference of the splitting density $\Delta\bar{\rho} = (\bar{\rho}_{med} - \bar{\rho}_{vac})/\bar{\rho}_{vac}$ for a selection of $p_{\mathrm{T}}t$. For small $p_{\mathrm{T}}t$ the splitting density is suppressed for the in-medium calculations whereas for large $p_{\mathrm{T}}t$ the modification is smaller. This is consistent with the expectation that for large formation times the medium effects should be of smaller magnitude as compared to splittings formed early. As the suppression seen in $\Delta\bar{\rho}$ selected on $p_{\mathrm{T}}t$ depends on the jet p_{T} we find similar suppression for high- and low-p_{T} jet selection for substantially different product of the p_{T} and formation time. In particular, for low momentum jets the modifications of $\Delta\bar{\rho}$ for large $p_T t$ is small. To further exploit the formula providing the approximate formation time dependence of the splittings we select two regions of the Lund diagram: "late" $t > 10$ and "early" $t < 10$. The "early" region should be dominated by splittings that form within the medium, whereas the "late" splittings are to be dominated by the shower evolution outside the medium of length $L \sim t$. In the right panel of Fig. 41 we present $\Delta\bar{\rho}$ for two selections of decoherence time. As expected, a small dependence on jet p_{T} for "late" and "early" splittings is seen - a similar suppression for "early" splittings independent of jet p_{T} and almost identical $\Delta\bar{\rho}$, with small deviations from unity, for "late" emmissions. The residual differences could be attributed to different fractions of the splittings resolved by the medium, and likely, different impact of non-perturbative effects (such as hadronization) for the two jet p_{T} selections.

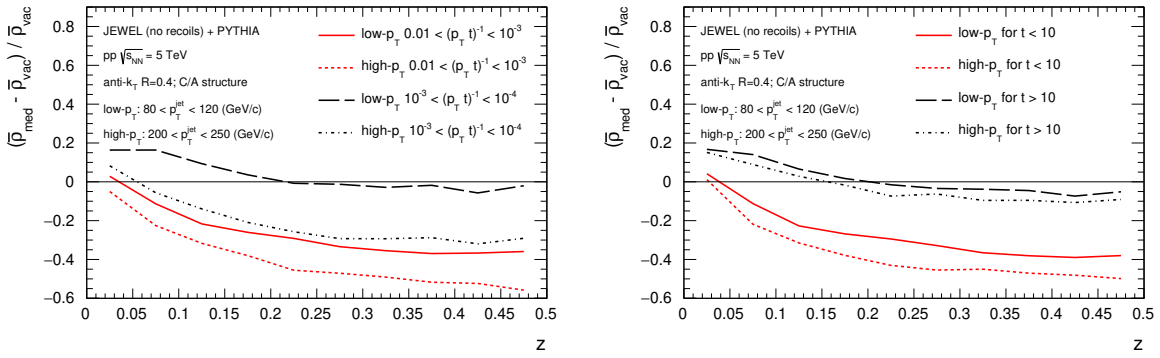

Fig. 41: Projections of the relative difference of the Lund diagram onto momentum imbalance of the splittings for two selections of jet p_{T}. Left: selection of splittings for different $\frac{1}{p_{\mathrm{T}}t}$. Right: selection of splittings for different t.

6.5 Opportunities for jet quenching studies with light-ion collisions

The ability of the LHC to collide ions lighter than Pb as discussed in section 2.4 provides an opportunity to enhance the heavy-ion programme with a very large number of rare probes as summarized in Sect. 11.1. Ar–Ar collisions are used as a test case for light ion running, although the optimal choice of ion is still under study. It is clear that due to the larger integrated luminosity obtainable for a given heavy-ion running period the number of jets produced in Ar–Ar collisions will be significantly larger than in Pb–Pb collisions. The question which will determine the value of the of light-ion running to the study of jets and parton energy loss is to what extent jet suppression effects will be reduced in smaller systems. To address this question, projections for Ar–Ar and Xe–Xe collisions at the LHC are considered using the JEWEL Monte Carlo event generator [390].

The jet nuclear modification factor R_{AA} (discussed in Sect. 6.2) in Ar–Ar collisions is here computed as the ratio of the jet transverse momentum spectrum in medium (Ar–Ar) over that in vacuum

(pp)

$$R_{\mathrm{AA}}^{\mathrm{jet}} = \frac{(\mathrm{d}N_{\mathrm{jets}}/\mathrm{d}p_{\mathrm{T}})^{\mathrm{med}}}{(\mathrm{d}N_{\mathrm{jets}}/\mathrm{d}p_{\mathrm{T}})^{\mathrm{vac}}} \,. \tag{22}$$

Table 7 summarizes the parameters used in JEWEL to calculate this quantity in 0–10% centrality Ar–Ar collisions, compared with the parameterization for Pb–Pb and Xe–Xe. The T_i^{v1} values were obtained assuming the same pre-factors as in [411]:

$$T(t) = \left(\epsilon(t)\frac{30}{47.5\,\pi^2}\right)^{1/4} , \tag{23}$$

where the energy density $\epsilon(t)$ follows a Bjorken evolution:

$$\epsilon(t) = \frac{1}{\pi R_{nucl}^2 t}\frac{\mathrm{d}E}{\mathrm{d}\eta} \,. \tag{24}$$

The energy per unit of pseudo-rapidity is taken from centrality-dependent measurements in Pb–Pb collisions. Finally the temperature T_i^{v1} is evaluated at τ_i.

Table 7: Energy and medium parameter used in JEWEL simulation of dijets and Z+jet events.

	Pb–Pb	Xe–Xe	Ar–Ar
$\sqrt{s_{\mathrm{NN}}}$ (TeV)	5.02	5.80	6.30
$\langle N_{\mathrm{part}} \rangle$	353	210	66
R_{nucl} (fm)	6.6	5.4	3.6
τ_i (fm/c)	0.6	0.57	0.63
T_i^{v1} (MeV)	360	350	318
T_i^{v2} (MeV)	260	250	218

With these medium parameters, JEWEL results lie quite below the ATLAS R_{AA} results for the Pb–Pb 0–10% centrality class [412]. JEWEL was run with medium recoil effects off, although they are known to contribute to increase the jet R_{AA} by $\sim$ 0.1–0.2 in the most central events [413]. This may explain the discrepancy. Alternatively, the discrepancy can be eliminated by reducing the temperature in JEWEL. Starting from the Pb–Pb temperature changed in order to match the ATLAS results for the Pb–Pb 0–10% centrality class, temperatures for Xe–Xe and Ar–Ar are obtained by assuming that the energy density scales with $A^{1/3}$. Thus, for an arbitrary collision system XX one has:

$$\left(\frac{T_{XX}}{T_{\mathrm{Pb-Pb}}}\right)^4 = \left(\frac{A_{XX}}{A_{\mathrm{Pb}}}\right)^{1/3} . \tag{25}$$

This parameterisation is used to obtain the T_i^{v2} values listed in Table 7 which are used to calculate the jet R_{AA} shown in Figure 42. The figure shows the JEWEL calculations for Pb–Pb, Xe–Xe, and Ar–Ar along with ATLAS Pb–Pb measurements in centrality classes chosen to match the $\langle N_{\mathrm{part}} \rangle$ values in Table 7.

To further investigate jet energy loss in Ar–Ar collisions, Z boson + jet events are studied within the same JEWEL framework. The importance of boson + jet events for the precision study of energy loss is discussed in Sect. 6.2. Events with a Z boson decaying into $\mu^+\mu^-$ associated with a jet were simulated with JEWEL + PYTHIA Monte Carlo [414]. Events were selected for a reconstructed Z boson with a mass within 70–110 GeV, a minimum p_{T} of 10 GeV/c for its decay muons, and an associated jet with a $p_{\mathrm{T}} > 30$ GeV/c and a $|\delta\varphi| > 7\pi/8$ with respect to the boson momentum direction. The resulting energy asymmetry distributions, $x_{\mathrm{jZ}} = p_{\mathrm{T}}^{\mathrm{jet}}/p_{\mathrm{T}}^{\mathrm{Z}}$, normalized to the number of reconstructed Z bosons are

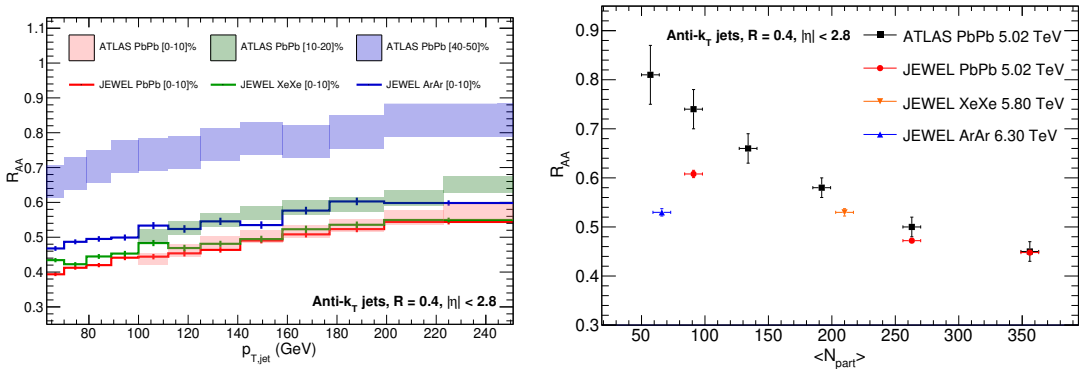

Fig. 42: Jet R_{AA} obtained from a JEWEL simulations using the medium parameters listed in Table 7, with the temperatures listed as T_i^{v2}. On the left, the jet R_{AA} is shown as a function of the jet p_{T}, and on the right as a function of $\langle N_{\mathrm{part}} \rangle$ for a jet $100 < p_{\mathrm{T}} < 126$ GeV/c.

shown in Figure 43.The distribution for central Ar–Ar collisions is similar to those for central and semi-central Pb–Pb collisions. The effect of jet quenching is very significant, as apparent in the comparison with the distribution in pp collisions.

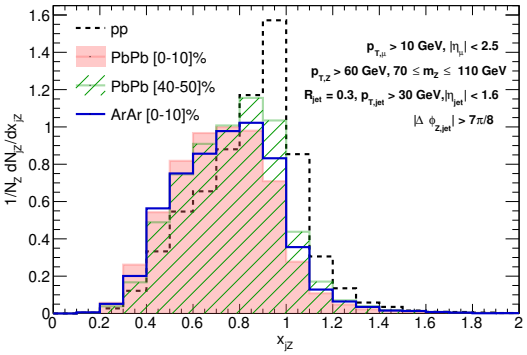

Fig. 43: Boson-Jet energy asymmetry, x_{jZ} obtained from JEWEL simulations using the medium parameters listed in table 7, with the temperatures listed as T_i^{v2}.

Taken together, these studies suggest that JEWEL does somewhat over-predict suppression in smaller systems, e.g. Xe–Xe. However, considering that central collisions are reproduced well by this model and that allowing as an upper limit the suppression measured in the Pb–Pb 40–50% centrality class, a significant suppression is expected in central Ar–Ar collisions. The expected suppression combined with the much larger nucleon–nucleon integrated luminosity (e.g. 8–25 larger with Ar–Ar than with Pb–Pb collisions) makes lighter ion collisions at the LHC an attractive possibility for the study of parton energy loss.

7 Quarkonia

7.1 Introduction

A key objective in high-energy heavy-ion physics is to determine the in-medium forces that give rise to the remarkable many-body features of the QGP. In the QCD vacuum, the unravelling of the fundamental force between two static Color charges was made possible by the discovery of the charmonium and bottomonium states in the 1970's. Subsequent quantitative analyses of the bound-state spectra established a phenomenological potential of the Cornell type [415],

$$V(r) = -\frac{4}{3}\frac{\alpha_s}{r} + \sigma r \,, \tag{26}$$

with a colour-Coulomb term due to gluon exchange dominant at short distances, and a linear term with string tension $\sigma \simeq 0.9\,\mathrm{GeV/fm}$ to account for confinement at large distance. This potential has also been quantitatively confirmed by lattice-QCD (lQCD) calculations [416, 417]. The corresponding effective field theory of QCD, potential non-relativistic QCD (pNRQCD), allows for the definition of the static potential [418] in a $1/m_Q$ expansion for large heavy-quark mass, m_Q [419, 420]. The heavy-quark (HQ) potential thus provides a well calibrated starting point to probe the QCD medium, and the in-medium spectroscopy of quarkonia is the natural tool to carry this out in heavy-ion collisions, cf. [421–425] for recent reviews. The string term in the HQ potential, eq. (26), characterises the long-range nonperturbative part of the force and is associated with the confining property of QCD. It is expected to play a critical role in the transition from hadronic to partonic degrees of freedom, and may be responsible for the remarkable transport properties of the QGP, *i.e.*, its strongly coupled nature, up to temperatures of 2-3 times the (pseudo-)critical temperature, T_c [426].

Much like in vacuum, a systematic investigation of the in-medium force must involve the *spectroscopy* of different states, as they subsequently dissolve with increasing temperature. The complexity in describing the in-medium properties of quarkonia and their implementation into transport calculations in heavy-ion collisions prevents their use as a straightforward thermometer of the medium produced in these reactions. On the contrary, using information on the space-time and temperature evolution in heavy-ion collisions from other sources (e.g.,, hydrodynamics and electromagnetic radiation), on can utilize quarkonium observables to deduce their in-medium properties and infer the fundamental interactions in QCD matter. In the vacuum, only the 1S ground-state bottomonia ($\Upsilon(1S)$ and η_b) are small enough in size to be mostly bound by the colour-Coulomb force. All excited bottomonia and all charmonia are predominantly bound by the nonperturbative string term (and/or residual mesonic forces). Thus, charmonia and excited bottomonia are excellent probes of the in-medium confining force, as originally envisioned for the J/ψ [427]. However, in the cooling of the expanding fireball, quarkonia can also be "(re)generated" through recombination of individual heavy quarks and anti-quarks diffusing through the medium. It is important to emphasise that quarkonium formation occurs also from quarks and antiquarks from different initial pairs. This mechanism [428–430] has turned out to be critical in understanding the rise of J/ψ production from RHIC to the LHC where (re)generation seems to constitute the major part of the yield observed in central Pb–Pb collisions [431]. The data is also compatible with production of J/ψ exclusively through statistical hadronisation at the crossover phase boundary [432]. Precise measurements of the $c\bar{c}$ production cross section and the extraction of the charm-quark diffusion coefficient

in Runs 3 & 4 will be important for making a more definite statement; these are key objectives discussed in the chapter 5 on open heavy-flavor production. Information from p_{T} spectra and elliptic flow will help to complete the picture.

Regarding bottomonia, the current understanding suggests that (re)generation is less important for $\Upsilon(1\mathrm{S})$, but possibly figures as a major component in the strongly suppressed yield of excited states [433, 434]. It is therefore of great importance to obtain additional information about the typical time at which quarkonia are produced, in particular through p_{T} spectra and elliptic flow which contain information about the fireball collectivity imprinted on the quarkonia by the time of their decoupling. A schematic illustration of the current knowledge extracted from in-medium quarkonium spectroscopy, *i.e.*, their production systematics in heavy-ion collisions is shown in Fig. 44.

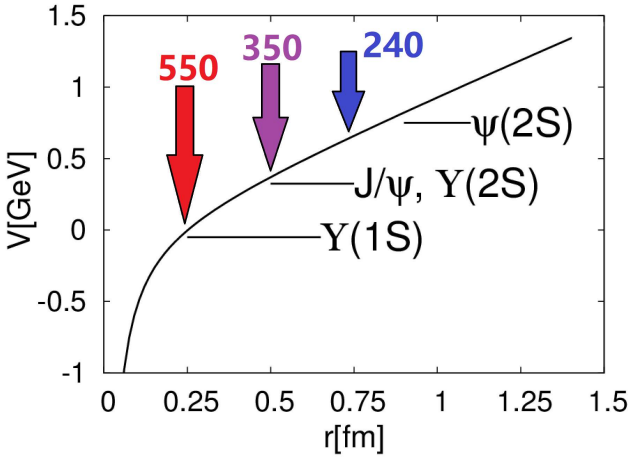

Fig. 44: The vacuum heavy-quark potential as a function of $Q\bar{Q}$ separation. The horizontal lines indicate the approximate locations of the vacuum bound states while the vertical arrows indicate the minimal screening distances of the media produced at the SPS, RHIC and LHC, as deduced from approximate initial temperatures reached in these collisions extracted from data (indicated above the arrows in MeV) and from quarkonium production systematics in Pb–Pb and Au-Au collisions. Figure taken from Ref. [431].

On the theoretical side, the basic objects are the quarkonium spectral functions which encode the information on the quarkonium binding energies, in-medium HQ masses and the (inelastic) reaction rates. Ample constraints on the determination of the quarkonium spectral functions are available from thermal lQCD, *e.g.*, in terms of the heavy-quark free energy, euclidean and spatial quarkonium correlation functions, and HQ susceptibilities, and are being implemented into potential model calculations [435–441]. In particular, the role of dissociation reactions has received increasing attention. Early calculations of gluo-dissociation [442, 443] or inelastic parton scattering [444] have been revisited and reformulated, e.g., as a singlet-to-octet transition mechanism [438] or in terms of an imaginary part of a two-body potential [445], respectively. In particular, the latter accounts for interference effects which reduce the rate relative to "quasi-free" dissociation [444] in the limit of small binding; interference effects can also be calculated diagrammatically [446]; they ensure that, in the limit of vanishing size, a Color-neutral $Q\bar{Q}$ dipole becomes "invisible" to the Color charges in the QGP.

The information from the spectral functions can then be utilised in heavy-ion phenomenology via transport models. The latter provide the connection between first-principles information from lQCD and experiment that greatly benefits the extraction of robust information on the in-medium QCD force and its emergent transport properties, most notably the (chemical) equilibration rates of quarkonia. Thus far

most transport models are based on rate equations and/or semiclassical Boltzmann equations. In recent years quantum transport approaches have been developed using, e.g., a Schrödinger-Langevin [447–450] or density-matrix [451, 452] formulation. These will enable to test the classical approximation underlying the Boltzmann and rate equation treatments and ultimately quantify the corrections. Quantum effects may be particularly relevant at high p_{T} in connection with the in-medium formation times of quarkonia, augmented by the Lorentz time dilation in the moving frame; schematic treatments of this effect in semiclassical approaches suggest that varying formation times can leave observable differences for high-momentum charmonia and bottomonia [433, 434, 453–455]. Finally, the implementation of phase-space distributions of explicitly diffusing heavy quarks into quarkonium transport is being investigated by various groups (see, e.g., Ref. [456]), which, as mentioned above, will provide valuable constraints on the magnitude and p_{T} dependence of (re)generation processes. In particular, the role of non-perturbative effects in the HQ interactions in the QGP (which are believed to be essential to explain the large elliptic flow observed for D-mesons [260]) needs to be accounted for; the associated large scattering widths are likely to require quarkonium transport implementations beyond semi-classical (or perturbative) approximations, which reiterates the need for a quantum treatment of recombination processes.

The larger experimental data samples in Runs 3 & 4, combined with improved detector performance and measurement techniques, will allow one to significantly improve over the current measurements, with extended kinematic coverage (in p_{T}) and allowing one to reach also currently-unobserved quarkonium states, like $\Upsilon(3S)$. The complementarity (and overlap) of all 4 LHC experiments is crucial in this endeavour and will call for a data combination strategy, for instance for Υ azimuthal anisotropy. Quarkonia are measured in the dimuon channel in ATLAS ($|y| < 2.0$), CMS ($|y| < 2.4$), LHCb ($2.0 < y < 4.5$), and ALICE ($2.5 < y < 4.0$), and in the dielectron channel with ALICE ($|y| < 0.9$). We present below data projections and simulations for a selection of observables and compare to model predictions (which sometimes constitute the basis for the projections). The model uncertainties shown in this section represent the current knowledge; significant improvements are expected both in what concerns the conceptual aspects discussed above as well for the input parameters, which will be constrained by data and theory (for instance in what concerns nuclear PDFs, see also Section 10.4).

All four LHC experiments will benefit from a large upgrade program, during the Long Shutdown 2 (2019–2020) for ALICE and LHCb, and during Long Shutdown 3 (2024–2025) for ATLAS and CMS. The addition of the Muon Forward Tracker (MFT) will allow ALICE to separate the prompt charmonium from the contribution from B meson decays. In addition, the background will be reduced, yielding to better signal over background ratios. Regarding ATLAS and CMS, the upgraded inner tracker will extend to $|\eta| \lesssim 4.0$ after LS3, and the muon system coverage to $|\eta| \lesssim 2.7$ (3.0) for ATLAS (CMS). While the detector improvements will have a smaller impact than the increase in data sample size, this increase in pseudorapidity coverage is appreciable in also giving an overlap with the range of ALICE and LHCb. Better track momentum resolution is also expected from these upgraded inner trackers, with an improvement of about 30% of the mass resolution of quarkonia for CMS [457]. The expected improvement in the relative statistical uncertainty, due to a better signal over background ratio, is in the range 10–25% [9].

7.2 Charmonia in Pb–Pb collisions

A remarkable discovery at the LHC was that the suppression of J/ψ is significantly reduced in comparison to lower energies [458] and that this reduction is concentrated at lower p_{T} [459, 460], compatible with predictions of (re)generation at the phase boundary of QCD [428] or throughout the deconfined phase [429, 461, 462], via recombination of diagonal (correlated pairs) or off-diagonal $\mathrm{c\bar{c}}$ pairs [430]. No significant difference is however found between measurements at $\sqrt{s_{\mathrm{NN}}} = 2.76\,\mathrm{TeV}$ and $\sqrt{s_{\mathrm{NN}}} = 5.02\,\mathrm{TeV}$ [460, 463]. Recently, the measurement of a significant elliptic flow coefficient v_2 both for D mesons [464–466] and J/ψ [262, 467–470], which was shown to be correlated to

the flow of the bulk particles [278, 470], can be seen as another indication for the thermalisation of charm quarks in the QGP. Transport model calculations [471, 472] currently underestimate the data for $p_{\mathrm{T}} \gtrsim 6$ GeV/c [262, 468, 469].

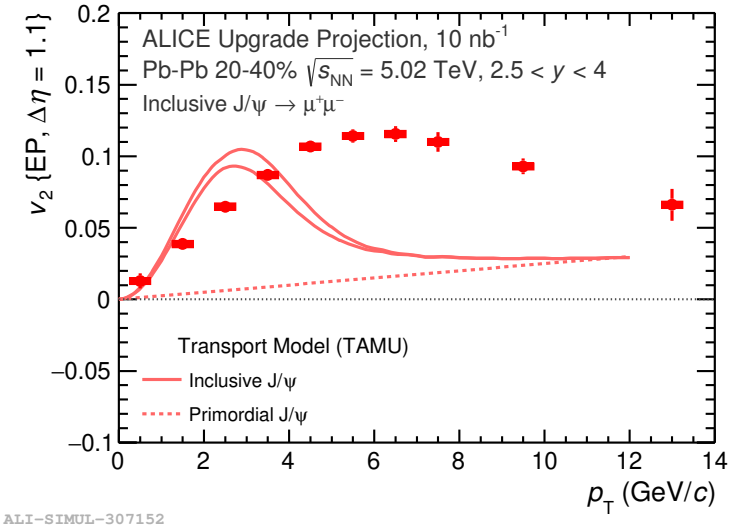

Fig. 45: Projected measurement of elliptic flow coefficient v_2 as a function of p_{T} for J/ψ mesons (measured in ALICE, for $2.5 < y < 4$), for the centrality class 20–40%, in comparison to model calculations [472]. Figure from Ref. [1].

The projected ALICE measurement of inclusive J/ψ v_2 as a function of p_{T} for the centrality class 20–40%, for $2.5 < y < 4$, in comparison to model calculations [472] is shown in Fig. 45. Disentangling the contributions of prompt and non-prompt J/ψ and considering (path-length dependent) energy loss seems mandatory to understand the details of the J/ψ v_2 pattern, which will be facilitated with the detector upgrades and higher luminosity of Runs 3 & 4. The measurement of higher harmonics, e.g., v_3, which are sensitive to initial state energy density fluctuations, will also become available and provide further insight into the charmonium production mechanisms. Precise prompt and non-prompt J/ψ v_2 and v_3 measurements at low p_{T} will be reachable using the ALICE central barrel. Polarisation will be measured too [2], providing further insight in the different production mechanisms involved in Pb–Pb collisions as compared to pp. Under the statistical hadronisation paradigm, the prompt J/ψ yield in Pb–Pb collisions should be unpolarised with the 3 polarisation states equally populated.

At high p_{T}, where a raising trend is currently hinted by Run 2 R_{AA} measurements [463, 473], the production mechanisms cannot currently be resolved, given the statistical limitation in the data (see Fig. 46, left). The high p_{T} reach of Runs 3 & 4 data (illustrated in Fig. 46 (right) for CMS) will allow one to conclude on the important question of whether J/ψ formation at high p_{T} is determined by the Debye screening mechanism [455, 474], or by energy loss of the charm quark or the c$\bar{\mathrm{c}}$ pair [475, 476].

The measurement of $\psi(2S)$ mesons is more difficult than that of J/ψ, because of a much smaller production cross section times branching ratio and even larger suppression in Pb–Pb, yielding a very low signal to background ratio. The projections for the measurement of the $\psi(2S)$ state in ALICE are shown in Fig. 47 as a function of centrality and compared to model predictions in the transport approach [472] and from the statistical hadronisation model [432]. This (p_{T}-integrated) measurement will significantly contribute to make a distinction between the two models. Projections are also available from the CMS experiment [8]. Other states, for instance χ_{c}, may be measured too, albeit the measurement down to $p_{\mathrm{T}} = 0$ will remain challenging. $\mathrm{B_c^+}$ mesons can also be measured, either in the J/$\psi\pi$ or

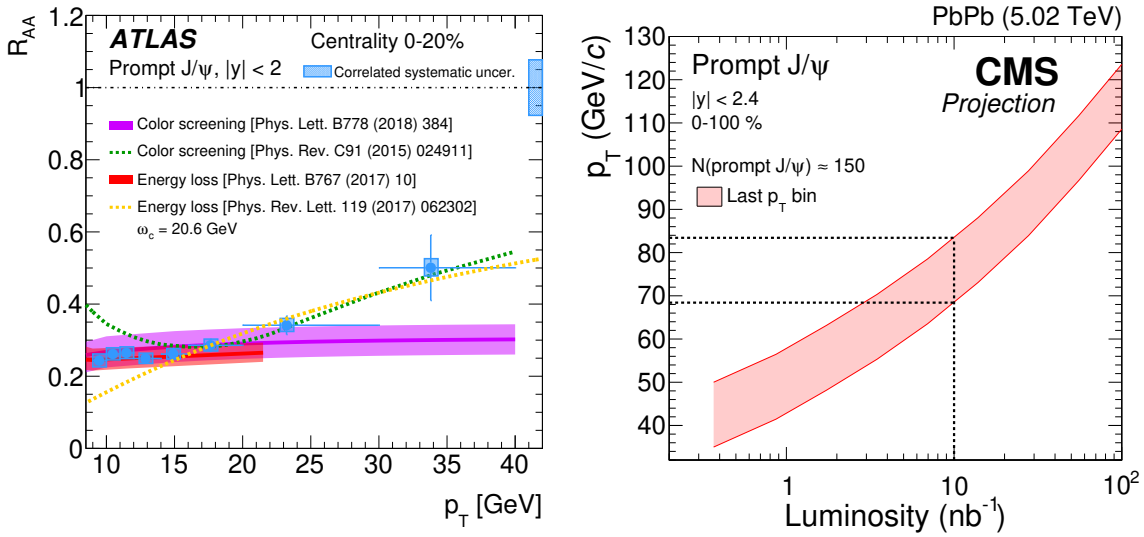

Fig. 46: Left: R_{AA} vs p_{T} for prompt J/ψ in central (0–20%) collisions (ATLAS, $|y| < 2$, [473]). Right: Prompt J/ψ high p_{T} bin boundaries as a function of luminosity with the CMS experiment [9]. The boundaries are chosen in such a way the number of mesons in the bin for the corresponding luminosity equals the number of mesons found in the last p_{T} bin of the current measurement [463].

J/$\psi\mu\nu_{\mu}$ channel, to further study recombination in the beauty sector.

7.3 Bottomonia in Pb–Pb collisions

The study of bottomonia with Pb–Pb data from the Runs 3 & 4 of the LHC will bring further information on the physics aspects described above. Although their production is a priori sensitive to the same effects as charmonia, in practice the two quarkonium families feature some fundamental differences. Binding energies differ, which is reflected in the different dissociation temperatures. Experimentally, compared to charmonia, the absence of contribution from B meson decays and the more similar cross section times branching ratio between the ground and excited states make bottomonia measurements easier. At the same time, in pp collisions, up to 30–50% of the measured $\Upsilon(1S)$ and $\Upsilon(2S)$ yields actually result from the feed-down from other states [258, 478]: a large portion of measured $\Upsilon(1S)$ suppression can be due to the stronger suppression of the feed-down states – $\Upsilon(2S)$ and $\Upsilon(3S)$ mesons also receive a significant contribution from feed-down. The impact of (re)generation from uncorrelated $b\bar{b}$ is also expected to be much smaller than for charmonia, because of the much smaller number of $b\bar{b}$ pairs per Pb–Pb event compared to that of $c\bar{c}$ pairs. The importance of regeneration for bottomonia, from correlated or uncorrelated pairs [450], is however still very model dependent, and no unambiguous experimental signal for it has been found yet. Possible ways of constraining this contribution will be discussed in this section.

Experimentally, the higher mass of bottomonia compared to charmonia implies higher p_{T} decay leptons, allowing the ATLAS and CMS experiments to measure the production down to zero transverse momentum, as is possible for ALICE for both charmonia and bottomonia [479, 480]. The proximity in mass between the different mass states, especially between the $\Upsilon(2S)$ and $\Upsilon(3S)$ states, also means that good muon (or electron) momentum resolution is essential to their measurement, especially for excited states.

It is useful to remind quickly the status in 2018, based on results from Run 1 and early Run 2 LHC data as well as RHIC data. Υ production is found to be suppressed in Pb–Pb compared to expectations

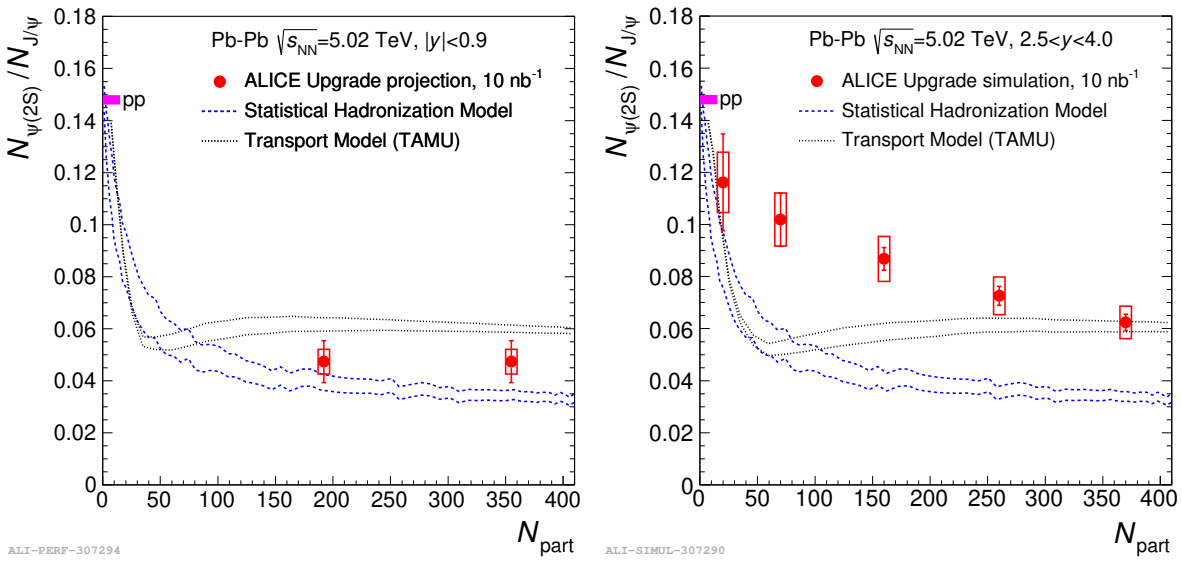

Fig. 47: Production ratio $\psi(2S)/J/\psi$ vs. N_{part} for $|y| < 0.9$ (left) and $2.5 < y < 4$ (right) [2, 477]. Model predictions in the transport approach [472] and from statistical hadronisation [432] are included. The values of the ratio used for the projections are quasi-arbitrary. Figures from Ref. [1].

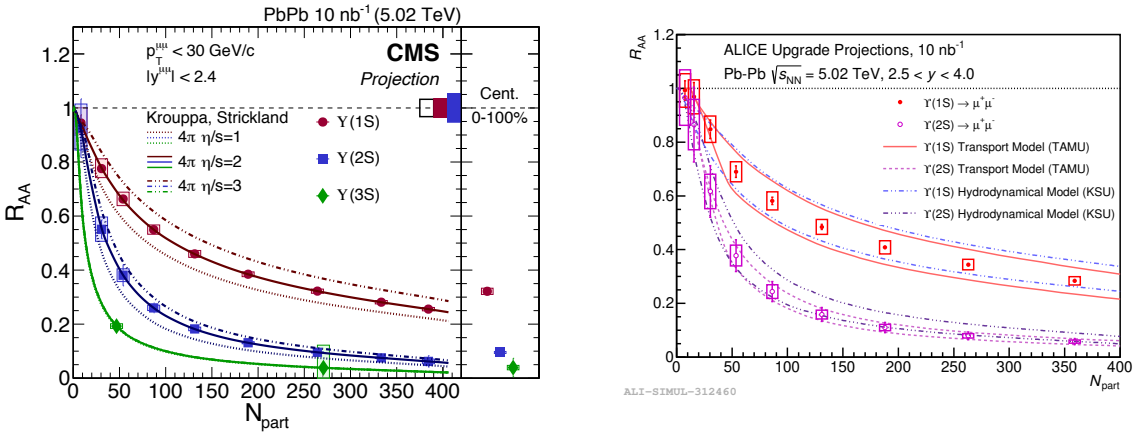

Fig. 48: Centrality dependence of $\Upsilon(1S)$, $\Upsilon(2S)$ and $\Upsilon(3S)$ R_{AA}, as projected by the CMS [8,484] (left) and ALICE [1] (right) experiments, and from a transport model [433]

from a scaling of incoherent pp collisions, in all rapidity, p_T and centrality ranges measured [479–482]. Suppression is stronger in central events, as expected from the hotter and longer-lived medium in such events. The results from the most central collisions suggest that a certain amount of suppression of the directly produced $\Upsilon(1S)$ might be needed to explain the data in addition to cold nuclear matter effects and melting of the excited Υ and χ_b states. The excited states $\Upsilon(2S)$ and $\Upsilon(3S)$ show higher suppression wrt the ground state, with R_{AA} values which respect the hierarchy expected based on their binding energies. The $\Upsilon(3S)$ is still unobserved in Pb–Pb collisions ($R_{AA}(\Upsilon(3S)) < 0.094$ at 95% confidence level, for $\sqrt{s_{NN}} = 5.02$ TeV [481, 483]). No significant dependence of the suppression of Υ states is found at the LHC on collision energy or rapidity.

Differences exist between models in the theoretical treatment of the suppression of the bottomonia in the medium, as summarised earlier in Section. 7.1. Different assumptions are used regarding the

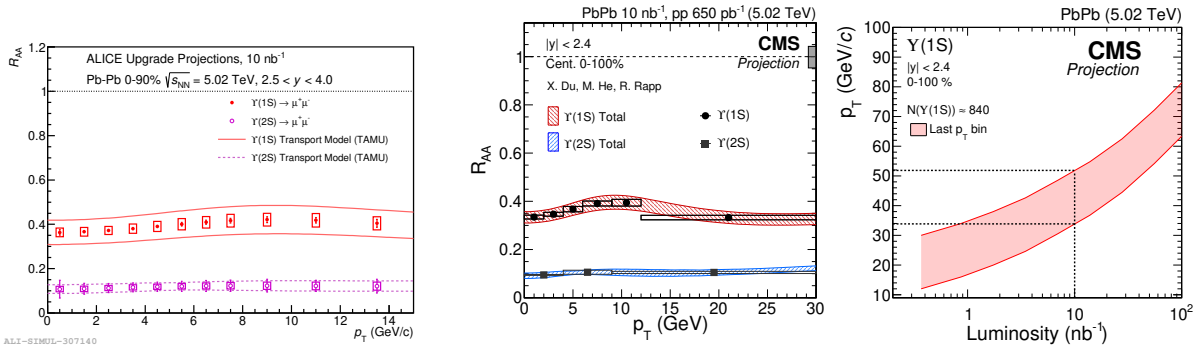

Fig. 49: Projected R_{AA} for $\Upsilon(1\mathrm{S})$ and $\Upsilon(2\mathrm{S})$ expected from the ALICE [1] (left) and CMS [9] (center) experiments, as a function of p_{T}, with $10\,\mathrm{nb}^{-1}$ of Pb–Pb data. The expected p_{T} reach for $\Upsilon(1\mathrm{S})$ from the CMS experiment is also shown [9], as the position of the last p_{T} bin of the measurement, with constant number of observed $\Upsilon(1\mathrm{S})$, as a function of integrated luminosity.

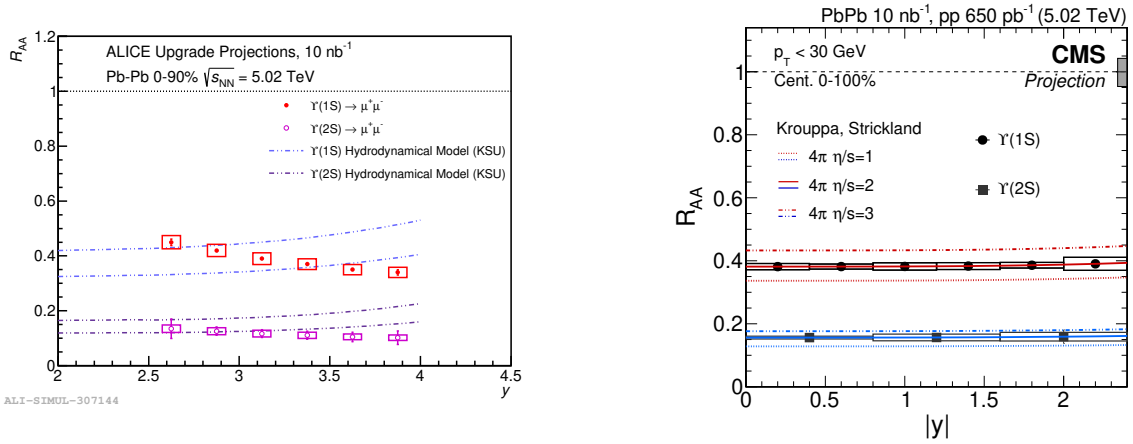

Fig. 50: Projected R_{AA} for $\Upsilon(1\mathrm{S})$ and $\Upsilon(2\mathrm{S})$ expected from the ALICE [1] (left) and CMS [9] (right) experiments, as a function of rapidity, with $10\,\mathrm{nb}^{-1}$ of Pb–Pb data.

production mechanism, the heavy quark potential, or the evolution of the quarkonia with the medium. The understanding of hot medium effects will be also improved thanks to higher precision measurements in pp collisions of the feed-down fractions and to stronger constrains of the cold nuclear matter and initial state effects (including nPDF or coherent energy loss effects [485]) from p–Pb collision measurements. Figure 48 shows that the projected uncertainty on the R_{AA} of Υ with $10\,\mathrm{nb}^{-1}$ will be much smaller than the current model uncertainties. Bottomonia may bring information complementary to other probes, using the sensitivity of the suppression to the medium shear viscosity or to the initial temperature of the fireball.

A precise measurement of the p_{T} dependence of the $\Upsilon(1\mathrm{S})$ R_{AA} will be possible using LHC data from Runs 3 & 4. At low and medium p_{T}, the measurement is sensitive to the possible regeneration component in Υ meson production [433]. Projections for the expected precision of Υ measurements from the ALICE and CMS detectors using an integrated luminosity of $10\,\mathrm{nb}^{-1}$ after the Runs 3 & 4 are shown as a function of p_{T} in Fig. 49 and y in Fig. 50, and compared to the expectations from two models [433, 434]. In the Kent state model calculations [434] (not shown), where Υ mesons are originating only from the primordial production, with no regeneration component, the R_{AA} is rather flat in the low and medium p_{T} range. Only at higher p_{T} (above 10–15 GeV/c) is a small rise predicted, which

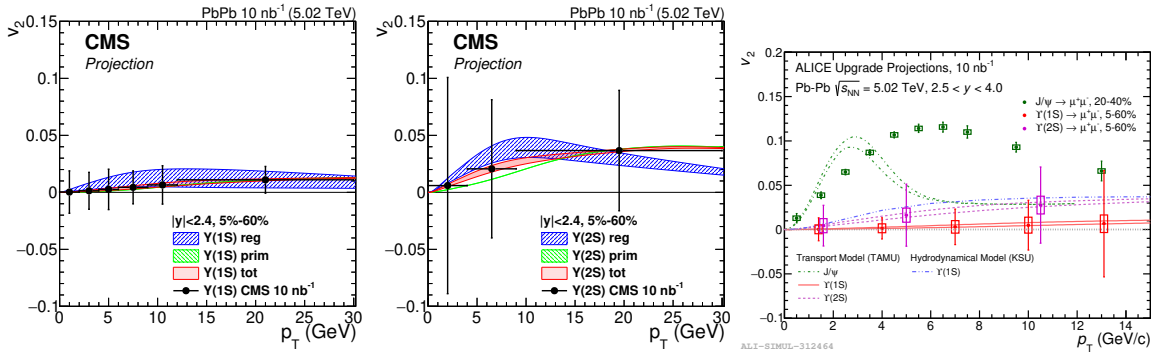

Fig. 51: v_2 projections for the CMS [9] (left and centre) and ALICE [1] (right) experiments for the $\Upsilon(1S)$ and $\Upsilon(2)$ mesons, assuming the predictions from a transport model [433].

can be looked for in Runs 3 & 4 data: as can be seen in Fig. 49, it is expected that a measurement up to a p_T of about 50 GeV/c can be performed with the ATLAS and CMS detectors with 10 nb^{-1} of data. In the TAMU model [433] however, a regeneration component is considered, and several assumptions are explored, especially on the degree of thermalisation of the bottom quarks. It predicts a maximum in the $\Upsilon(1S)$ R_{AA} at a p_T around 10 GeV/c. The current data is not precise enough to confirm or disfavour such a local maximum in the R_{AA}, but Runs 3 & 4 data will allow to conclude.

Almost no rapidity dependence is expected at the LHC for the nuclear modification factor of Υ mesons within the acceptance of ATLAS and CMS ($|\eta| \lesssim 2.5 - 3$), which can be better tested using Runs 3 & 4 data. This will be further made significant considering the ALICE acceptance ($2.5 < y < 4$), allowing to confirm or disprove the prediction of the hydrodynamic model, see Fig. 50.

Coming back to the matter of regeneration, much can be learnt about it by a measurement of the elliptic flow of $\Upsilon(1S)$ mesons [486], unmeasured to date in any collision system. A parallel can be drawn with that of J/ψ, which is still not properly described by models. This observable requires a more detailed implementation of the dynamics of the interactions between the quarkonium and the medium: thermalisation of the heavy quarks, time dependence of regeneration, path length dependence of energy loss, as well as initial geometry fluctuations and elastic rescattering of the quarkonia in the medium. Thus, collective flow brings complementary information to the R_{AA}, and its measurement can help disentangle some effects. In the case of $\Upsilon(1S)$ mesons, a small v_2 (order of 1–2%) is expected [433,487, 488], as can be seen in Fig. 51. The elliptic flow of $\Upsilon(2S)$ could be significantly higher [433,488], both from the regenerated and primordial components. For both states, projections show that experimental precision may not be enough for a significant v_2 measurement, assuming v_2 values as in Ref. [433]. For this reason, combining results between the different LHC experiments would be beneficial to reach a better sensitivity.

While we have focused on the R_{AA} and v_2 in this section, bottomonium production can be studied using other observables. For instance, fully corrected yields or cross sections in Pb–Pb can be studied, without making the ratio to a pp measurement in a R_{AA}. Such a measurement, already reported in some of the available experimental results [481], can directly be compared to production models.

7.4 Quarkonia in p–Pb and pp collisions

7.4.1 p–Pb *collisions*

Quarkonium-production studies in high-energy p–Pb collisions are usually carried out to measure how much specific nuclear effects, those which do *not* result from the creation of a deconfined state of matter, can alter the quarkonium yields. They should indeed be accounted for in the interpretation of Pb–Pb

results. They are also interesting on their own as they provide means to probe the modification of the gluon densities in the nuclei, the interaction between such pure heavy-quark bound states and light hadrons, or phenomena such as the coherent medium-induced energy loss of these quark-antiquark pairs. The measurements as a function of event activity brought several surprises, hotly discussed presently.

Usually, a separation into initial-state and final-state effects is done (coherent energy loss effects [489] can be seen as an interplay between the two types of effects). Yet, it is probably more instructive to separate out the effects which are believed to impact *all* the states of the charmonium or the bottomonium family with the *same* magnitude from those which are expected to impact differently the ground and the excited states. In principle, initial-state effects (in particular gluon shadowing [329]) are of the first kind as the nature of the to-be-produced quarkonium state is not yet fixed when the effects are at work. On the contrary, final-state effects (like regeneration [490]) do depend on the properties of the produced quarkonium state and are thus be of the second kind.

However, in p–Pb collisions at LHC energies, final-state interactions between the heavy-quark pair and the nuclear matter likely occur *before* the pair hadronises. This is due to the large boost between the nucleus and the pair – and thus the quarkonium. At rest, a $c\bar{c}$ or $b\bar{b}$ pair takes 0.3–0.4 fm/c to hadronise; seen from the nucleus, at, for instance $y^{\rm lab}_{\rm pair} - y_{\rm beam} \sim 7$, it takes $\gamma = \cosh(7) \simeq 500$ times longer. As such, final-state interactions with the compounds nucleus likely do not discriminate ground and excited quarkonium states, unless rescattering in the nucleus affects the $\rm Q\bar{Q}$ wave function, overlapping with the quarkonium wave function at large distance [491]. Such an argument based on the existence of a large boost is nevertheless not applicable if one considers effects arising from the interactions between the pair and other particles *produced* by the p–Pb collisions, not those contained in the Pb nucleus. The former are indeed not moving at the Pb projectile rapidity. In fact, some of these particles can have similar rapidities as the quarkonium and can thus be considered as comoving with it [492–494].

The simultaneous study of open-heavy flavoured hadrons along with both ground and excited quarkonium states can shed light on all these phenomena. Along the lines exposed above, one expects forward-quarkonium production in p–Pb collisions (namely when the quarkonia flies in the direction of the proton) to be sensitive to low-x phenomena (like the gluon shadowing or saturation in the lead ion) and to the coherent energy loss. On the contrary, the backward production should be sensitive to the gluon antishadowing and to fully coherent energy loss. Moreover, the scatterings of quarkonia with comoving particles occur more often backward than forward, due to the rapidity-asymmetric particle multiplicities, and more often as well with the larger and less tightly bound excited states.

With a wide rapidity coverage spanning from about -5 to 5, the LHC data from the 4 experiments are unique as they allow one to probe much smaller x values than at RHIC and with a larger reach in $p_{\rm T}$. The higher c.m.s. energy, the competitive luminosities and the resolution of the detectors also allow for more extensive studies of the bottomonium family. In fact, an important observation made with Run 1 data was that of a relative suppression in p–Pb collisions of the excited $\Upsilon(2S)$,$\Upsilon(3S)$ states compared to that of the $\Upsilon(1S)$ observed by CMS [495] as a function of the event activity (recently confirmed by ATLAS [496], but also observed in pp collisions by CMS [497]). Not only was it unexpected, but it constitutes a challenge to the conventional interpretation of suppression observed in Pb–Pb collisions [481, 483, 498], which is of a significantly larger magnitude, but of a similar pattern. Such a relative suppression was also observed in the charmonium sector [499], where it is as well remarkable.

As far as the suppression of the $\Upsilon(1S)$ and J/ψ is concerned, they seem to follow the expectations based on the RHIC results with a strong forward suppression described by shadowing – of a compatible magnitude to that observed with HF data [329], or with the coherent energy loss mechanism [489]. More data, including that on $\Upsilon(nS)$ and Drell-Yan production, are clearly needed to disentangle both effects [500] (see also Section 10.3.4). More precision for $\Upsilon(nS)$ and non-prompt J/ψ is in general critically needed as the typical experimental uncertainties are still on the order of the expected effects.

As a case in point, backward y data are not yet precise enough to quantify the magnitude of the gluon antishadowing, see Section 10 for the possible relevance of quarkonium p–Pb LHC data on nuclear PDF fits. Direct inclusion of this data in nPDF fits is however not yet possible, pending unambiguous clarification of the different effects impacting quarkonium production in p–Pb collisions.

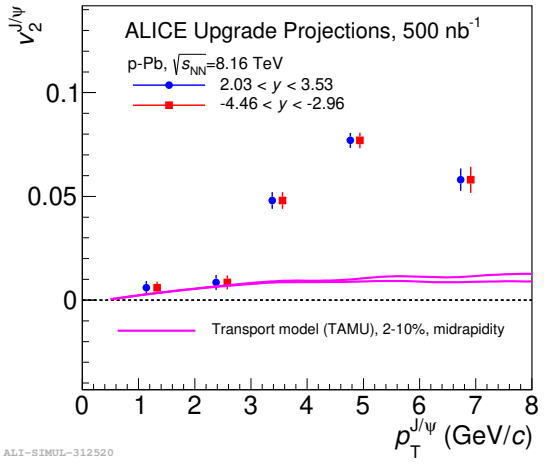

Fig. 52: The p_{T} dependence of the v_2 coefficient of J/ψ mesons in p–Pb collisions, for 500 nb^{-1} (ALICE). The projections are based on current ALICE data for 0–20% centrality [501] and are shown separately for negative and positive y_{CM}), assuming the same magnitude and are compared with transport model (TAMU) calculations [490] for midrapidity. Figure from Ref. [1].

Recently, the measurement of v_2 of J/ψ in p–Pb collisions became available [501,502], indicating a large azimuthal anisotropy, $v_2 \lesssim 0.1$ up to $p_{\mathrm{T}} \lesssim 8$ GeV/c. Recent transport model calculations [490], which are successful in describing the features of the data, including the transverse momentum and centrality dependence of J/ψ and $\psi(2S)$ production in p–Pb, cannot reach the high value of the v_2 coefficient seen in data [501, 502] (see Fig. 52), suggesting that the observed v_2 in p–Pb collisions might also originate from initial state effects. A precision measurement in Runs 3 & 4 for a broad rapidity range will clarify this.

In addition to conventional LHC collider data, one should not overlook the discriminating power of data which can be collected in the fixed-target mode [503, 504]. Not only they correspond to completely different energy and (c.m.s.) rapidity ranges, but extremely competitive luminosities, up to a few fb^{-1}, are easily reachable, beyond what can be reached in the collider mode during Runs 3 & 4. The LHCb collaboration has paved the way for a full fixed-target program at the LHC with their SMOG luminosity monitor [505] used as an internal (He, Ne, Ar) gas target [506] (see also Section 11.4). It is now clear that corresponding studies to those suggested above are possible [507] with the LHCb and ALICE detectors with minor technical adjustments. They would drastically expand the scope of current proton-nucleus quarkonium studies.

7.4.2 High-multiplicity pp *collisions*

Systematic studies of the quarkonium production in high-multiplicity pp events can play an important role in understanding hadronisation. In particular, the correlation of the quarkonium yields with the charged-particle multiplicity can provide new insights into the interplay between hard and soft processes in particle production. Hidden and open heavy-flavour production measurements as a function of the event activity were carried out at the LHC during Run 1 [495, 508]. The striking feature of the data is that the production yields of quarkonia in high multiplicity events are significantly enhanced

relative to minimum bias events, like for D mesons [509]. Specifically, the measurements of the self-normalised yields (the yield divided by the mean yield in minimum bias collisions) as a function of the self-normalised charged-particle multiplicity show an increase which is stronger than linear at the highest multiplicities. The similarity between the D-meson and J/ψ results [508, 509] suggests that this behaviour is most likely related to the production processes, and that hadronisation may only play a secondary role. When comparing J/ψ preliminary results at $\sqrt{s} = 13$ TeV [510] to the ones previously obtained at $\sqrt{s} = 7$ TeV [508], no significant energy dependence is observed, *i.e.* the relative J/ψ yields for events with identical relative multiplicities give similar results. In addition, a dependence of the excited-to-ground-state ratio with charged particle multiplicity is observed in the bottomonium sector in pp collisions [495, 497].

The data are described both by initial-state models as well as by a model assuming hydrodynamic evolution [511], considering that the energy density reached in pp collisions at LHC is high enough to apply such evolution. Initial-state (saturation) effects are considered within i) the Color-Glass-Condensate (CGC) framework [512]; ii) the percolation approach [513, 514]; iii) a model with higher Fock states [515], based on parameters derived from p–Pb collisions. The energy dependence of the cross sections is controlled by the saturation momentum $Q_s(x)$ in the case of the CGC or density of colour ropes $\rho_s(y, p_T)$ in the percolation model, which also governs the charged-hadron multiplicity; events at different energies with the same Q_s or ρ_s are therefore identical. For a given event multiplicity, they predict the relative yields to be almost energy independent. It seems that, in any case, multiple interactions at the partonic level need to be taken into account in order to reproduce the data [516–518].

Runs 3 & 4 data, reaching unprecedented high multiplicities because of larger data samples, and allowing for differential studies in $p_{\rm T}$, will certainly help discriminate models. For instance, in the percolation model, where colour interactions produce a reduction of the charged-particle multiplicities, the deviation from the linear behaviour is expected to be steeper for high-$p_{\rm T}$ quarkonia (and D mesons). Moreover, measurements of J/ψ yields relative to those of D mesons with the same transverse mass could help elucidate the relative contribution of hadronisation and initial-state effects.

Studies of double differential ratios of excited-to-ground quarkonium states versus relative multiplicity could help clarify the presence of final-state effects, either QGP-like or the ones proposed by the comover model [519, 520]. Also, within the CGC+NRQCD framework [512], the relative contributions of the 4 leading J/ψ Fock states have been calculated as a function of the event activity, showing a different dependence for different Fock states.

8 Electromagnetic radiation

The strongly interacting system formed in ultrarelativistic heavy-ion collisions emits electromagnetic radiation that can be detected using different probes: real *direct* photons or virtual photons measurable via dilepton pairs. Direct photons can be split into *prompt* photons, emitted by the partons of colliding nuclei during their inter-penetration, and *thermal* photons, emitted by the almost thermalized hot system. For dileptons these contributions are called Drell-Yan and thermal, respectively. In contrast to real photons, dileptons carry a mass and thus can be used to study the decay of massive particles, such as the in-medium modified spectral shape of vector mesons, the ρ meson being the most prominent one, and the search for particles beyond the Standard Model, e.g., dark photons. In this section, we outline the measurement of photons via calorimetry and the so-called photon conversion method, as well as dielectron (e^+e^-), and dimuon ($\mu^+\mu^-$) pairs in A–A collisions in the ALICE detector at the LHC. Moreover, the photoproduction of dilepton pairs in peripheral collisions and the expected sensitivity for the search of dark photons are discussed in subsections 8.2 and 8.3, respectively. We begin with a short review of previous experimental results together with a summary of the basic theoretical models employed to describe these data.

8.1 Thermal radiation and in-medium spectral function

Electromagnetic radiation from the hot and dense system formed in ultrarelativistic heavy-ion collisions in the form of real photons was measured for the first time at the SPS by WA98 [521]. The direct photon spectrum measured in Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 17.3$ GeV showed an excess above the extrapolated prompt photon signal based on measurements in proton induced reactions. The excess is described by a large variety of hydrodynamic and cascade models (see [522] for review), most of which assume the formation of a QGP phase. Also at the SPS, a modification of low-mass dilepton pairs in S–Au and Pb–Au collisions relative to the expectation of in-vacuum hadron decays was observed by CERES [523–527] and studied with high precision by NA60 in In–In collisions [528–531]. The data are consistent with an in-medium ρ spectral function that, driven by the coupling to baryons, melts and approaches the one from $q\bar{q}$ annihilation in the vicinity of the phase transition [532–534], which is compatible with chiral symmetry restoration [136, 535]. On the other hand, the data cannot be described with a dropping mass scenario, in which the ρ mass drops to zero as chiral symmetry is restored [536]. Beyond the issue of chiral symmetry restoration, NA60 measured an excess of prompt dimuons in the intermediate mass region between the ϕ and the J/ψ masses [529, 530]. Contrary to transverse-mass spectra of the dimuon continuum at lower masses, this excess shows no increase of the exponential inverse slope with mass, i.e., blue shift, that is typical for radial flow. This suggests that the source of this enhancement is from the earliest phase of the collision, before significant radial flow has built up. This supports the idea that the inverse slope of the invariant mass spectrum is insensitive to the expansion of the medium and therefore a true measure of the average temperature. NA60 measured a value of $T = 205 \pm 12$ MeV [531], which significantly exceeds the temperature of 154 ± 9 MeV, above which the formation of a QGP has been predicted [50, 135].

At RHIC energies, PHENIX and STAR have measured an enhancement of e^+e^- pairs in the low mass region in Au–Au collisions [537–540] that can be described with the same model of collisional

broadening as used at the SPS. STAR measured that the enhancement above the hadron decay background does not change with collision energy between $\sqrt{s_{\rm NN}} = 19$ and 200 GeV [540]. Despite a marked decrease of the net-baryon chemical potential in this energy range, the total baryon plus antibaryon density does not change much, providing further evidence that the ρ coupling to baryons and antibaryons is responsible for the enhancement. Real direct photon production in Au–Au collisions was measured by PHENIX [541–543]. An excess was observed compared to binary scaled direct photon production in pp collisions. The signal was measured via quasi-real virtual photons, i.e., e^+e^- pairs with small invariant mass, as well as real photons converting in detector material. The excess yield at low $p_{\rm T}$ appears to have a universal multiplicity dependence, scaling with the charged-particle multiplicity at midrapidity to the power of about 1.25, independent of collision energy between $\sqrt{s_{\rm NN}} = 39$ and 200 GeV [543]. The transverse momentum spectrum of the excess yield has an exponential inverse slope of $T = 221 \pm 19\ (\text{stat.}) \pm 19\ (\text{syst.})$ MeV for central collisions and values close to that for other centralities. The spectrum, however, is strongly blue shifted by radial flow in the later stages of the fireball radiation, which is further supported by a sizeable elliptic flow (v_2) of the direct photon signal [544]. Therefore, the inverse slope cannot directly be interpreted as an average temperature, which highlights the importance of thermal dilepton measurements as a function of invariant mass. However, the modelling of the space-time evolution offers the possibility of extracting temperature information from the photon data [545]. The direct photon v_2 is indeed comparable to the v_2 of pions, which suggests late emission of direct photons dominated by the hadronic phase [546]. A simultaneous description of the elliptic flow effect, as well as the large direct photon excess, which implies early production, poses a significant challenge to theoretical models.

The first measurement of direct photon production in Pb–Pb collisions with the ALICE detector [547] at the LHC also show an excess of thermal production at low $p_{\rm T} < 3$ GeV/c with respect to the prompt direct photon expectation [548]. The extracted effective temperatures $T = 297 \pm 12\ (\text{stat.}) \pm 41\ (\text{syst.})$ MeV in central collisions and $T = 410 \pm 84\ (\text{stat.}) \pm 140\ (\text{syst.})$ MeV in semi-central collisions are higher than those at RHIC energies, as expected. The direct photon elliptic flow was also extracted in central and semi-central collisions [549]. The measured flow is close to the one at RHIC energy and at low $p_{\rm T} < 4$ GeV/c to the one of final hadrons. However, this measurement does not cause the same challenges to models, since the experimental uncertainties are still large at this point. The reduction of systematic uncertainties of the direct photon measurement is the main objective for Run 3 to improve its significance. Moreover, a low magnetic field run will allow one to access the $p_{\rm T} < 1$ GeV/c region where the thermal photon production increases rapidly. Theoretical calculations of thermal and prompt photon productions are available at $\sqrt{s_{\rm NN}} = 5.02$ TeV (Fig. 53) [209, 550–552]. The thermal contribution dominant at low $p_{\rm T}$ is given by the QGP photon emission rates and the hadronic photon production rates, integrated over the space-time evolution of the system. In [209] a (2+1)D hydrodynamic evolution with IP-Glasma initial conditions with initial flow and finite shear and bulk viscosity is followed by a hadronic phase modelled using UrQMD. A longitudinal boost invariant (2+1)D ideal hydrodynamics is used in [551], while in [552] a (2+1)D ideal hydrodynamic model including non-vanishing initial flow is employed. The prompt photon component, dominant at high $p_{\rm T}$, is very similar in all models. It is obtained from NLO pQCD calculations using the BFG-II photon fragmentation function and the CTEQ6.6 [551] or nCTEQ15 parton distribution function [550]. An increase by a factor $\sim$ 1.5 at about $p_{\rm T} \approx 1$ GeV/c and by a factor 1.5 to 2 for the prompt photons is predicted compared to yields at $\sqrt{s_{\rm NN}} = 2.76$ TeV. The predicted thermal photon elliptic flow parameters for central collisions are close to each other at the two LHC energies and are very small. Differences become larger as one goes towards peripheral collisions. Simultaneous measurements of photon yields and photon flow with high accuracy and lower $p_{\rm T}$ reach will provide constraints to theoretical models.

Dilepton measurements by ALICE at the LHC are not yet sensitive to possible low-mass enhancement and thermal signals [555]. A precise measurement of the low-mass dielectron continuum will be one of the main objectives of the ALICE physics programme during the LHC Run 3 and 4. In the mean-

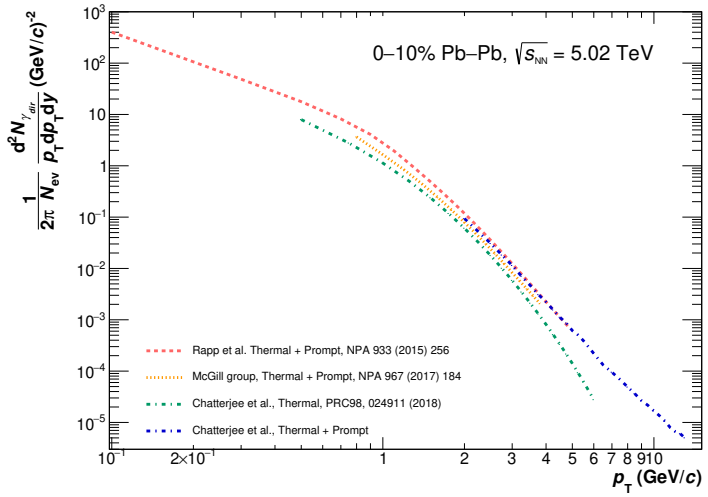

Fig. 53: Direct photon differential invariant yield for central 0–10% Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.02$ TeV as predicted by several models [209, 551–554].

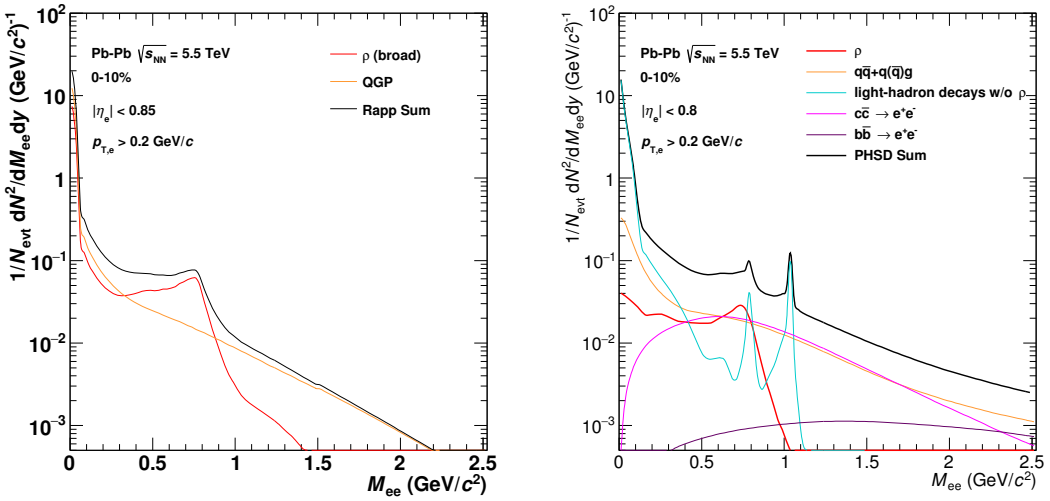

Fig. 54: Model predictions for the invariant mass spectrum of e^+e^- pairs in central (0–10%) Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.5$ TeV. Left panel: in-medium radiation plus decays of the ρ meson at the end of the system evolution by R. Rapp *et al.*. Right panel: Expectations from the PHSD model including the in-medium ρ meson, $q\bar{q} \rightarrow e^+e^-$, $q\bar{q} \rightarrow e^+e^-g$, and $q(\bar{q})g \rightarrow e^+e^-q(\bar{q})$, hadronic sources, and semileptonic decays of $c\bar{c}$ and $b\bar{b}$.

while, the dominant background of dielectrons from correlated semileptonic open heavy-flavour decays is utilised to learn more about open heavy-flavour production in pp collisions at LHC energies [556,557].

The model by R. Rapp *et al.*, an approach that has been proven to provide a quantitative description of the existing dilepton results [558], is based on two ingredients that are put into a realistic space-time evolution [559]. The thermal dilepton radiation is modelled by emission rates from the hadronic phase and the Quark–Gluon Plasma [534, 560]. A hadronic many-body approach [533] is used for the medium-modified spectral functions of ρ and ω mesons. In addition, the equation of state is updated to a cross-over transition around $T_{\rm c} = 170$ MeV extracted from with recent lattice QCD computations, and hadro-chemical freezeout at $T_{\rm chem} = 160$ MeV [561]. Figure 54 (left) shows the calculations performed

for central Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.5$ TeV for in-medium radiation plus decays of the ρ meson at the end of the system evolution. The pair-yield is estimated for the rapidity range $|y_{\rm e}| < 0.85$ and transverse momentum of single electrons $p_{\rm T}^{\rm e} > 0.2$ GeV/c and is normalized to the number of events $N_{\rm evt}$.

A complementary approach to study dilepton spectra and thermal radiation is provided by the parton-hadron-string dynamics (PHSD) transport approach, which also successfully describes the existing experimental data [562, 563]. The in-medium modification of the ρ meson is incorporated in PHSD by an off-shell transport of vector mesons with a dynamically changing set of spectral functions [564] evolving towards the vacuum spectral function at the end of the collision history. The electromagnetic radiation of the QGP is modelled by $q\bar{q} \rightarrow e^+e^-$, $q\bar{q} \rightarrow e^+e^-g$, and $q(\bar{q})g \rightarrow e^+e^-q(\bar{q})$ using effective propagators for quarks and gluons from a dynamical quasi-particle model [565]. Figure 54 (right) shows both contributions to the dielectron spectrum in central Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.5$ TeV calculated from PHSD together with other sources of dielectrons: decays of long-lived light mesons into e^+e^- (the so-called hadronic cocktail) and the semileptonic decay of hadrons containing heavy quarks, such as D and B mesons.

Important input for models aiming to describe the dilepton yield at LHC energies are the in-medium spectral functions for the vector mesons, most importantly the ρ meson, as well as the photon and dilepton rates from the QGP. For the latter, Lattice QCD calculations, which are currently limited to the quenched approximation, will hopefully be extended (e.g., larger lattices, especially in the time direction, or facilitating extrapolations to the continuum limit) and be available at higher accuracy for realistic systems including light dynamical degrees of freedom in the future. Recent updates on calculations of the photon rate [566], the electrical conductivity [567], and dilepton rates [568] are promising. The photons and dilepton rates from Lattice calculations should in the future be combined with dynamical models like those in Fig. 54, thus improving their results. In addition, the in-medium spectral functions could also use direct input from Lattice QCD [569, 570] or from a functional renormalization group approach [571]. These models can further be refined by including the effects of dissipation, and in that case the electrical conductivity will become of interest to both the dynamical evolution of the medium as well as the electromagnetic rates. In order for that to be achieved self-consistently, the evolution of the medium and the electromagnetic rates need to be modified to account for dissipative effects, which is a currently ongoing effort [209, 572, 573].

More differential information can be used to study the equation of state of the system throughout the full collision history. The measurement of the elliptic flow coefficient v_2 of thermal photons and dileptons, especially if combined with results from hadronic channels, should put tighter constraints on fundamental properties of the medium (e.g., transport coefficients), as well as its "initial conditions" or "pre-equilibrium" dynamics [574]. For example, owing to the penetrating nature of dileptons, the invariant mass dependence of the dilepton v_2 is sensitive to the temperature dependence of both shear [573] and bulk viscosity [572] in a way that is difficult to access using hadronic observables alone.

8.1.1 Real photons

ALICE has measured direct photon spectra in three centrality classes in Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 2.76$ TeV [548]. An excess of direct photons was quantified by the $p_{\rm T}$ dependent double ratio

$$R_\gamma \equiv \frac{\gamma_{\rm incl}}{\pi^0_{\rm param}} \Big/ \frac{\gamma_{\rm decay}}{\pi^0_{\rm param}} = \frac{\gamma_{\rm incl}}{\gamma_{\rm decay}}, \tag{27}$$

where $\gamma_{\rm incl}$ is the measured inclusive photon spectrum, $\pi^0_{\rm param}$ a parametrization of the measured π^0 spectrum, and $\gamma_{\rm decay}$ the calculated decay photon spectrum. The double ratio has the advantage that some of the largest systematic uncertainties cancel partially or completely. The measurement combines

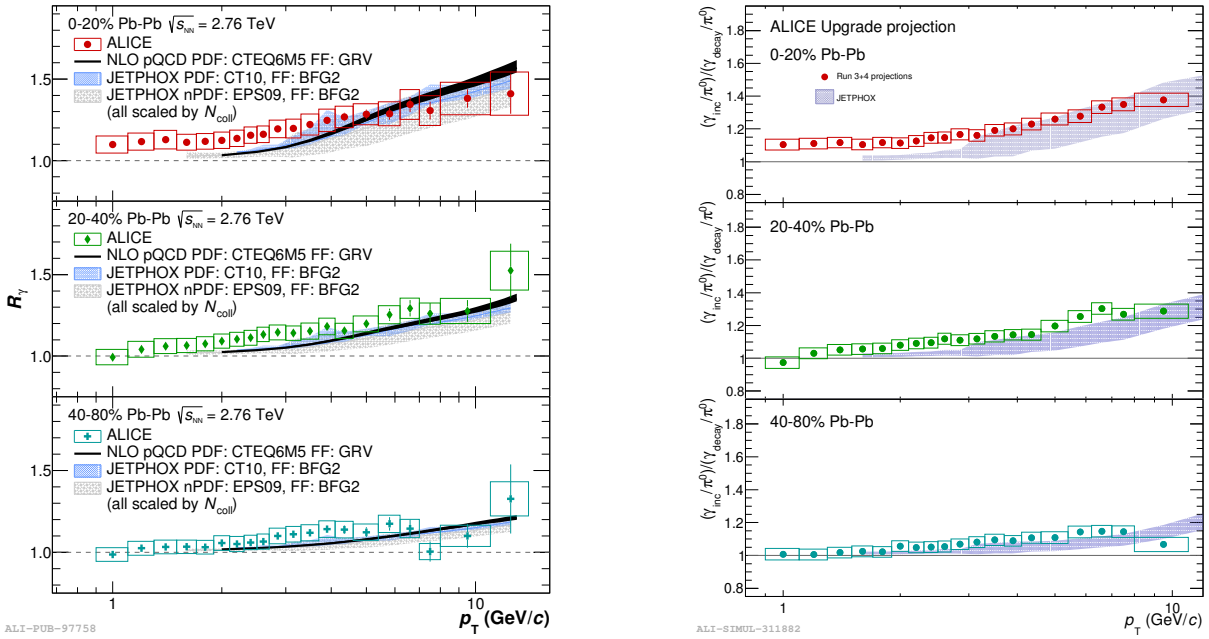

Fig. 55: R_γ measured [548] (left) and R_γ projected [1] keeping the measured values of R_γ and recalculating the uncertainties as explained in the text.

results of the Photon Conversion Method (PCM) and of the Photon Spectrometer (PHOS), see Fig. 55, left. In central collisions at low $p_{\mathrm{T}} < 4$ GeV/c an excess with respect to prompt photon predictions is observed that is attributed to thermal photon emission from the QGP. In the 20% most central collisions the low p_{T} excess is of the order of 10–15%, while the total uncertainty of the order of 6%. A signal of direct photons is found in central collisions, but on the level of $\sim 2\sigma$, while in mid-central and especially in peripheral the significance is even smaller. On the other hand, peripheral collisions are important since there one can estimate and restrict the contribution from prompt direct photons.

For Run 3 the PCM measurement will be influenced by the ALICE Inner Tracking System (ITS) and Time Projection Chamber (TPC) upgrades, while PHOS and the Electromagnetic Calorimeter (EMCal) will be kept unchanged. The new ITS shows an improved low p_{T} tracking efficiency, that will partially compensate the efficiency loss due to the $\sim$ 30% reduction of its material thickness. Two 1 mm tungsten wires with well known thickness will be installed parallel to the beam direction for precise calibration of the material thickness as described later. The TPC continuous readout mode together with large pile-up may prevent the use of photon conversions beyond a radius of 35 cm. This restriction will translate into a $\sim$ 35% lower photon efficiency. On the other hand, the PCM measurement will also profit from the dedicated heavy-ion run with reduced magnetic field of the ALICE solenoid, which will considerably increase the low p_{T} reconstruction efficiency. To estimate how one can improve the accuracy of the measurement, the uncertainties are split into three classes: those which can be improved with increase of statistics (statistical uncertainties, uncertainties related to π^0 spectrum extraction, η/π^0 ratio); uncertainties which can be reduced using new techniques and some special methods (material budget estimate - with calibrated material analysis, energy scale in calorimeters with new hybrid π^0 methods); and uncertainties related to the properties of the detector which can not be improved (hadron contamination in calorimeters, electron identification in conversion method etc.). To estimate the improvement of the uncertainties it is assumed that the integrated luminosity will reach $L_{\mathrm{int}} = 3.1$ nb^{-1} per Pb–Pb run and in total $L_{\mathrm{int}} = 13$ nb^{-1} at the end of Run 4, which is more than a factor of 100 larger the than integrated luminosity $L_{\mathrm{int}} = 10$ µb^{-1} used in the published analysis [548]. The major improvement foreseen for Run 3 is the use of calibrated tungsten wires inserted into the ITS to determine

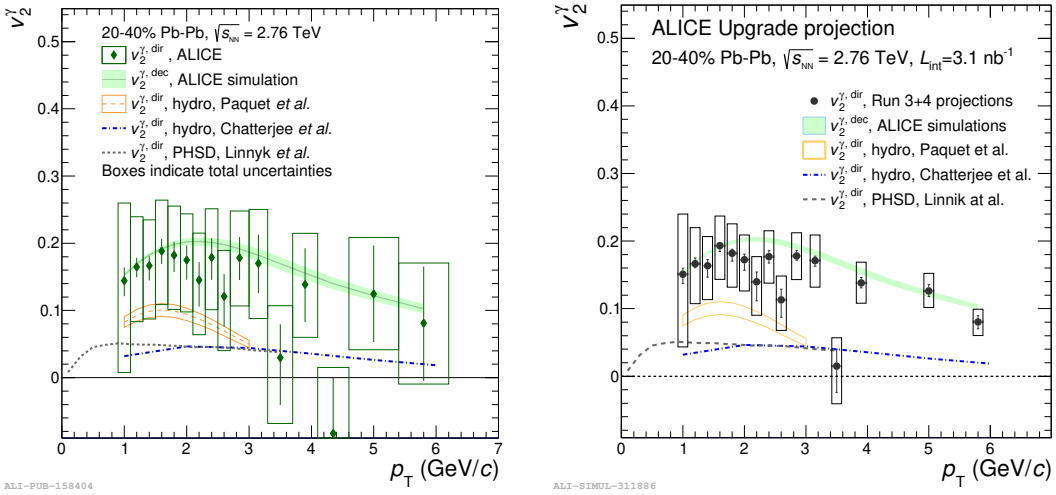

Fig. 56: Direct photon flow in mid-central collisions. Left: direct photon collective flow measured in Pb–Pb collisions compared to decay photon flow and several theoretical predictions. Right: expected accuracy in Run 3 keeping the measured values of R_γ and v_2^γ and recalculating the uncertainties as explained in the text. Figure from Ref. [1].

the product of the photon flux times the γ reconstruction efficiency. This product would then be used to precisely determine the material thickness in the rest of the ITS (assuming φ-independent photon flux and taking the radial dependence of the reconstruction efficiency from simulation). The proposed calibration method is based on weights calculated as the double ratio:

$$\omega_i = \left(\frac{N_\gamma^{\rm rec}(r_i)}{N_\gamma^{\rm rec}(r_{\rm wire})} \right)^{\rm data} \Big/ \left(\frac{N_\gamma^{\rm rec}(r_i)}{N_\gamma^{\rm rec}(r_{\rm wire})} \right)^{\rm MC} \tag{28}$$

where $N_\gamma^{\rm rec}(r_i)$ and $N_\gamma^{\rm rec}(r_{\rm wire})$ are the number of reconstructed γ's in data or in MC simulations in a given radial bin and the calibrated wire, respectively. For the Run 3 projections a systematic uncertainty of 1% on the ITS thickness is taken. The uncorrelated systematic uncertainties on the π^0 and η measurements will be reduced by a factor 10 due to the increased luminosity as they are defined mostly by the raw yield extraction uncertainties which scale proportional to statistical uncertainties. The systematic uncertainties on the photon selection and particle identification are expected to be reduced by 50%. Figure 55 (right) shows the projection of the R_γ measurement for Run 3 calculated with these assumptions: the measured values of R_γ are kept but the uncertainties are recalculated. The total errors are reduced by $\sim$ 50%. In addition to the reduction of the uncertainties, the large data set foreseen for Run 3 will allow exploration of the 0–1% centrality range.

The ALICE Collaboration carried out measurements of the direct photon elliptic flow [549] in Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 2.76$ TeV for the two centrality classes, 0–20% and 20–40%, see Fig. 56, left plot for 20–40% centrality. The measured direct photon elliptic flow $v_2^{\gamma,{\rm dir}}$ is compared to the estimated decay photon elliptic flow $v_2^{\gamma,{\rm dec}}$, marked as cocktail, and to the predictions of several theoretical models. Similar to RHIC measurements, the direct and decay photon elliptic flow are very close and systematically higher than theoretical predictions of hydrodynamic [575, 576] and the transport [577]

models. However, because of the large uncertainties one can not presently exclude either of theoretical calculations. Using the same assumption concerning photon and neutral measurements in Run 3 as for R_γ, the expected accuracy of $v_2^{\gamma,\mathrm{dir}}$ measurements in Run 3 is estimated, see Fig. 56 (right). The mean values are kept the same but the uncertainties are reduced as expected. Similar to R_γ with the current assumptions the total errors will be reduced by factor ~ 2 and one will be able to exclude or confirm available theoretical calculations.

8.1.2 Dileptons

The sensitivity to the expected signal of thermal radiation and an in-medium modification of the ρ spectral function in the dielectron and dimuon channels with the ALICE detector [86, 547] was studied already in preparation for ITS upgrade in 2019/20 [2,3,68,477]. The measurement of low-mass dileptons after this upgrade will profit from

- an improved vertex resolution, which leads to a better separation of electrons from prompt sources, like thermal radiation, and electrons from the decays of heavy-flavour hadrons, for which $c\tau$ is about 150 μm (open-charm hadrons) or 400 μm (open-beauty hadrons),
- a reduced material budget and improved tracking efficiency at low transverse momentum p_T, which leads to a smaller background of electrons and positrons from photon conversion in the detector material,
- the installation of the muon forward tracker, that will lead to an improved mass resolution and reduced background in the dimuon channel,
- and a higher rate capability (50 kHz in Pb–Pb collisions) that will increase the expected number of events in the central barrel detector by a factor of 100. The increased rate capability also enables the possibility to record in a single Pb–Pb run a large data sample with reduced magnetic field value in the ALICE central barrel ($B = 0.2$ T instead of 0.5 T), which increases the phase-space acceptance and the reconstruction efficiency of low momentum electrons and positrons.

The expected measured spectra discussed in this section closely follow the strategy that is discussed in more detail in [2, 3, 68, 477].

For the dielectron channel an integrated luminosity $L_\mathrm{int} \approx 3$ nb^{-1} is assumed, which should be collected in the dedicated Pb–Pb run at low field. The corresponding number of events in central (0–10%) collisions is 2.5×10^9. The input for the signal is composed of:

- contributions from the decays of long-lived light pseudoscalar and vector mesons (hadronic cocktail consisting of π^0,η,η',ω, and ϕ), with particle ratios and spectral shapes extrapolated from existing heavy-ion data at lower energies,
- correlated semileptonic charm decays based on calculations from the PYTHIA event generator [578],
- and the radiation of thermal dileptons and a medium-modified spectral function for the ρ meson in a realistic space-time evolution (see Fig. 54 (left)).

With respect to earlier calculations [2, 3, 68] a fast simulation of central Pb–Pb collisions is used here to estimate the combinatorial background and the statistical significance of the signal. The particles are produced with the event generator HIJING [579] and then propagated through the detector material by GEANT3 [580]. An updated geometry of the ITS is utilised in the detector description and leads to a more realistic treatment of conversion electrons and the subsequent background. Electrons are reconstructed and identified via signals in the ALICE Time Projection Chamber (TPC) and Time-Of-Flight (TOF) detector, a parametrised efficiency from runs at low magnetic field during LHC Run 2

is applied. After pairing electrons and positrons an additional selection on the pair distance of closest approach

$$DCA_{ee}(\sigma) = \sqrt{\left(\mathrm{DCA}_{\mathrm{xy},1}/\sigma_{\mathrm{xy},1}\right)^2 + \left(\mathrm{DCA}_{\mathrm{xy},2}/\sigma_{\mathrm{xy},2}\right)^2} \tag{29}$$

is applied to reduce the contribution from correlated semileptonic charm decays. The selection is chosen such that 95% of these pairs are rejected, while having an efficiency for prompt pairs of $\sim$ 17%. The signal distribution S, which includes the remaining charm and beauty hadron decays, is obtained by subtraction of the combinatorial background from all $\mathrm{e}^+\mathrm{e}^-$ pairs. The combinatorial background B is estimated from like-sign pairs and a correction factor R that takes into account the different acceptance of the apparatus for unlike- and like-sign pairs [555–557]. The significance that is used to project the statistical uncertainty on the measurement is calculated as $S/\sqrt{S+2B}$. The signal S is shown in Fig. 57 (left) together with all input distributions. In order to extract the QGP component and the in-medium modified ρ spectral function, the hadronic cocktail and the contribution from correlated semileptonic charm decays is subtracted and shown in Fig. 58 (left). In addition, the systematic uncertainties from the combinatorial background and signal extraction, as well as physical backgrounds after subtraction are shown. The relative systematic uncertainty of the signal, from tracking, track matching, and particle identification, is assumed to be 10%. For the systematic uncertainty of B a mass independent uncertainty of the R factor of 0.02% is used. Relative systematic uncertainties from the light-hadron cocktail and the total charm cross section of 10% and 15%, respectively, are applied.

In the dimuon channel, the integrated luminosity of Pb–Pb collisions ($L_{\mathrm{int}} \approx 10\mathrm{nb}^{-1}$) is used. In this channel, the main source of background is represented by the combinatorial pairs of muons coming from uncorrelated semimuonic decays of light-flavoured mesons, mainly pions and kaons, copiously produced in high-energy nuclear collisions. The opposite-sign dimuon mass spectrum obtained after the subtraction of the combinatorial background evaluated by means of an event mixing technique, results from the superposition of several opposite-sign correlated dimuon sources, represented in the right panel of Fig. 57. In order to isolate the thermal dimuon radiation and the in-medium modified line shapes of the ρ meson, the known and well-identifiable sources of the hadronic cocktail — 2-body and Dalitz decays of the η, ω, ϕ mesons, for which no in-medium effect is expected — are subtracted from the total opposite-sign correlated dimuon mass spectrum. A 10% systematic uncertainty in the evaluation of the shape and the normalization of these sources has been considered in the performance studies. The same procedure has been also applied for the subtraction of the dimuons from the open charm and open beauty processes; alternatively, these two sources could be separated from the prompt ones by means of an analysis based on the discrimination of the dimuon offset at the primary vertex.

The spectral function of low-mass dielectrons and dimuons in the mass region of the modified ρ-meson spectral function $M_{\mathrm{ee}} \approx 0.5$ GeV/c^2 can be extracted with a systematic uncertainty of $\approx$ 15% and $\approx$ 20%, respectively (see Fig. 58). The sizeable contribution of thermal dilepton pairs above $M_{\mathrm{ee}} > 1.1$ GeV/c^2 can be used to extract the temperature of the system. An exponential fit with $\mathrm{d}N/\mathrm{d}M_{\mathrm{ee}} \sim M_{\mathrm{ee}}^{3/2} \exp(-M_{\mathrm{ee}}/T_{\mathrm{fit}})$ to the subtracted $\mathrm{e}^+\mathrm{e}^-$ spectra in the invariant mass region $1.1 < M_{\mathrm{ee}} < 2.0$ GeV/c^2 was performed. Comparing the fit parameter T_{fit} to the real temperature T_{real} from the fit to the thermal contribution, a statistical uncertainty of 5% and systematic uncertainty of 10% and 20% for the background and the charm subtraction, respectively, were estimated. The same kind of measurement is also expected to be possible in the dimuon channel, considering a dedicated set of cuts optimized for the analysis of the intermediate mass region (the cuts considered in the right panel of Fig. 58 being optimized for the signal extraction in the mass region below ~ 1 GeV/c^2).

An alternative method to separate the thermal component from the modified heavy-flavour production in the intermediate mass range, is to fit the measured DCA_{ee} distribution as a function of the dielectron invariant mass and pair transverse momentum with a three component function, including the contributions from prompt dielectron sources, from open-charm hadron decays and from open-beauty hadron decays. Since the shape of the heavy-flavour DCA_{ee} spectra is quasi model independent, the

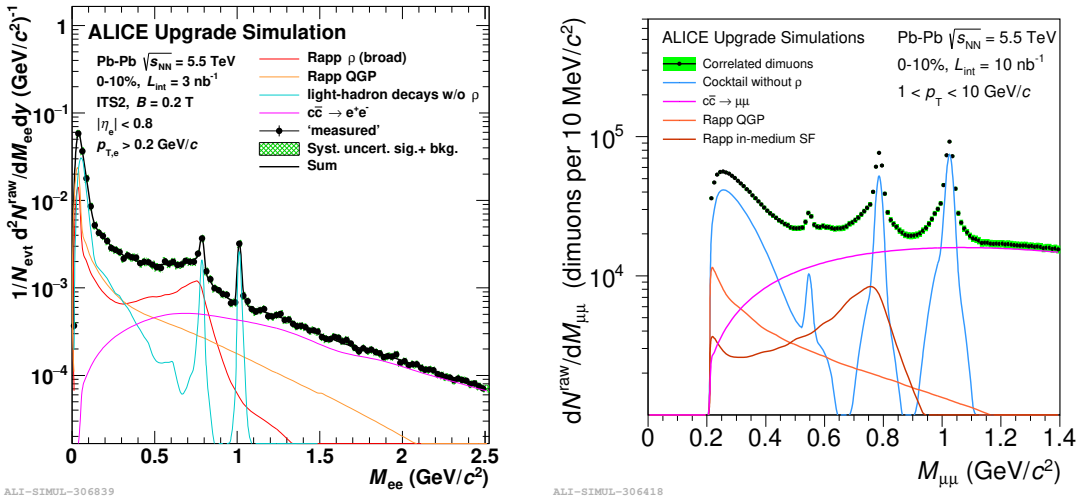

Fig. 57: Inclusive e^+e^- (left) and $\mu^+\mu^-$ (right) invariant mass spectrum for 0–10% most central Pb–Pb collisions at $\sqrt{s_{NN}} = 5.5$ TeV. The green boxes show the systematic uncertainties from the combinatorial background subtraction. Figures from Ref. [1].

dielectron yield of open heavy-flavour decays in the ALICE acceptance can be determined from the data with small uncertainties, without relying on theoretical calculations. Such fits were performed already with the Run 1 data in pp collisions at $\sqrt{s} = 7$ TeV [556]. Nevertheless, the statistics available did not allow for a differential study.

The measurement of the dielectron elliptic flow coefficient v_2 as a function of M_{ee} in peripheral Pb–Pb collisions (40–60%) was studied already in [2]. It was shown that an absolute statistical uncertainty on v_2 of $\sigma_{v_2} \approx 0.01$ can be achieved. Such uncertainties present a very encouraging prospect for dilepton studies since temperature dependent shear viscosity [573], bulk viscosity [572, 581], and early stages of reaction dynamics [574] have effects on the order of a few up to tens of percent on dilepton v_2, and thus future constraints on these properties will greatly benefit from a statistically improved dilepton v_2 measurement.

8.2 Two-photon and photonuclear interactions

Heavy ions carry strong electromagnetic fields. Their electric and magnetic fields are perpendicular, so may be treated as a flux of nearly-real photons [582]. These photon fields can give rise to photonuclear (photon on nucleus) and two-photon interactions. Although these interactions are expected to occur in both ultra-peripheral (UPC) and more central collisions, they were not generally expected to be visible in non-UPC collisions. The few final state particles from the photon-mediated interactions were expected to be swamped by the more copious hadronically produced particles. That expectation changed recently, when ALICE [583] and then STAR [584, 585] and ATLAS [586] observed excesses of dileptons produced at very small pair p_T, $p_T < 100$ MeV/c. These pairs were prominent in Pb–Pb and Au–Au collisions, but not in pp interactions; the excess corresponded to $R_{AA} > 5$. This is inconsistent with all expectations for hadroproduction, but consistent with photoproduction, where the pair p_T scale is set by the nuclear radius R_A, with $p_T \approx \hbar/R_A$. The kinematics of these pairs may be affected by the medium in which they are produced or propagate, so they may probe the evolving Quark–Gluon Plasma or associated magnetic fields.

UPC photon-mediated interactions have been studied at both RHIC and the LHC [582, 587–590]. The agreement between data and calculations is quite good. Photoproduction of ρ, ω, ρ' , J/ψ, J/ψ',

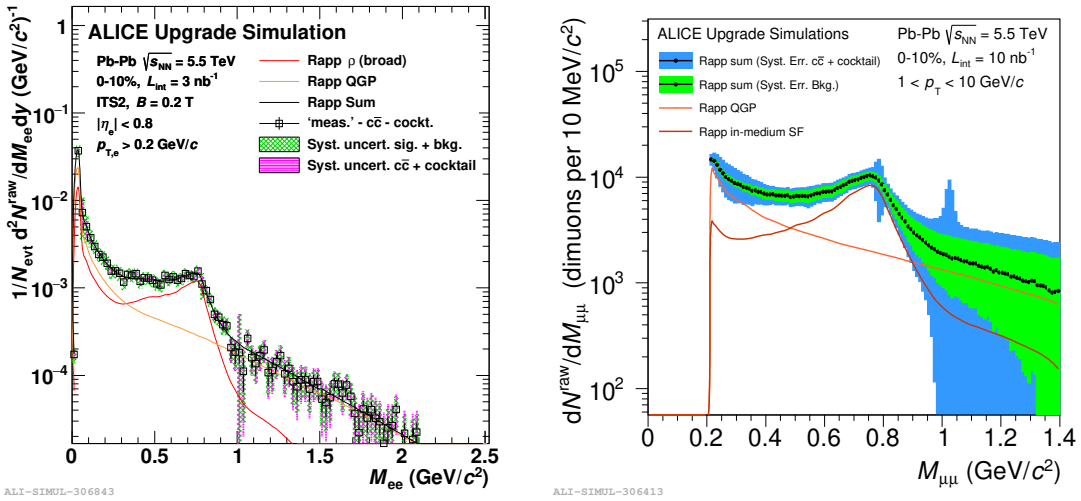

Fig. 58: Excess (after subtraction of light hadron decays and from correlated charm semileptonic decays) e^+e^- (left) and $\mu^+\mu^-$ (right) invariant mass spectrum for 0–10% most central Pb–Pb collisions at $\sqrt{s_{NN}} = 5.5$ TeV. The green boxes show the systematic uncertainties from the combinatorial background subtraction, the magenta (left) and blue (right) boxes indicate systematic errors related to the subtraction of the cocktail and charm contribution. Figures from Ref. [1].

Υ and direct π^+ π^- pairs has been observed, along with two-photon production of dilepton pairs and light-by-light scattering. In peripheral collisions, photon-mediated interactions might be used to probe the nuclear medium that they may occur in, including the QGP [584, 586]. The produced leptons may interact with this medium, leading to alterations in their momentum.

Peripheral collisions introduce several new considerations for photon-mediated reactions, particularly evolving coherence conditions for both photon emission and coherent photon-nucleus scattering. Photon emission in both γγ and photonuclear interactions is expected to be completely coherent, governed by the nuclear form factor $F(q)$ [591]. The photon emission from a nucleus moving with Lorentz boost γ should occur before the hadronic interaction (which is taken to occur at $t = 0$), at a retarded time, $t - x/c$ [592], where $x = |b|/\gamma$; $|b|$ is the transverse distance from the photon emission point to where it interacts. For very small impact parameters, some coherence may be lost, and a more detailed calculation is needed. For photon-nucleus collisions, the situation is more complicated, and will be discussed below.

Here, two-photon interactions and coherent photonuclear interactions are discussed.

8.2.1 Two-photon interactions

In two-photon interactions, each nucleus emits a photon, which then interact and form a lepton pair. In UPCs, this process is well described by the Weizsäcker-Williams approach (where each photon is treated as real), except at very low pair p_{T}, where a lowest-order QED calculation works better [593]. UPC calculations can be easily extended to include peripheral collisions [594–596]. The kinematic distributions are similar to those in UPCs, and the cross-section depends on the range of impact parameters.

Recently, the ATLAS collaboration [586] presented results showing a dramatic modification to $\gamma\gamma \to \mu^+\mu^-$ in peripheral collisions. Figure 59 shows the pair acoplanarity α, the azimuthal angular deviation from being perfectly back-to-back, and A, the energy imbalance between the two leptons. For UPCs, they found good agreement with the STARlight [597, 598] reference, with the data and

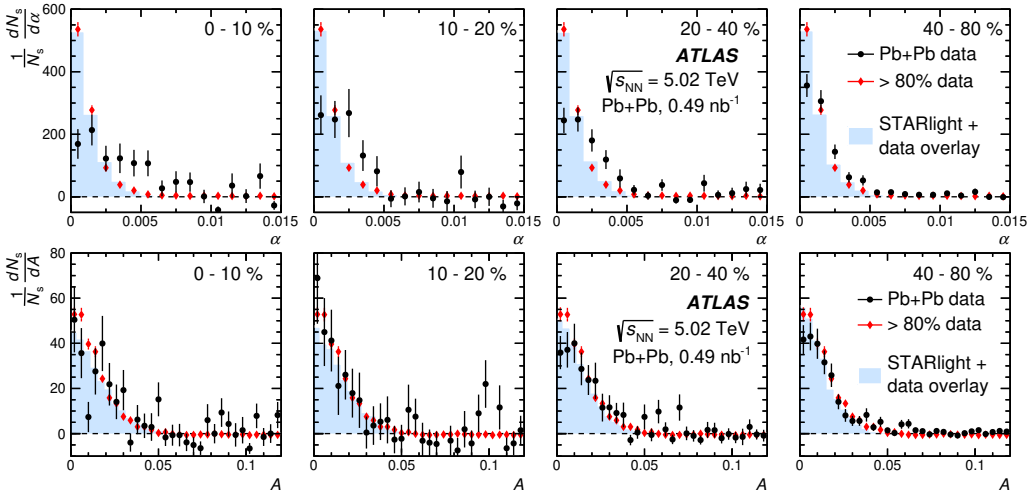

Fig. 59: Acoplanarity (α, top) and lepton energy imbalance (A, bottom) as a function of centrality, for dimuon pairs with pair mass above 10 GeV/c^2, observed in the ATLAS detector. From Ref. [586].

calculations peaked at small α and A. More central collisions show dramatic changes with the low-α peak largely disappearing, and the A distributions only minimally changed. ATLAS described this as "Consistent with order of magnitude estimates from kinetic theory for multiple scattering off electric charges in thermal plasma." Multiple scattering would remove the peak at low α, but leave A largely unaffected. A recent calculation finds that the magnitude of the change in α is at least roughly consistent with that expected for leptons propagating through a Quark–Gluon Plasma [599]. If multiple scattering is large, though, one might also expect some bremsstrahlung, which should increase A. To evaluate this further requires a calculation of how many of the produced leptons are produced in the medium, and/or traverse it. An alternate explanation could involve the leptons bending in the magnetic field from the QGP. If a QGP is electrically conducting, then it may acquire an induced magnetic field from the short-lived magnetic fields carried by the two nuclei [600]. The QGP field, however, will be longer lived, and could bend the produced leptons in opposite directions, reducing their coplanarity. Symmetry also predicts that it should disappear for the most central collisions [599], except possibly for event-by-event fluctuations.

The STAR Collaboration also has studied two-photon e^+e^- production in peripheral Au–Au collisions; they found a small difference between their pair p_T spectrum and calculations, and suggest that it might be due to medium effects [584]. ALICE has not yet seen these pairs [583], likely because their pair acceptance requires lepton $p_T > 1$ GeV/c, eliminating most pairs from $\gamma\gamma$ reactions.

Coupled with better theoretical calculations, the large Pb–Pb integrated luminosity in Run 3 and 4 can confirm and dramatically expand our understanding of this effect. One important goal is to expand the study to cover a much wider range of masses. Figure 60 shows the expected mass spectrum obtainable by ATLAS for a 13 nb^{-1} integrated luminosity run, assuming no changes in the trigger; masses up to 100 GeV/c^2 should be accessible. These high mass pairs correspond to two-photon interactions in or very near the two nuclei, so should show increased effects due to interactions with the medium or magnetic fields associated with the Quark–Gluon Plasma.

In contrast, lower masses correspond to larger distances between the dilepton production point and the nuclei, so in-medium effects may be smaller. These lower masses should be accessible with a softer requirement on the muon momentum. It would also be interesting to compare e^+e^- with $\mu^+\mu^-$ (and possibly $\tau^+\ \tau^-$), since the lighter leptons should interact more. If the leptons interact with the medium, then the electron A distribution should show more change than that for muons.

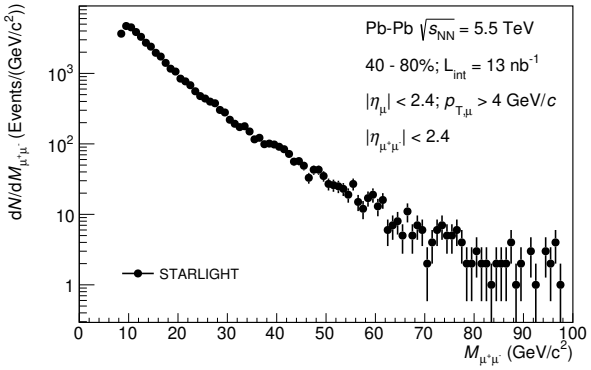

Fig. 60: Expected dimuon yield in ATLAS acceptance (both muons with $p_{\mathrm{T}} > 4$ GeV/c and $|\eta| < 2.4$), for 40–80% centrality Pb–Pb collisions and the expected Run 3/4 integrated luminosity of 13 nb^{-1}. Masses up to 100 GeV/c^2 are accessible. The effective 8 GeV/c^2 minimum mass is because of the nearly back-to-back topology and the 4 GeV/c minimum muon p_{T} cut. This was calculated using STARlight [594, 598].

8.2.2 Photonuclear interactions

In photonuclear interactions, a photon emitted by one nucleus fluctuates to a quark-antiquark dipole, which then scatters elastically from the other (target) nucleus, emerging as a real vector meson. The scattering occurs via Pomeron exchange, which preserves the photon quantum numbers. In perturbative QCD, Pomerons are made up of gluons, so the process is sensitive to the gluon distribution in the target nucleus. UPC measurements are consistent with moderate gluon shadowing. In coherent scattering, the typical pair p_{T} is $\hbar/R_{\mathrm{A}}$. Incoherent scattering is also possible, with a lower cross-section. There the quark-antiquark dipole scatters elastically from a single nucleon (or, at still higher p_{T} inelastically from a single nucleon), producing a vector meson with a typical p_{T} of a few hundred MeV/c.

Both ALICE [583] and STAR [585] have observed coherent J/ψ photoproduction in peripheral heavy-ion collisions. There are a number of parallel theoretical calculations [592, 601]. The photon emission process is similar to the two-photon case, but the dipole-nucleons scattering happens at the same time as the hadronic interaction, introducing several complications to the calculations. This immediately raises several questions: What happens to the coherence if a target nucleon is involved in an interaction? Does the dipole-nucleon interaction occur before or after the nuclear collisions? If the hadronic interaction occurs first, the target nucleon will have lost energy, so the photon-nucleon cross-section will be smaller. A detailed calculation should consider both possibilities. There is also destructive interference between photoproduction from the two possible target nuclei [602]; this interference extends to higher p_{T} for more central collisions, and should reduce the cross-section for the region where nuclear collisions occur. At $b = 0$, we expect complete destructive interference. Ref. [592] makes predictions for a variety of coherence conditions, and as Fig. 61 shows, finds that the ALICE and STAR data likely lie below the region where there is complete coherence for both photon emission and scattering, but probably above that where coherence is limited to only the spectator nucleons. This is not surprising, but there is at least one element missing from this calculation. The lifetime of J/ψ particles is of the order 10^{-20} s, far shorter than that of the expanding Quark–Gluon Plasma. Coherently photoproduced J/ψ have $p_{\mathrm{T}} \sim 100$ MeV/c, so, near mid-rapidity, are moving at a small fraction of the speed of light. Particularly for more central collisions, one would expect many of them to be engulfed by the expanded QGP, before they have a chance to decay.

The ALICE error bars are large, and more data, from the current and future runs are needed to pin down the centrality dependence of the cross section. More data will also allow access to additional observables. A detailed study of the shape of $\mathrm{d}\sigma/\mathrm{d}p_{\mathrm{T}}$ would shed more light on the possible loss of

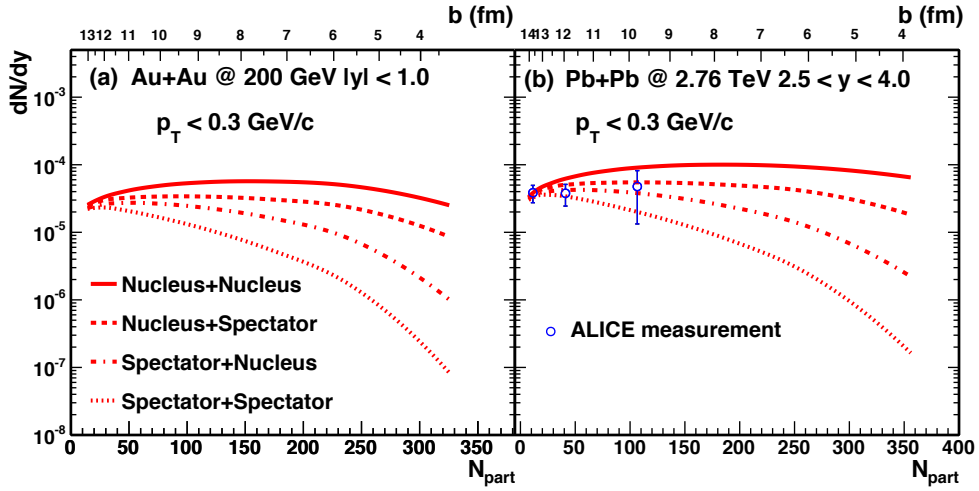

Fig. 61: J/ψ coherent photoproduction cross-sections in peripheral collisions, as a function of the number of participants (bottom), and impact parameter (top) with Au–Au collisions at RHIC (left) and Pb–Pb at the LHC (right). The four curves are for different assumptions regarding centrality for the photon emitter (first particle listed) and the target (second particle listed). From Ref. [583, 592].

coherence in more central collisions. There are also expected correlations between the reaction plane, which can be determined from the hadronic part of the collision, with the photonuclear interaction. Because the destructive interference between photoproduction at mid-rapidity on the two nuclei goes as $\sigma \sim |1 - \exp{(i\vec{b} \cdot \vec{p_{\rm T}})}|^2$ [603], the azimuthal direction of $\vec{p_{\rm T}}$ provides information about the azimuthal direction of $\vec{b}$, i.e., the reaction plane. Thus, it can be used either as an independent measurement of the reaction plane, or as a test of the loss of correlation. Also, the J/ψ polarization follows that of the photon that produced it, so it also follows $\vec{b}$, providing another probe of the reaction plane. With a large data sample, one may also be able to probe incoherent J/ψ photoproduction, at least in very peripheral hadronic collisions, where the signal-to-noise ratio is high.

It will be very interesting to study ψ' and Υ photoproduction in peripheral collisions. Since these mesons have different sizes from the J/ψ, they should interact with the medium with different strengths. These studies should be possible at HL-LHC.

8.3 Dark photons

Dark Matter is a hypothetical form of matter that is responsible for accounting for approximately 80% of the matter in the Universe [604]. Dark matter cannot be incorporated into the Standard Model, so the introduction of dark matter requires new interactions between dark matter particles and the ordinary Standard Model particles via unknown dark-sector forces [605]. The dark sector could have a rich structure with a few possible candidates, where one of them is regarded as Dark Photon (A') with $L_{mix} \propto \frac{g}{2} F^{\mu\nu} X_{\mu\nu}$. The dark photon is introduced as an extra-$U(1)$ gauge boson and acts as a messenger particle of a dark sector with the residual interaction (g) to the Standard Model particles. Understanding of possible interactions of dark photons has been motivated by a number of astrophysical anomalies such as antiproton spectrum in the cosmic rays measured by AMS Collaboration, positron excess in the cosmic rays observed earlier by PAMELA [606] and confirmed by FERMI [607] and AMS [608], and the long standing discrepancy between the measured and the calculated anomalous magnetic moment of the muon $(g-2)_\mu$, where the difference is more than three standard deviations away from zero [609].

If the dark photon is the lightest state of the dark sector and therefore can decay only into the

Standard Model particles, dark photons with mass $m_{A'} \leq 2m_{\mu}$ decay only into electron-positron pairs. For dark photons above 2 muon threshold ($m_{A'} \geq 2m_{\mu}$), dark photons can decay into muon pairs. For ($m_{A'} \geq 2m_{\pi}$), dark photons can decay into hadrons as well. A lot of experimental activities have been seen recently and constraints of mixing parameter (g^2) as a function of dark photon mass ($m_{A'}$) has been done from many experiments. They are, for example, beam-dump experiments (measurement of lepton pairs from dark photons behind a sufficiently long shield. Examples are E141 [610] and E137 [611] at SLAC, E774 [612] at Fermilab), fixed-target experiments (by scattering the electron beam on a nuclear target, the dark photon may be emitted in the initial or final state and coupling to electron-positron pairs is studied by looking for a bump in the electron-positron invariant mass. Examples are A1 [613] at MAMI in Mainz, APEX [614] at JLAB, DarkLight [615] at JLAB) and collider experiments (BABAR [616], NA48/2 [617] at SPS, WASA [618] at COSY, HADES [619] at GSI, PHENIX [620] at RHIC, LHCb [621] and ALICE at LHC). Since any process in which a virtual photon couples to lepton pairs or hadrons can be used to search for dark photons, following processes are used in the collider experiments: measurements of Dalitz decays of the $\pi^0/\eta/\eta' \rightarrow \gamma A'$ mesons and rare meson decays such as $K \rightarrow \pi A'$, $\phi \rightarrow \eta A'$, and $D^* \rightarrow D^0 A'$, Bremsstrahlung process ($e^- Z \rightarrow e^- Z A'$ with A' emitted at very forward direction), radiative decay of vector resonances and initial state radiation (done by BABAR using radiative decays of $\Upsilon(3S)$ and done by KLOE [622] using $\phi \rightarrow e^+e^-$). The 79-string IceCube search for dark matter in the Sun public data is used to test Secluded Dark Matter models [623]. Dark matter particles can be captured by the Sun, annihilate, and produce a neutrino flux that can be observed at Earth and that depends on the dark matter scattering cross section off nuclei and on the dark matter annihilation rate and final states. This analysis constrains a kinetic mixing parameter $g \sim 10^{-9}$ between 0.22 and ~ 1 GeV [623].

ALICE has good capabilities for electron identification in the low transverse momentum region, that enables the measurement of a large sample of the π^0 Dalitz decays [556]. ALICE searches for possible decays of $\pi^0 \rightarrow \gamma A'$, $A' \rightarrow e^+e^-$ by examining the electron-positron invariant mass in a large sample of π^0 Dalitz decay for $20 \leq M_{ee} \leq 90$ MeV/c^2 in pp collisions at 7 TeV ($L_{\rm int} \sim 4$ nb^{-1}) and p–Pb collisions at 5.0 TeV ($L_{\rm int} \sim 40$ μb^{-1}) as shown in Fig. 62.
LHCb has good capabilities to measure muons and hardware and software triggers enable the accumulation of a large sample of dimuon pairs. LHCb searches for prompt-like and long-lived dark photons produced in pp collisions at 13 TeV, using $A' \rightarrow \mu^+\mu^-$ decays from a large data sample corresponding to $L_{\rm int} \sim 1.6$ fb^{-1} collected during 2016, where the prompt-like A' search is shown in Fig. 62 [621].

The ALICE upgrade during LS2 will greatly improve the efficiency of electron-positron measurements and data taking capability. Figure 63 shows expected constraints that will be achieved by ALICE and LHCb together with the future experiments. After the major ALICE upgrade, ALICE will accumulate 6 pb^{-1}, 0.3 pb^{-1}, 10 nb^{-1}, 0.3 pb^{-1}, and 3 nb^{-1} of pp, p–Pb, and Pb–Pb collisions at 0.5 T, and p–Pb and Pb–Pb collisions at 0.2 T, respectively. LHCb will improve sensitivity of dark photon searches to large regions of the unexplored space. These new constraints leverage the improved invariant-mass and vertex resolution, as well as the unique capabilities of the particle-identification and real-time data-analysis with triggerless readout, that enables to accumulate $L_{\rm int} \sim 15$ fb^{-1} [625].

8.4 Limitations and outlook

While the statistical precision for the measurement of low mass dielectrons and dimuons as well as real photons will be sufficient in LHC Run 3 and 4 to study their yield as a function transverse momentum and with respect to the event plane (elliptic flow), more differential measurements might still be limited. The measurement of the photon polarization via the angular distribution of dileptons can not only provide information on the thermalization of the system, but also on the early stages of the collision [626]. Experimentally these distributions have been measured in the NA60 experiment [627], where no polarization was found concluding that the observed excess dimuons are in agreement with the thermal

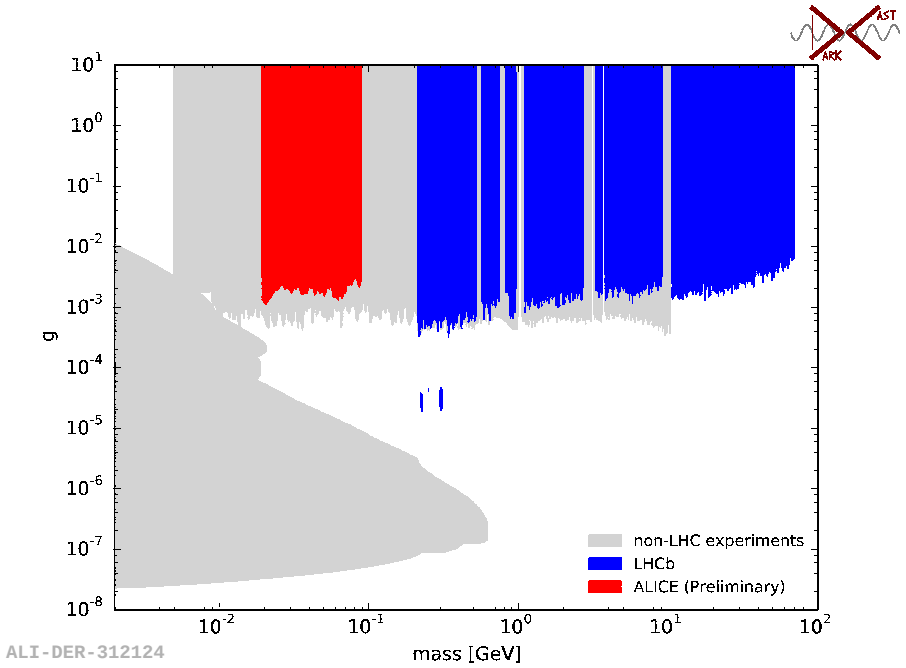

Fig. 62: 90% of confidence level of mixing parameter as a function of dark photon mass. Figure is adapted from Ref. [624]. Red and blue are from ALICE and LHCb [621]. Light grey band contains results from BABAR, KLOE, A1, APEX, NA48/2, E774, E141, E137, KEK, Orsay, BESIII, CHARM, HPS, NA64, NOMAD, NuCAL, and PS191 [624].

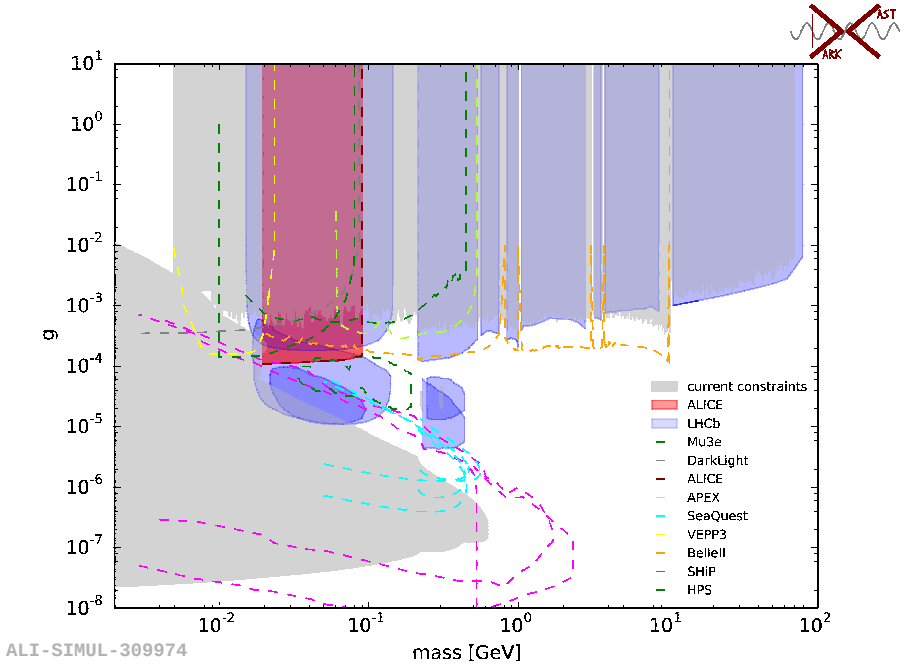

Fig. 63: 90% of CL constrained by ALICE and LHCb in HL-LHC era. Constraints by ALICE are based on 6 pb^{-1}, 0.3 pb^{-1}, 10 nb^{-1}, 0.3 pb^{-1}, and 3 nb^{-1} of pp, p–Pb, and Pb–Pb collisions at 0.5 T, and p–Pb and Pb–Pb collisions at 0.2 T and by LHCb are based on 15 fb^{-1}. ALICE projection from Ref. [1]. The other projections are adopted from Ref. [624].

emission from a a randomized system. In order to study the angular distributions, for example in the Collins-Soper reference frame [628–630] in the polar angle θ and the azimuthal angle φ, a large data set is needed (NA60 used ~ 50000 excess $\mu^+\mu^-$ pairs).

Another promising direction is measurement of Bose-Einstein (BE) correlations of direct photons. With this probe one can trace space-time dimensions of the hottest part of the fireball and moreover, varying k_{T} of the photon pair, one can select pairs coming mostly from earlier or later stages of the collision and thus look at evolution of the fireball. On the other hand, from the correlation strength parameter one can extract the direct photon spectrum down to very low $p_{\mathrm{T}} \sim 100$ MeV/c. So far there was one successful measurement of direct photon BE correlations by the WA98 Collaboration [631], while at RHIC and LHC energies these measurements are still unavailable. The reason is that the expected strength of these correlations $\lambda_{PGg} = 1/2(N_\gamma^{\mathrm{dir}}/N_\gamma^{\mathrm{tot}})^2$ is extremely small. Moreover, in contrast to massive particles, averaging of full 3D correlation function $C_2(q_{\mathrm{out}}, q_{\mathrm{side}}, q_{\mathrm{long}})$ to 1D $C_2(q_{\mathrm{inv}})$ results in further dramatic decrease of correlation strength [631]. This requires very large statistics in addition to understanding the detector response.

A first step to increase the statistical precision and the available data set for low-mass dileptons could be a further upgrade of the inner barrel of silicon detectors of the ALICE apparatus that is currently under discussion [302]. The planned reduction of the material budget would reduce conversion probability. In addition, an improvement of the tracking efficiency especially at low momentum would increase the conversion rejection efficiency even further. First studies [302] showed that the statistical uncertainty can be reduced by a factor 1.3, while the systematic uncertainty from the subtraction of the combinatorial background would be reduced by a factor of two. With a better pointing resolution the rejection of charm background is improved and would lead to a reduced systematic uncertainty from the subtraction of the light-hadron and charm decay backgrounds by a factor of two.

Finally, the detection of thermal radiation using low invariant mass and transverse momentum dielectron pairs is one of the main physics goals driving the concept for a possible new heavy-ion experiment at the LHC [306]. This experiment, which could be a follow-up of the ALICE experiment in the 2030s, would be mainly based on ultra-thin and granular silicon pixel detectors.

9.1 Introduction

In the program of proton–proton collisions at the LHC, the main effort is focused on hard processes which are embedded in an underlying event consisting of soft low-p_{T} particles. The underlying event is described using models, such as Pythia [516] or HERWIG [632], based on essentially free streaming (i.e. no final-state interactions) of the produced particles, supplemented by a non-perturbative cluster or string fragmentation picture [633, 634] to model the non-perturbative soft-particle production. The same models are used to describe minimum-bias events, i.e. events without any signal trigger, primarily consisting of soft QCD interactions. In the past years at LHC, during Run 1 and 2, this picture was challenged by several observations that qualitatively differ from the model expectations and cannot be accommodated by tuning of the existing models used to describe minimum-bias collisions and the underlying event [635].

The first such observation was the unexpected discovery in 2010 of azimuthal correlations of final-state hadrons in very high multiplicity proton–proton collisions [315], referred to by *the ridge*. These persist at large separation in rapidity on the near side surrounding the jet-like peak. A few years later, a similar observation was made in high multiplicity p–Pb collisions [316]. By subtracting the jet-like contribution in p–Pb collisions, a second long-range rapidity correlation on the away side, back-to-back in azimuth to the first observed correlation, was extracted [317, 318]. Even later, the procedure was adapted to pp collisions, allowing one to identify two long-range contributions also in high-multiplicity pp collisions [636,637]. Under certain assumptions even lower-multiplicity pp collisions show the same features [636]. With these observations the similarity of small and large collision systems with respect to azimuthal correlations had been clearly demonstrated.

The second observation was that of enhanced production of multi-strange hadrons in high-multiplicity pp collisions extending the puzzle from final-state particle kinematics to include also hadrochemistry. Already after Run 1, several experiments reported that ratios of strange to non-strange particle yields, in minimum-bias collisions, could not be described using model fits obtained from LEP data [638–641]. After systematic studies of this discrepancy, it was found that not only does strangeness increase smoothly with particle density at mid-rapidity in pp collisions, the dependence on this observable continues smoothly to p–Pb and Pb–Pb collisions [642].

Initially, these collision systems were thought as a reference for the effects observed in Pb–Pb collisions. But the discovery of these qualitatively new features has turned the study of small systems into a field on its own, with significant interest in both the heavy-ion and the high-energy physics community.

In ultra-relativistic nucleus–nucleus collisions, ranging from early SPS experiments at CERN through the Relativistic Heavy-Ion Collider (RHIC) at Brookhaven National Laboratory (BNL) to LHC, similar observations have been interpreted as evidence of formation of a droplet of thermalised Quark–

Gluon Plasma. The long-range azimuthal correlations, and in particular their lowest harmonic component v_2, have been used in combination with relativistic fluid-dynamical modeling to constrain the material properties of the plasma. The striking result from RHIC was that the plasma formed in central nucleus–nucleus collisions flows as a liquid nearly without dissipation such that its specific shear viscosity η/s – quantifying the dissipative properties of the medium – was found to be smaller than that of any other known substance. The inferred value of the specific shear viscosity $\eta/s \sim 0.07 - 0.16$ was found to be significantly smaller than the expectation from perturbative QCD and other quasiparticle models, and closer to the expectation of holographic model calculations of strongly coupled (maximally supersymmetric $N = 4$) gauge theories in the limit of large number of colors $N_c \to \infty$. These models can be seen as models of fluids with minimal dissipation allowed by basic principles of quantum mechanics thus giving rise to the paradigm of Quark–Gluon Plasma as a perfect liquid. Perfect liquid models do, by definition, not have any quasi-particle structure. This means that they do not have any degrees of freedom which can free stream for an appreciable amount of time, compared to their de Broglie wavelength. In that context it is notable that the observation of fluid–like signatures in small systems can be described as a small modification of the free streaming evolution, challenging the perfect-fluid paradigm.

There are several theoretical pictures that have been suggested to explain the smooth onset of signals of collectivity in small systems. The pp event generators have been supplemented on the one hand with elements describing string or cluster fragmentation in a dense medium [643, 644] to address the hadrochemistry, and on the other hand with final-state interactions between the fragmenting strings to account for the final-state kinematical correlations [645]. The models underlying pp event generators can then in turn be extrapolated to cover p–Pb and Pb–Pb collision systems, which is an approach used since the 1980's [579, 646]. Recent theoretical developments [647, 648] have improved the state of such extrapolations to a degree where also the supplemented hadronisation models can be extrapolated in order to provide a microscopic picture of the QGP even in large systems. The question whether such extrapolations will give even a qualitative description of the observed features is still open.

At the same time, the description of large systems has been employed in regimes initially thought to be not accessible by models implementing the perfect-fluid paradigm. Their application down to proton–proton collisions [211, 649, 650], taken at face value, would imply the formation of a nearly perfect liquid even in the smallest collision systems. Furthermore, pQCD based saturation models can describe the emergence of charged-particle azimuthal anisotropy ($v_{\rm n}$) [651]. In these models the final-state azimuthal correlations can arise either from the intrinsic correlations in the nuclear wave function (initial-state correlations) as correlated anisotropic particle production or as a final-state interaction after the initial particle production. In heavy-ion collisions, statistical models [652] have been very successful in describing the hadrochemistry of particle yields. Their extension to pp collisions shows promise, but similarly with points of tension [653]. Regardless of whether the approach is to extrapolate from pp to Pb–Pb collisions or the other way around, it is crucial to establish that any such model can capture the essential features of intermediate systems. Asymmetric collision systems such as p–Pb, provide challenges and opportunities for both approaches. They may be used as a necessary intermediate stepping stone for pp to A–A extrapolations, and they provide possible discrimination between saturation and fluid approaches as a possible point of tension [654, 655].

A question remains to what extent these different models are describing qualitatively different physical phenomena or to what extent they are different representations of the same underlying physics of final-state interactions. For this reason it is important to develop theoretical tools that encompass both the fluid-dynamic limit and the free-streaming limit to theoretically describe how the microscopic physics that leads to fluid-dynamic behavior in A–A collisions should represent itself in small systems. An attempt to do so comes from transport theory, which can describe microscopic interactions but in the limit of large number of final-state interactions allows for a coarse-grained effective description in terms of fluid dynamics. As such, transport theory has the potential to bridge the gap between small

systems, where final-state interactions act as small modification to the free-streaming evolution, and central nucleus–nucleus collisions where the final-state interactions bring the matter to the fluid-dynamical limit [216].

The experimental program in the large intermediate region — spanning from mid-central Pb–Pb and Xe–Xe collisions, through p–Pb collisions down to minimum-bias pp collisions — offers a possibility to bridge the difference between the two limits by providing a setup where the microscopic final-state interactions that lead in central Pb–Pb collision to the formation of a QGP may be studied in isolation in the limit of small number of final-state interactions.

The suggested theoretical pictures may have implications for high-energy physics analyses, which depend on reliable models of the underlying event. As an example, it has been recently shown that the discussed long-range correlations are also present in the underlying event of Z-tagged pp collisions [656]. The direct implication is the necessity for questioning the correct description of the underlying event of MC models. As the usual models used to describe the underlying event do not describe such long-range correlations, even qualitatively, the uncertainty introduced by imposing a model dependence, might be larger than expected, as *e.g.* shown for colour reconnection effects on $t\bar{t}$ final states [657]. As such, better descriptions of collective effects in small systems could also probe vital for reducing uncertainties in high-energy physics analyses.

The main experimental task in future years is a detailed examination and characterization of the observed effects in pp, p–Pb and Pb–Pb collisions, in order to understand whether such effects are different or similar in origin in small and large systems. For such a task to be successful, all three types of collision systems, pp, p–Pb and Pb–Pb must be utilized, as they each offer unique features not obtainable from the other systems. The central Pb–Pb collision system is so far the only one where all features of collectivity (including multi–particle correlations, jet quenching, quarkonia supression, thermal photons and hadrochemistry) have been observed. For the study of small collision systems, central Pb–Pb offers the only viable *true collective* reference. Conversely, pp is so far the smallest collision system where collective effects have been observed, and the only system where a smooth transition to the e^+e^- expectation could be reasonably expected. In the intermediate region p–Pb collisions are the only one of the three collision systems which offer, both, a saturation dominated initial state with a well known geometry, and, in a single event the Pb-going and p-going direction allowing the study between both regimes. The potential study of O–O collisions provides an interesting system with smaller fluctuations in the number of participating nucleons. Furthermore, the detailed study of asymmetric collision systems provides valuable input both to models extrapolating pp dynamics to Pb–Pb collisions, and for providing quantitative distinction between initial-state saturation effects and final-state interactions.

This chapter is structured as follows: Section 9.2 gives an overview presenting the observations that have been made and comparing them between pp, p–Pb and Pb–Pb collisions. Subsequently, Sect. 9.3 summarizes the open questions and discusses how these can be addressed at HL-LHC. Sect. 9.4 details the multiplicity distribution which needs to be extrapolated to be used for performance studies, the expected energy densities and the data-taking conditions assumed. A set of performance studies which address the open questions are introduced in Sect. 9.5–9.9 ranging from correlation measures, over hadrochemistry to signatures of energy loss and thermal radiation. Finally, Sect. 9.10 presents the opportunities of a short run of O–O collisions.

9.2 Overview of experimental results and critical assessment

This section will give an overview where the measurements in Pb–Pb, p–Pb and pp collisions at LHC provide a consistent picture and where differences emerge. In addition, it is pointed out where measurements are missing and where additional data is needed which forms the basis for the projections given in the subsequent sections of this chapter. Table 8 lists the different observables and if they have been

Table 8: Summary of bulk observables or effects in Pb–Pb collisions, as well as in high multiplicity p–Pb and pp collisions at the LHC. References to key measurements for the various observables and systems are given. See text for details. Table adapted from Ref. [669].

Observable or effect	Pb–Pb	p–Pb (high mult.)	pp (high mult.)	Refs.
Low p_{T} spectra ("radial flow")	yes	yes	yes	[47, 71, 321, 322, 658, 660, 666, 667, 670, 671]
Intermediate p_{T} ("recombination")	yes	yes	yes	[321, 660–666]
Particle ratios Statistical model	GC level $\gamma_s^{\mathrm{GC}} = 1$, 10–30%	GC level except Ω $\gamma_s^{\mathrm{GC}} \approx 1$, 20–40%	GC level except Ω MB: $\gamma_s^{\mathrm{C}} < 1$, 20–40%	[322, 642, 667, 668] [322, 642, 672]
HBT radii ($R(k_{\mathrm{T}})$, $R(\sqrt[3]{N_{\mathrm{ch}}})$)	$R_{\mathrm{out}}/R_{\mathrm{side}} \approx 1$	$R_{\mathrm{out}}/R_{\mathrm{side}} \lesssim 1$	$R_{\mathrm{out}}/R_{\mathrm{side}} \lesssim 1$	[673–680]
Azimuthal anisotropy (v_{n}) (from two particle correlations)	v_1–v_7	v_1–v_5	v_2–v_4	[48, 316–318, 636, 637, 656, 681–691]
Characteristic mass dependence	v_2–v_5	v_2, v_3	v_2	[48, 319, 330, 686, 689, 692–694]
Directed flow (from spectators)	yes	no	no	[695]
Charge-dependent correlations	yes	yes	yes	[249, 253, 254, 696–699]
Higher-order cumulants (mainly $v_2\{n\}$, $n \geq 4$)	"$4 \approx 6 \approx 8 \approx$ LYZ" +higher harmonics	"$4 \approx 6 \approx 8 \approx$ LYZ" +higher harmonics	"$4 \approx 6$"	[218, 320, 686, 691, 700–710]
Symmetric cumulants	up to $\mathrm{SC}(5,3)$	only $\mathrm{SC}(4,2), \mathrm{SC}(3,2)$	only $\mathrm{SC}(4,2), \mathrm{SC}(3,2)$	[227, 690, 711–714]
Non-linear flow modes	up to v_6	not measured	not measured	[715]
Weak η dependence	yes	yes	not measured	[218, 231, 688, 716–720]
Factorization breaking	yes ($n = 2, 3$)	yes ($n = 2, 3$)	not measured	[217, 219, 685, 687, 721]
Event-by-event v_{n} distributions	$n = 2$–4	not measured	not measured	[722–724]
Direct photons at low p_{T}	yes	not measured	not observed	[548, 725]
Jet quenching through dijet asymmetry	yes	not observed	not observed	[352, 364, 378, 726–728]
Jet quenching through R_{AA}	yes	not observed	not observed	[327, 348, 350, 351, 356, 729–736]
Jet quenching through correlations	yes (Z–jet, γ–jet, h–jet)	not observed (h–jet)	not measured	[358, 361, 379, 380, 384, 392, 732, 737–739]
Heavy flavor anisotropy	yes	yes	not measured	[262, 330, 464–468, 501, 740–744]
Quarkonia production	suppressed†	suppressed	not measured	[262, 458, 460, 463, 482, 483, 495, 496, 498, 499, 501, 583, 745–754]

measured in the Pb–Pb, p–Pb and pp collision systems. In the following a critical assessment of the findings is performed.

Particle spectra In all three systems, the p_{T} spectra of identified particles harden with increasing multiplicity. If this is interpreted by using a combined blast-wave parametrisation in Pb–Pb collisions[4] a larger radial flow is observed in pp and p–Pb collisions at the same multiplicity [653] as expected by Ref. [659]. In the intermediate p_{T} region ($2 < p_{\mathrm{T}} < 5$ GeV/c), enhancement of baryon-to-meson ratios is observed in all three systems. Recombination models suggest that the number of constituent quarks of the hadrons determine this enhancement [321, 660–666]. Particle ratios and yields are described as in the Grand Canonical ensemble by the statistical model with the strangeness undersaturation factor $\gamma_S \approx 1$ with an accuracy of approximately 10–30% for Pb–Pb collisions and at 20–40% level for p–Pb collisions (except for the Ω meson). The statistical model has been so far applied to minimum-bias pp collisions and when treated as a canonical ensemble, was found to describe the yields with $\gamma_S^C < 1$ and deviations of only about 20–40% from the expected yields [322, 642, 667, 668].

Pressure-driven expansion and anisotropies Assuming that the pressure gradients build up early in the evolution of the created system, initial spatial anisotropies (ε_{n}) translate into final momentum anisotropies, namely anisotropic flow (v_{n}) in a system with small viscosity. A large number of detailed studies have been done on different coefficients of anisotropic flow. Higher-order flow harmonics are in particular more sensitive to initial-state fluctuations and therefore can constrain the initial conditions of the system. Anisotropic flow has been measured with two-particle correlation techniques up to v_7 in Pb–Pb, v_5 in p–Pb, and v_4 in pp collisions for charged particles. These v_{n} coefficients exhibit weaker multiplicity dependence in pp and p–Pb collisions than in Pb–Pb collisions where this is closely related to the shape of the overlap region [48, 316–318, 636, 637, 681–691].

Higher-order cumulants have been measured using Lee-Yang Zeros (LYZ) method and multi-particle correlation techniques with up to 8 particles in both Pb–Pb and p–Pb collisions and up to 6 particles in pp collisions [218, 320, 686, 691, 700–710]. Interestingly, for each collision system, the measurements of the cumulants at different orders ($n \geq 4$) are similar within 10%. The presence of non-zero higher-order cumulants with similar magnitude can be interpreted as evidence for a hydrodynamically evolving system. However, some disfavor this interpretation since models that do not incorporate hydrodynamics have also been able to reproduce these results [755–757]. The p_{T}-differential v_{n} measurements for identified particles show the characteristic mass dependence of anisotropic flow up to v_5 in Pb–Pb, v_3 in p–Pb, and v_2 in pp collisions where heavier particles are depleted at low p_{T} [48, 319, 330, 686, 689, 692–694]. In Pb–Pb collisions this is ascribed to the interplay between radial flow and anisotropic flow harmonics at low p_{T} and recombination at higher p_{T}. This characteristic mass dependence has been described by hydrodynamic calculations to a good approximation in all three systems. In the intermediate p_{T} values in all three systems a meson-baryon grouping can be observed which points to a combination of hydrodynamics and quark coalescence (or recombination).

The non-linear hydrodynamic response of the system has been probed using symmetric cumulants which quantify the correlation between different anisotropic flow harmonics. Symmetric cumulants, that are also known as mixed harmonics, have been measured in all three systems up to SC(5,3) in Pb–Pb and SC(4,2) in p–Pb and pp collisions [227, 690, 711–714]. Different order harmonic correlations have different sensitivities to the transport properties of the system and the initial conditions. Based on the hydrodynamic calculations the data favour a small shear viscosity [758]. In addition, the linear and non-linear hydrodynamic response has been investigated in Pb–Pb collisions up to the sixth order flow harmonic [715]. These new observables, i.e. linear and non-linear flow modes, are very sensitive to details of the hydrodynamic modelling, i.e. initial conditions and the transport properties of the

[4] A combined blast-wave parametrisation model is a blast-wave model that fits charged pions, kaons and (anti-)protons simultaneously. In [658], combined blast-wave parametrisation perfectly describes $\pi^{\pm}$ ($0.5 < p_{\mathrm{T}} < 1$ GeV/c), $K^{\pm}$ ($0.2 < p_{\mathrm{T}} < 1.5$ GeV/c) and $\mathrm{p} + \overline{\mathrm{p}}$ ($0.3 < p_{\mathrm{T}} < 3$ GeV/c).

system. Current data–model comparison show this sensitivity which help to constrain the transport properties of the QGP created in Pb–Pb collisions [715]. Linear ($v_{\rm n}^{\rm L}$) and non-linear ($v_{\rm n}^{\rm NL}$) flow modes in pp and p–Pb collisions are not yet measured and can constrain the transport properties as well as initial conditions of these small systems. Furthermore, hydrodynamic calculations capture qualitatively "higher-order" details, such as the breaking of factorization due to event-plane angle decorrelations in $p_{\rm T}$ and η measured in both Pb–Pb and p–Pb collisions [217, 687, 721]. With the existing data such measurements are not yet possible in pp collisions. Similarly, event-by-event $v_{\rm n}$ measurements have only been done in Pb–Pb collisions [722–724] and it would be interesting to study those in both p–Pb and pp collisions.

Directed flow, for the rapidity-odd as well as the rapidity-even components, of charged particles at mid-rapidity was measured relative to the collision symmetry plane defined by the spectator nucleons, and evidence for dipole-like initial-state density fluctuations in the overlap region was found in Pb–Pb collisions [695]. In small systems, the concept of directed flow is less clear, especially in pp collisions. If there is collectivity in pp collisions, one could also expect a non-zero directed flow measurement. This is technically challenging since the measurement of the spectator plane is not feasible in small systems and, hence, v_1 could only be measured using higher-order ($n \geq 4$) cumulants. The width of the balance functions, $\langle\Delta\eta\rangle$ and $\langle\Delta\varphi\rangle$, have been measured for charged particles in pp, p–Pb and Pb–Pb collisions [696, 698]. The balance function probes the charge creation time and the development of collectivity in the produced system. These measurements are consistent with the picture of a system exhibiting larger radial flow with increasing multiplicity but also whose charges are created at the later stages of the collision. The charge-dependent azimuthal correlations are measured in both Pb–Pb and p–Pb collisions [675–678, 680]. These correlations quantify the influence of the chiral magnetic effect (CME) and the chiral magnetic wave (CMW) on the produced particles. These correlators are also sensitive to strong background contributions, for example from local charge conservation and possibly radial and anisotropic flow.

The freeze-out radii in three orthogonal directions ("out", "side", "long") can be deduced from measurements of quantum-statistic correlations between pairs of same-charge pions and kaons (HBT) at low-momentum transfer. The HBT radii in all collision systems are found to scale with $\sqrt[3]{N_{\rm ch}}$ indicating a constant density at freeze-out, and to decrease with increasing pair momentum $k_{\rm T}$ as expected from hydrodynamics. The size along the emission direction is similar to the geometric size of the system ($R_{\rm out}/R_{\rm side} \approx 1$) in Pb–Pb collisions [673–675, 678, 679, 679] and $R_{\rm out}/R_{\rm side} \leq 1$ for both p–Pb and pp collisions [675–678, 680].

Direct photons Direct-photon measurements in the low $p_{\rm T}$ region are so far performed in Pb–Pb and pp collisions. The measurements are reproduced by models assuming the formation of a QGP in Pb–Pb collisions [548]. In this measurement, one cannot discriminate between the available models due to the large systematic uncertainties: models incorporating different initial temperatures, i.e. from 385 to 740 MeV in the most central Pb–Pb collisions, are able to reproduce the measurements. Nevertheless, the comparison among these models suggests that the initial temperature in central Pb–Pb collisions must exceed about 400 MeV [548]. No significant direct-photon signal has been extracted in pp collisions at current available center-of-mass energies [725].

Energy loss The created system in Pb–Pb collisions is opaque for high-$p_{\rm T}$ colored probes. Due to radiational and collisional energy loss high-$p_{\rm T}$ colored probes are strongly suppressed (jet quenching) whereas the system is transparent for photons and other colorless probes [327, 348, 350, 351, 356, 729–731, 734]. Jet quenching leads to a large asymmetry in back-to-back jet $p_{\rm T}$ and slightly modified jet fragmentation functions inside small jet cone sizes ($\mathrm{R} = 0.4$). Most of the radiated energy appears at large angles ($\mathrm{R} > 0.8$) [352, 364, 378, 726, 727].

On the contrary, the picture is different in p–Pb collisions: measurements of inclusive high-$p_{\rm T}$ hadron and inclusive jet yields in minimum-bias p–Pb collisions at the LHC are consistent with

$R_{\rm pPb} = 1$ within the current accuracy of approximately 20%; i.e. no evidence of medium-induced modification is observed [327, 732, 733, 735, 736]. For event classes split by event activity, neither medium-induced modification in inclusive hadron production nor dijet transverse momentum imbalance are observed [327, 728, 736]; in contrast, for inclusive jet yields $R_{\rm pPb}$ is strongly suppressed relative to unity in "central" p–Pb collisions, and strongly enhanced in "peripheral" p–Pb collisions [735], attributed to selection biases [737].

The semi-inclusive yield of jets recoiling from a high-$p_{\rm T}$ trigger hadron has been used to search for jet quenching in p–Pb collisions [737]. This observable is trigger-normalized and semi-inclusive, and it therefore has greater systematic sensitivity to jet quenching effects in small systems than inclusive jet observables. Nevertheless, no significant jet quenching effects within the uncertainties of the measurement have been observed. These uncertainties can be expressed as an upper limit of 400 MeV (at 90% CL) on medium-induced energy transport outside a jet cone with $R = 0.4$. This value is a factor 20 smaller than the magnitude of out-of-cone energy transport measured by a similar approach in Pb–Pb collisions [358].

Heavy flavour Due to interactions and rescattering with the medium, also heavy-flavour particles exhibit finite anisotropies as shown with non-zero v_2 measurements for heavy flavour particles in both Pb–Pb and p–Pb collisions [262, 330, 464–468, 501, 740–744], see also Chapter 5. In addition, J/ψ suppression in Pb–Pb collisions shows an enhancement w.r.t. RHIC energies [749]. Models incorporating a J/ψ regeneration component from deconfined charm quarks in the medium can reproduce these measurements [458, 749]. The limited understanding of cold nuclear matter effects in the open charm cross section determination, however, restricts the ability of these models to fully describe the experimental data on J/ψ production in Pb–Pb collisions [754]. The size of these effects can be quantified by measurements in p–Pb collision. In p–Pb collisions, J/ψ is suppressed relative to pp collisions [754]. The production of the excited charmonium state, $\Psi(2S)$ as well as different bottomonium states (Υ(nS)) have been measured in both Pb–Pb and p–Pb collisions [482, 496, 747, 749, 753] which shows a suppression w.r.t. the ground state.

9.3 Open questions and new opportunities at HL-LHC

The previous section has extensively reviewed the state-of-the-art experimental knowledge of pp and p–Pb collisions. Certain gaps in knowledge became apparent due to either insufficient available data or shortcomings in the present detectors. The HL era of LHC can make a significant step ahead in many areas. The most relevant ones are discussed with dedicated performance projections in the remainder of this chapter.

Run 3 and 4 will allow the study of unprecedentedly high-multiplicity pp collisions. In order to do estimates in this regime, Sect. 9.4 will establish a firm extrapolation of the multiplicity distribution based on current LHC data together with a review of the data sample to expect. The large multiplicities bring a qualitatively new feature: a wide overlap between pp and Pb–Pb collisions up to about 65% central collisions allowing a unique opportunity to compare observables in a small (pp) and large (Pb–Pb) system at the same multiplicity. Studies in p–Pb collisions amend the picture. Given that multiplicity is not the only driving variable of a system, comparisons of estimates of the energy density in pp, p–Pb and Pb–Pb collisions are made below. The uniqueness of these extreme multiplicity pp collisions warrants that the study of their global-event properties are an interesting subject in itself, see Sect. 9.5.

Subsequently, a set of key observables is presented which require either the large data samples or the upgraded detectors. In particular the measurement of thermal dileptons profits from the new ALICE pixel detector with reduced material budget, and the measurement of higher-order correlations from the extended tracker acceptance in Run 4 in ATLAS and CMS. Correlations at higher orders using the subevent method will provide an essentially non-flow free measurement of $v_{\rm n}$ coefficients and their inter-correlations measured through symmetric cumulants, see Sect. 9.6. These measurements focus on

two interesting regimes: at high multiplicity where the overlap with Pb–Pb collisions will be studied, and at low multiplicity to answer the question on the onset of collective phenomena. This section also shows that the measurement of the probability distribution of event-by-event v_2 becomes for the first time feasible in small systems, a quantity presently completely unknown in pp collisions.

The smooth increase of strange-particle production across system size is one of the key surprising findings from Run 2 pp physics. A projection of the reach at HL-LHC is given in Sect. 9.7 showing that the question if the thermal limit, given by statistical models in Pb–Pb collisions, is reached also in pp collisions can be answered. A puzzling finding is the absence of jet quenching in p–Pb collisions with the measurements performed in Run 1 and 2. If final-state interactions are to explain the observed collective phenomena, also energy loss of traversing partons should be measurable. Section 9.8 discusses how jet quenching can be observed in Run 3 and 4 if present, or alternatively how a stringent limit can be set. Performance studies are presented for hadron–jet, γ–jet and Z–jet correlations, both, in p–Pb and pp collisions. Finally, the potential to detect thermal radiation and extract a medium temperature in p–Pb collisions is presented in Sect. 9.9. Such a measurement would constitute a strong indication of the formation of an emitting medium. Finally, the potential of colliding smaller nuclei, in particular oxygen, is assessed in Sect. 9.10.

9.4 Proton–proton collisions at extreme multiplicities

9.4.1 Multiplicity distribution

For the performance estimates at high multiplicity in pp collisions, a multiplicity-distribution extrapolation has been used which is based on existing ALICE ($|\eta| < 1.5$) [759] and ATLAS ($|\eta| < 2.5$) [760,761] data. Data from CMS [762] is compatible with the used distributions and is therefore not explicitly included in the extrapolation. A parameterisation with a single[5] negative binomial distribution is used to characterize the multiplicity distribution [763, 764].

The data is shown in Fig. 64 overlaid with the fit with a single negative binomial distribution of the tail of the distribution (20–40% of the cross-section). The three parameters of this fit are itself fit with a power law to extrapolate to $\sqrt{s} = 14$ TeV.

The resulting extrapolated multiplicity distribution for 14 TeV is shown in Fig. 65 for the ALICE and ATLAS case. In addition, these are compared scaled by their respective average multiplicities. The agreement is rather good, with some discrepancy in the tail of the distribution. The extrapolation based on the smaller phase-space region falls off more quickly with multiplicity, and is therefore used as the conservative estimate for the extrapolations in this chapter.

9.4.2 Energy density

While the multiplicity is a convenient and well-defined observable to compare different collision systems, the underlying dynamics may be driven by other properties. In large collision systems, the energy density ϵ is often used to characterize the system and the expected effects. Figure 66 shows an estimate of the energy density for pp, p–Pb and Pb–Pb collisions based on IP-Glasma [765] as well as on the Bjorken estimate:

$$\epsilon = \frac{1}{A\tau}\langle E\rangle \frac{3}{2}\frac{dN_{ch}}{dy}. \tag{30}$$

For the latter, the input is the multiplicity-dependent $\langle p_{\mathrm{T}}\rangle$ [734,766] as well as the multiplicity-dependent transverse overlap from a Glauber MC [767]. The energy density is calculated at fixed $\tau = 0.2\,\mathrm{fm/c}$. It should be noted that these assumptions can be challenged and other ways to calculate ϵ are available which can lead to largely different value in particular in pp and p–Pb collisions. Here the aim is only to

[5] At LHC energies two NBDs are needed for a good fit to the full distribution, but one is sufficient for the tail of the distribution.

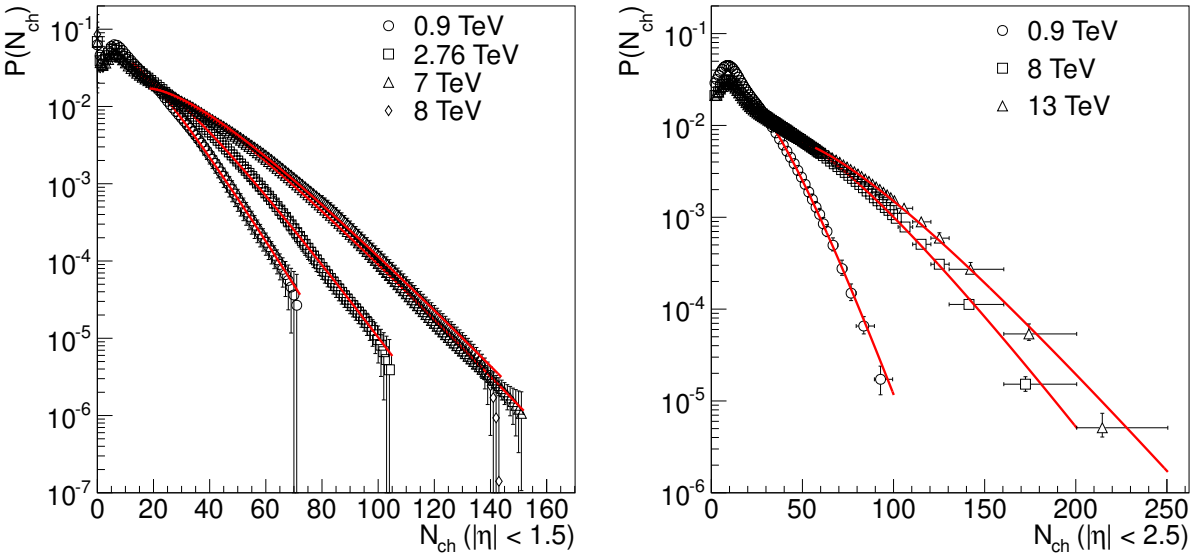

Fig. 64: Multiplicity distributions measured by ALICE [759] (left panel) and ATLAS [760, 761] (right panel) overlaid by the fit with a negative binomial distribution. For details see text.

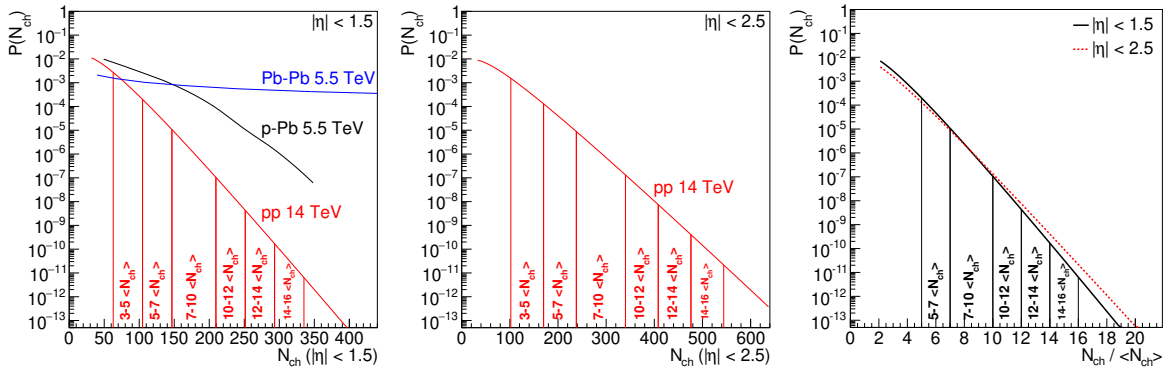

Fig. 65: Extrapolated multiplicity distributions in pp collisions within $|\eta| < 1.5$ (left panel) and $|\eta| < 2.5$ (centre panel). The indicated regions are (from left to right) 5–7, 7–10, 10–12, 12–14, 14–16 times the average multiplicity. In the left panel the multiplicity distribution of Pb–Pb and p–Pb collisions is also plotted. The right panel compares these two distributions scaled by the average multiplicity. The extrapolation for $|\eta| < 2.5$ turns out to be a bit wider at large multiplicities; therefore the one based on $|\eta| < 1.5$ is used as baseline.

show that the energy density depends on the system at a fixed multiplicity, and can reach large values in pp and p–Pb collisions, of the order of central Pb–Pb collisions.

9.4.3 Data-taking conditions and integrated luminosity for pp *collisions*

For the performance studies in this chapter, a high-multiplicity sample of $L_{\text{int}} = 200\,\text{pb}^{-1}$ is assumed per experiment. In order to assure a clean trigger, collisions at low $\mu \approx 1$ are needed which requires special runs or special conditions at the end of fill for ATLAS and CMS. For LHCb, the comparatively low pileup and good vertex resolution should allow for recording high-multiplicity events during normal running conditions at a pile up of about five visible pp interactions. ALICE generally runs at low μ and can collect a similar sample over a longer data-taking period. For Run 4, the upgraded tracking and vertex detectors in ATLAS and CMS may allow to isolate high-multiplicity collisions also in a large μ

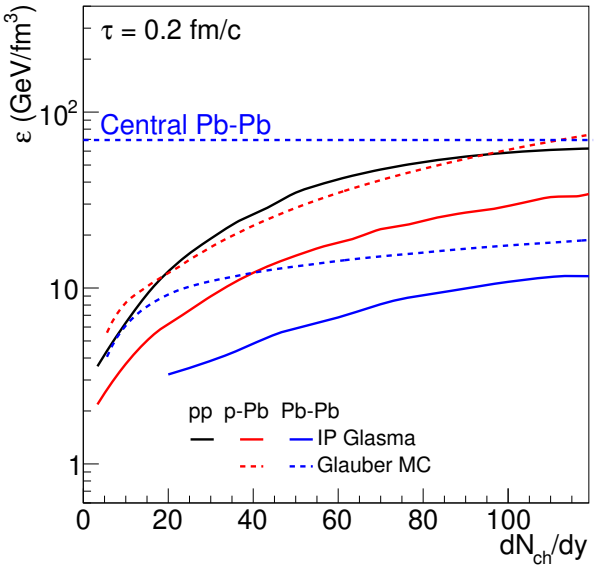

Fig. 66: Energy density as a function of $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}y$ calculated by IP-Glasma (solid lines) and with MC Glauber and the Bjorken formula (dashed lines); for details see text. Compared are pp ($\sqrt{s} = 7$ TeV), p–Pb ($\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV) and Pb–Pb ($\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV) collisions at $\tau = 0.2\,\mathrm{fm/c}$. The horizontal line indicates the energy density reached in central Pb–Pb collisions ($\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}y \approx 2000$).

Table 9: Number of pp events at $\sqrt{s} = 14$ TeV in selected high-multiplicity bins.

Range	$\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta$	Fraction	Events per pb^{-1}	Events in 200 pb^{-1}
5–7 $\langle N_{\mathrm{ch}} \rangle$	35–49	2.4e-03	1.9e+08	3.7e+10
7–10 $\langle N_{\mathrm{ch}} \rangle$	49–70	1.3e-04	1.0e+07	2.0e+09
10–12 $\langle N_{\mathrm{ch}} \rangle$	70–84	1.1e-06	9.0e+04	1.8e+07
12–14 $\langle N_{\mathrm{ch}} \rangle$	84–98	4.7e-08	3.7e+03	7.3e+05
14–16 $\langle N_{\mathrm{ch}} \rangle$	98–112	1.8e-09	1.4e+02	2.8e+04

environment. This option needs to be carefully studied.

Table 9 gives the fraction of cross-section and the number of events in five multiplicity classes: 5–7, 7–10, 10–12, 12–14 and 14–16 times the average multiplicity. Table 10 gives the number of events of bins with equivalent multiplicity than commonly measured multiplicity bins in p–Pb and Pb–Pb collisions. For the calculation of the number of events $\sigma_{\mathrm{inel}} = 78.4\,\mathrm{mb}$ [767] is used. These tables are the key input for the performance figures presented in this chapter. The conversion of the provided $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta$ to multiplicity ranges with larger pseudorapidity coverage is done for simplicity assuming a flat pseudorapidity distribution within $|\eta| < 2.5$. For the conversion to a phase space with a p_{T} cut as employed in many current measurements a set of conversation factors is used, listed in Tab. 11.

9.5 Global-event properties

The measurement of global-event observables in rare high-multiplicity pp collisions are of interest in itself. The shape of the multiplicity distribution, which has been largely extrapolated in the previous section, is today a challenge for models. The dynamics of producing very large multiplicity events is not understood in detail and therefore the shape of the distribution is an important input. Furthermore, studies of $\langle p_{\mathrm{T}} \rangle$ as a function of multiplicity [766] have shown a strong increase with multiplicity. However, those measurements exist only up to $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta \approx 55$, while the measurements at HL-LHC promise

Table 10: Number of events in pp collisions at $\sqrt{s} = 14$ TeV sliced in equivalent multiplicity bins as in p–Pb and Pb–Pb collisions.

Range	$\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta$	Events per pb^{-1}	Events in 200 pb^{-1}
0–5% p–Pb	41–56	4.9e+07	9.8e+09
5–10% p–Pb	34–41	1.9e+08	3.8e+10
10–20% p–Pb	27–34	6.6e+08	1.3e+11
60–65% Pb–Pb	98–137	1.5e+02	3.0e+04
65–70% Pb–Pb	68–98	1.6e+05	3.1e+07
70–75% Pb–Pb	45–68	2.1e+07	4.2e+09
75–80% Pb–Pb	29–45	5.9e+08	1.2e+11

Table 11: Conversion factors between N_{ch} with a p_{T} threshold, and N_{ch} including particles down to $p_{\mathrm{T}} = 0$. The factor shown is $N_{\mathrm{ch}}/N_{\mathrm{ch}}(p_{\mathrm{T}} > X)$, extracted with Pythia 8, tune CUETP8M1 [768]. A potential multiplicity dependence of this factor is neglected for the projections in this chapter.

$\lvert\eta\rvert$ \ p_{T}	> 0.1 GeV/c	> 0.2 GeV/c	> 0.3 GeV/c	> 0.4 GeV/c	> 0.5 GeV/c
$\lvert\eta\rvert < 1.5$	1.03	1.11	1.22	1.31	1.40
$\lvert\eta\rvert < 2.4$	1.04	1.14	1.27	1.42	1.55

a measurement beyond twice that value.

The shape of the multiplicity distribution and the growth of $\langle p_{\mathrm{T}} \rangle$ are closely connected to the physics of multiple parton interactions: high-multiplicity collisions are understood as originating from the collision of multiple partons within the same pp collisions. It has been shown that the number of (low momentum transfer) parton interactions increases linearly with multiplicity with a possible saturation at large multiplicity [769]. The prospect of showing that adding another parton interaction to an already busy event may be strongly suppressed, is an important ingredient to a revised conceptual understanding of particle production in high-energy pp collisions. Together with the studies of symmetric cumulants (see the subsequent Section), HL-LHC will determine not only if there is a saturation limit for multiple parton interactions, but also the parton structure within the proton.

9.6 Particle correlations

The measurements of two-particle correlations and higher-order cumulants have been the initial observations of collective-like effects in small systems. In pp collisions, two distinct regions are of interest at HL-LHC: the high-multiplicity tail to compare to p–Pb and Pb–Pb collisions and the low-multiplicity region to investigate the onset of these effects. In the following, several performance estimates are given as examples for the rich physics which can be addressed.

State-of-the-art measured 4-particle cumulants of v_3 ($c_3\{4\}$) in pp and p–Pb collisions are presented in Fig. 67 overlaid with the projection for HL-LHC. In order to remove non-flow contributions, the 3-subevent method is applied. In pp collisions, with the data collected in Run 2, the statistical uncertainties are large and the $c_3\{4\}$ values are consistent with zero in most of the N_{ch} range. On the contrary, in large systems, significant non-zero $c_3\{4\}$ up to $-0.4 \cdot 10^{-6}$ depending on centrality has been measured [707], which reflects the nucleonic fluctuations in the initial state. Whether similar behaviour is observed in small systems still needs to be studied. The increase in luminosity in Run 3 and 4 provides a great opportunity to measure $c_3\{4\}$ in pp collisions with high precision: the statistics are sufficient to measure a signal as small as $v_3\{4\} = 1.5\%$ for $N_{\mathrm{ch}} \gtrapprox 170$, while 2% are accessible with large significance over a wide multiplicity range ($N_{\mathrm{ch}} \gtrapprox 100$). Similarly, in p–Pb collision, the current result shows

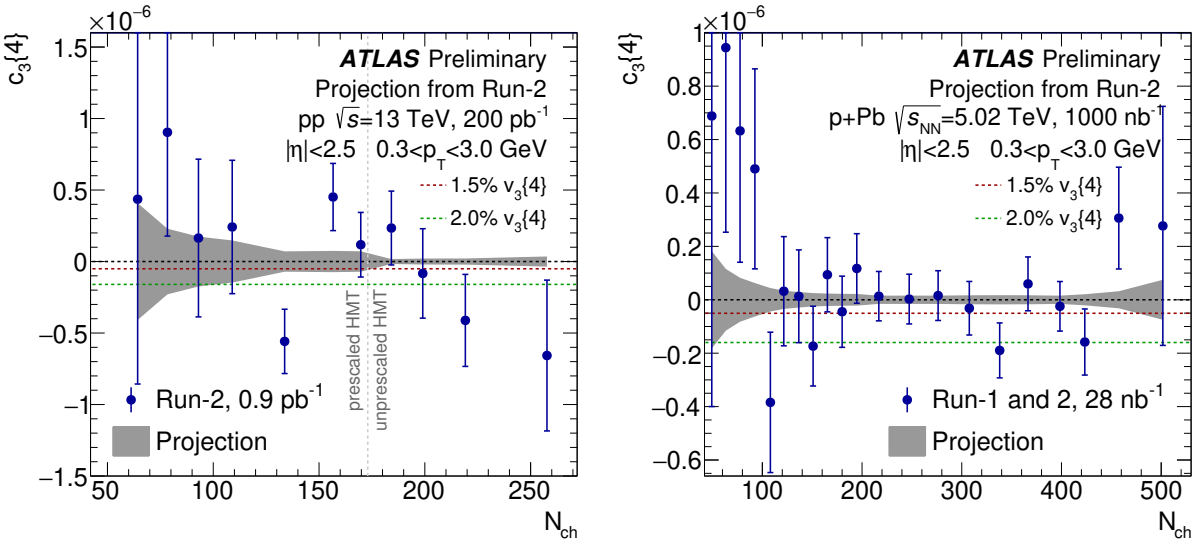

Fig. 67: 4-particle cumulants $c_3\{4\}$ measured with 3-subevent method for pp (left panel) and p–Pb collisions (right panel) as a function of $N_{\rm ch}$ ($|\eta| < 2.5$ and $0.3 < p_{\rm T} < 3$ GeV/c). Only statistical uncertainties are shown in the figure and the gray band represents the projected statistical uncertainty, with $c_3\{4\}$ assumed to be zero. The red and green dash lines represent 1.5% and 2.0% $v_3\{4\}$ signal, respectively. The vertical line in the left panel indicates the transition between minimum-bias and high-multiplicity triggered data. Figures from Ref. [6].

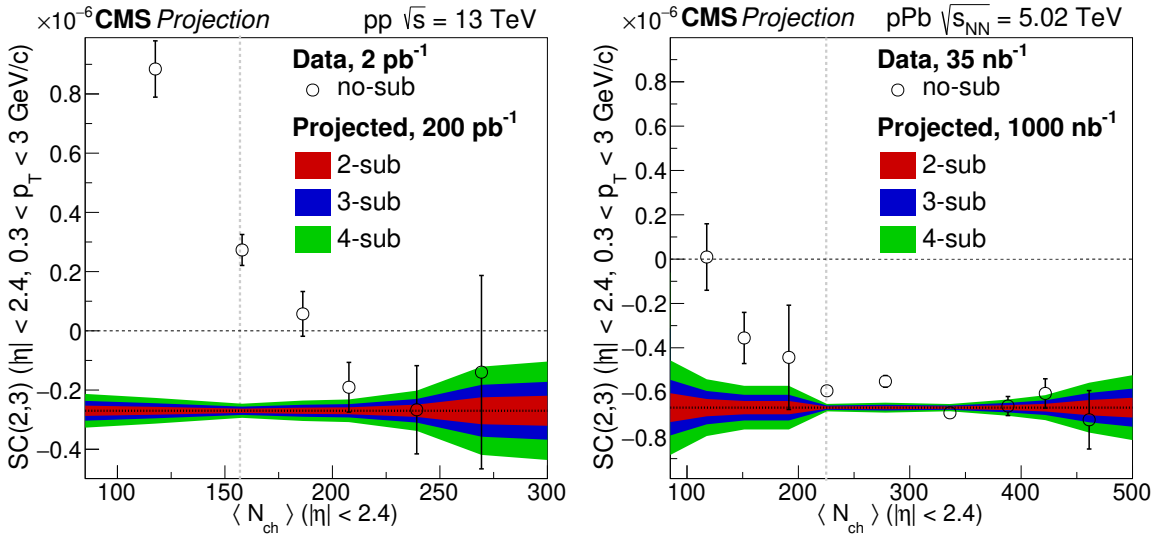

Fig. 68: Symmetric cumulants extracted with and without applying subevents for pp (left panel) and p–Pb collisions (right panel) as a function of $N_{\rm ch}$ ($|\eta| < 2.4$ and $0.3 < p_{\rm T} < 3$ GeV/c). The projected reach is shown for the case of 2, 3 and 4 subevents assuming a constant signal as a function of multiplicity indicated by the lower horizontal line. The vertical line indicates the transition between minimum-bias and high-multiplicity triggered data. Figures from Ref. [11].

that $c_3\{4\}$ is consistent with zero, but increased statistics will help to detect a potential non-zero $c_3\{4\}$ smaller than 1.5% for $100 \lessapprox N_{\rm ch} \lessapprox 500$. Similarly, the precision of the already measured non-zero $c_2\{4\}$ will be greatly improved [6].

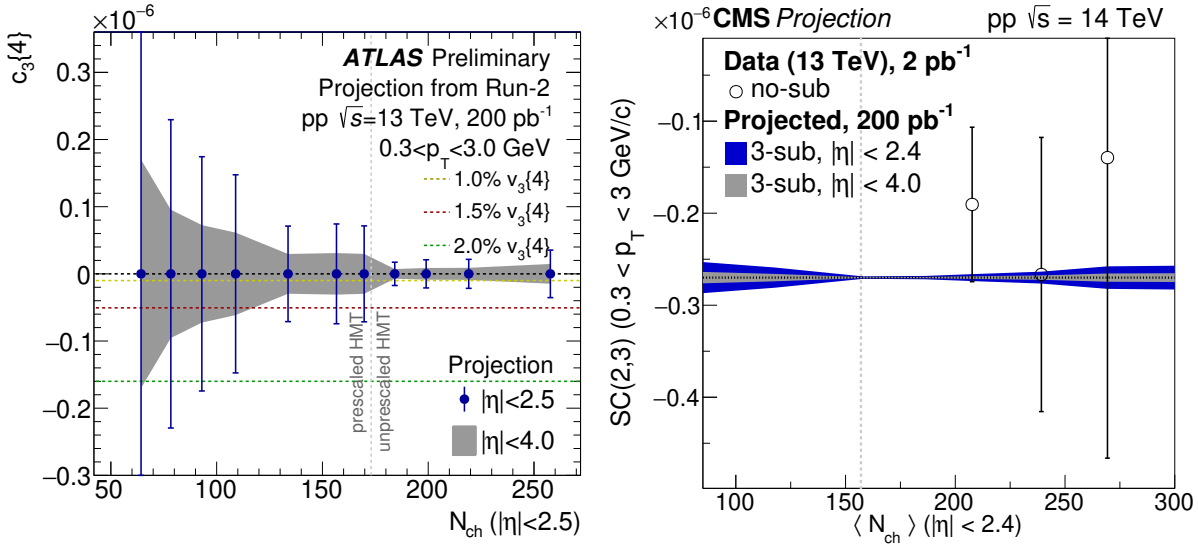

Fig. 69: Demonstration of the influence of the larger tracking acceptances for ATLAS and CMS available in Run 4. Left panel: 4-particle cumulant $c_3\{4\}$ (as in the left panel of Fig. 67) for pp collisions with $L_{\text{int}} = 200\,\text{pb}^{-1}$. The data points indicate the reach with the detector in Run 3 ($|\eta| < 2.5$) while the gray band the enlarged acceptance of $|\eta| < 4$ in Run 4. The yellow, red and green dash lines represent 1.0%, 1.5% and 2.0% $v_3\{4\}$ signal, respectively. Figure from Ref. [6]. Right panel: Symmetric cumulants with 3 subevents (as in left panel of Fig. 68) for pp collisions with $L_{\text{int}} = 200\,\text{pb}^{-1}$. The blue (gray) area indicates the projected uncertainty for Run 3 (4). Figure from Ref. [11].

The correlations of flow harmonics between different orders, called symmetric cumulants, are very sensitive to the initial state and the hydrodynamic evolution in heavy-ion collisions. In Pb–Pb collisions these are, for instance, used to constrain the shear viscosity over entropy ratio η/s. In addition, they challenge the description of the observed phenomena within initial-state saturation models. Their measurement in small systems can provide important insight in the validity of the hydrodynamic description of the observed phenomena. Here, symmetric cumulants probe in particular the proton substructure [770] which is needed to provide a solid description of the initial state, a necessary ingredient for the hydrodynamic description. The present uncertainties of such measurement in small systems are too large for a definitive conclusion, in particular in pp collisions, due to the dominance of non-flow like jets and resonance decays. Figure 68 shows the performance projection of $\text{SC}(2,3) = \langle v_2^2 v_3^2 \rangle - \langle v_2^2 \rangle \langle v_3^2 \rangle$ for HL-LHC for pp and p–Pb collisions. The uncertainties of the measurement without subevents would become practically invisible, however, those stay dominated by non-flow effects. A measurement requiring two, three and even four subevents becomes possible with uncertainties of the order of a few times 10^{-7} depending on multiplicity. Such results can give a definitive answer if a similar hydrodynamic footprint is observed in small and large systems.

Figure 69 illustrates the reduction of the statistical uncertainty due to the larger tracker acceptance in Run 4 for ATLAS and CMS. For this 4-particle correlator a reduction of the uncertainties of about 2.5 is expected, and therefore even the measurement of a 1% $v_3\{4\}$ signal comes into reach. The influence of the acceptance increase on the uncertainties of 6- and 8-particle cumulants will be larger, factor 4 and 6.5, respectively. Similarly, the uncertainties on the SC measurement reduce significantly at larger p_{T}.

Figure 70 (left panel) illustrates the reach which can be obtained for the v_2 measurement of heavy-flavoured objects in p–Pb collisions. Shown are projections for heavy-flavour electrons and inclusive J/ψ by ALICE as well as for prompt D and J/ψ by CMS. Minor uncertainties are expected for this observable with the potential to demonstrate for the first time with significance the final-state interaction

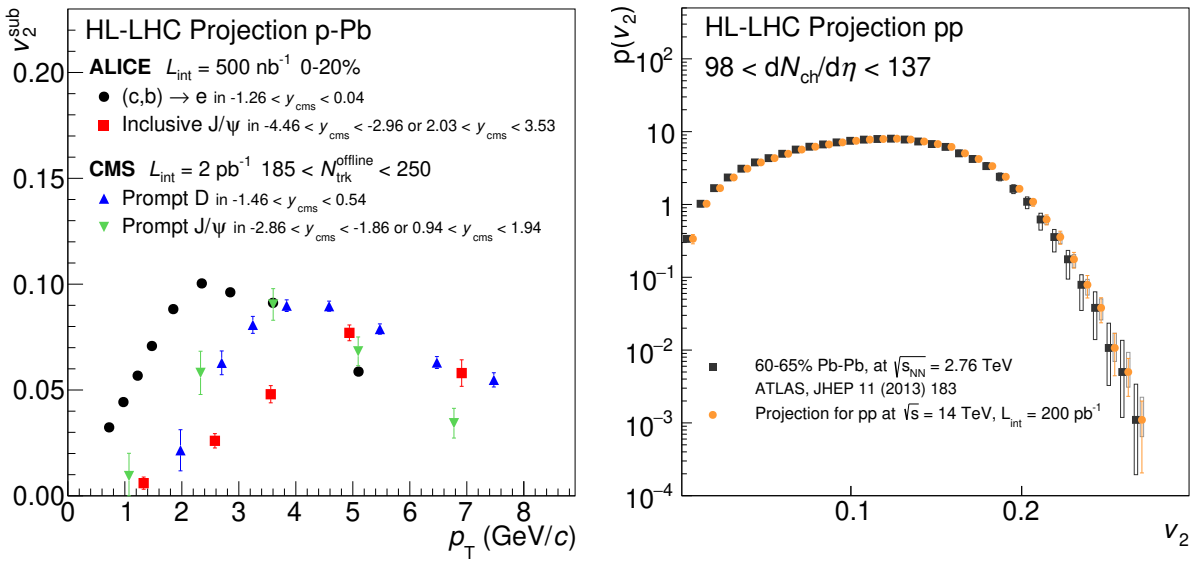

Fig. 70: Left panel: Particle identified v_2 coefficients for p–Pb collisions as a function of p_{T}. Two different cases are shown: the ALICE projections are for the 20% highest-multiplicity collision ($L_{\mathrm{int}} = 500\,\mathrm{nb}^{-1}$) demonstrating the negligible statistical uncertainties for heavy-flavour decay electrons and J/ψ, while the CMS projection is for a bin with $4 - 5\langle N_{\mathrm{ch}}\rangle$ ($L_{\mathrm{int}} = 2\,\mathrm{pb}^{-1}$) demonstrating the wide reach in multiplicity achievable for D mesons and J/ψ. Right panel: Projection of the measurement in pp collisions of the probability distribution of v_2. To illustrate the reach the same signal as in Pb–Pb [722] is assumed although the mean and the width of the distribution is most likely smaller in pp collisions. The projection is for the equivalent pp multiplicity (circles) as in 60–65% centrality in Pb–Pb collisions (squares).

of charm and beauty in a small collision system.

The v_{n} fluctuates on an event-by-event basis as no two nuclei have identical parton distribution. The probability density distribution of v_{n}, $\mathrm{p}(v_{\mathrm{n}})$ is closely related to event-by-event fluctuations of the eccentricities, $\mathrm{p}(\varepsilon_{\mathrm{n}})$ as $v_2 \propto k_2\epsilon_2$. Therefore its measurement provides crucial information about the initial conditions and the final-state dynamics of the medium. To characterise the initial-state spatial anisotropy these measurements are fitted with Bessel-Gaussian and elliptic power functions. The measurements of probability density distributions for v_2 at Pb–Pb collisions are described well by the Bessel-Gaussian function at central collisions and less in peripheral collisions [722–724]. This deviation from the Bessel-Gaussian function is expected in peripheral collisions as k_2 increases slightly at large ϵ_2 values [771]. Measurements are well described by the elliptic power functions in all centrality intervals of Pb–Pb collisions [723]. These measurement have not yet been attempted in small systems due to the insufficient available statistics. Figure 70 (right panel) presents a projection for the measurement of $\mathrm{p}(v_{\mathrm{n}})$ in pp collisions. This extrapolation is based on the $\mathrm{p}(v_2)$ measurement in 60–65% centrality Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 2.76$ TeV [722]. In this simple study, the same signal is assumed although the mean and width of the distribution is most likely smaller in pp collisions. Such a measurement would constitute the first measurement of $\mathrm{p}(v_{\mathrm{n}})$ in pp collisions, and can shed important light on the nature of the observed v_2 coefficients.

9.7 Strangeness enhancement

The unexpected increase of the strange-particle yield normalized by the pion yield as a function of N_{ch} is one of the key observations in small systems. In pp collisions these ratios are measured up

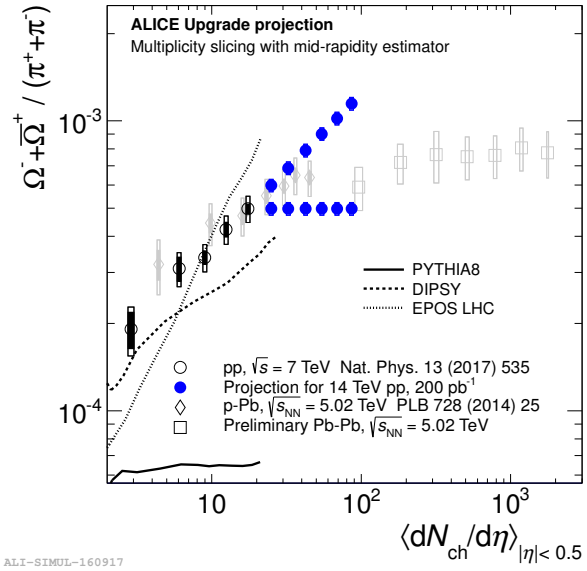

Fig. 71: Ω/π ratio as a function of $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta$ for pp, p–Pb, and Pb–Pb collisions. The existing data (from Ref. [642]) is shown in open black symbols (pp), grey diamonds (p–Pb) and grey squares (Pb–Pb), while the extrapolation for pp collision is shown in blue filled circles. Two scenarios are shown: a) assuming that the ratio continues increasing following the measured trend, and b) assuming that the value stays the same as at the largest measured $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta$. Figure from Ref. [1].

to $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta \approx 17$ with some overlap with p–Pb collisions. The most peripheral Pb–Pb collisions measured have a $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta \approx 96$, nearly 6 times larger. Figure 71 presents the expected reach of the Ω/π ratio in pp collisions which will bridge the present gap between pp and Pb–Pb collisions. In particular, if the measured increasing trend would continue, the Ω/π ratio would grow larger than in peripheral Pb–Pb collisions. Assuming that strangeness enhancement scales with the energy density of the system, Fig. 66 suggests that it should indeed be possible to see that the high-multiplicity pp results exceed the low multiplicity Pb–Pb results (crossover). Whether the signature will be as striking as the projection in Fig. 71, depends on the details of the assumed scaling law. At this point simulations are not precise enough to provide quantitative predictions of such a crossover, and HL-LHC experimental results on strangeness enhancement will as such be driving the theoretical development. The scenario with a clear crossover will be immediately distinguishable from a scenario where the Ω/π ratio flattens, and connects smoothly with the Pb–Pb result. Such a result will in itself also be groundbreaking, as it will indicate that the thermal limit reached in Pb–Pb collisions will already be realized in high-multiplicity pp collision.

9.8 Energy loss

As discussed in Sect. 9.2, inclusive high-p_{T} hadron and jet yields show at present no evidence of medium-induced energy loss in p–Pb collisions, and suffer from selection biases if measured in event classes. Inclusive measurements with the large event set expected at HL-LHC therefore do not help to resolve the question of energy loss in small systems. However, coincidence measurements of jets recoiling against a trigger object are not subject to such biases, and have the potential to identify small energy-loss effects or put stringent upper limits. In this section, projections are given for correlations between high-p_{T} hadrons and jets, as well as jets and γ and Z.

Figure 72 shows a projection of the measurement of semi-inclusive hadron–jet correlations in LHC Run 3 and 4, for pp collisions at $\sqrt{s} = 14$ TeV and p–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.02$ TeV. The

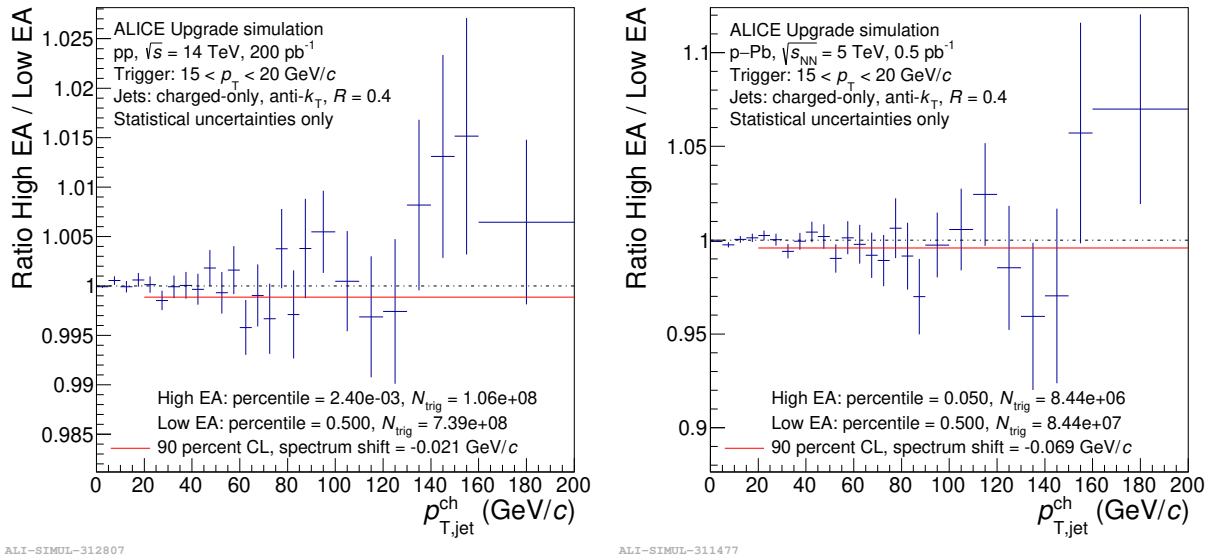

Fig. 72: Modification of jet-recoil yields extracted from semi-inclusive hadron–jet correlations for pp collisions (left) and p–Pb collisions (right) within the ALICE acceptance. Shown is the ratio of high event-activity (EA) and low-EA recoil spectra as a function of $p_{\mathrm{T,jet}}^{\mathrm{ch}}$, with high-EA corresponding to 5–7 $\langle N_{\mathrm{ch}} \rangle$ in pp collisions (left panel), and the 0–5% bin for p–Pb collisions (right panel). Since no EA-dependent shift is imposed, the parent distribution of the ratio has the value of unity at all p_{T}. The red lines show the 90% CL limit for a possible EA-dependent spectrum shift. Figures from Ref. [1].

figure shows the ratio of trigger-normalized recoil spectra for events selected on high and low event-activity (EA) classes. This projection is based on Pythia simulations for pp collisions, which gives the expected number of charged-hadron triggers in the interval $15 < p_{\mathrm{T,trig}} < 20$ GeV (scaled by A to model p–Pb collisions), and the per-trigger recoil jet spectrum. The measured enhancement in the per-event high-p_{T} hadron yield for pp collisions in high-multiplicity collisions [653] has been taken into account.

The projection represents the case where no energy loss occurs for high-EA relative to low-EA collisions, and demonstrates the statistically achievable limit. The 90% confidence level for a possible EA-dependent spectrum shift due to large-angle energy transport from jet quenching [737] is 70 MeV/c for p–Pb (5% highest EA) and 21 MeV/c for pp collisions (5–7 $\langle N_{\mathrm{ch}} \rangle$). These values are over 100 times smaller than the spectrum shift measured in Pb–Pb collisions [358]. The high statistics of the HL-LHC dataset enables this approach to be applied to yet more stringent EA selections; for 7–10 $\langle N_{\mathrm{ch}} \rangle$ (10–12 $\langle N_{\mathrm{ch}} \rangle$) the corresponding 90% CL limit on energy loss is expected to be 69 MeV/c (590 MeV/c).

Projections for the correlation of jets and γ as well as jets and Z are presented in Fig. 73 for pp and p–Pb collisions. Shown are distribution of the momentum fraction $x_{jX} = p_{\mathrm{T}}^{\mathrm{jet}}/p_{\mathrm{T}}^{X}$ where X is the γ or Z. Given that the γ and Z can be considered unmodified by final-state interactions, a potential energy loss acting on the jet would directly alter the x_{jX} distribution. For pp collisions, the left panel of Fig. 73 presents the distribution for different classes in multiplicity based on Pythia, demonstrating the reach. It can be also seen that the distribution shifts significantly as a function of multiplicity without final-state interactions, but purely due to the presence of an underlying event. This shift is caused by selection biases, e.g. the likelihood of multi-jet events is increased by requiring higher event multiplicity. In order to extract a firm conclusion on energy loss, this observable needs to be compared to theoretical calculations or tuned generators which reproduce multiplicity and underlying-event fluctuations in $\mathrm{e^+e^-}$ and pp collisions. The right panel of Fig. 73 presents the projection for p–Pb collisions for MB collisions but in different pseudorapidity intervals sensitive to potential differences in

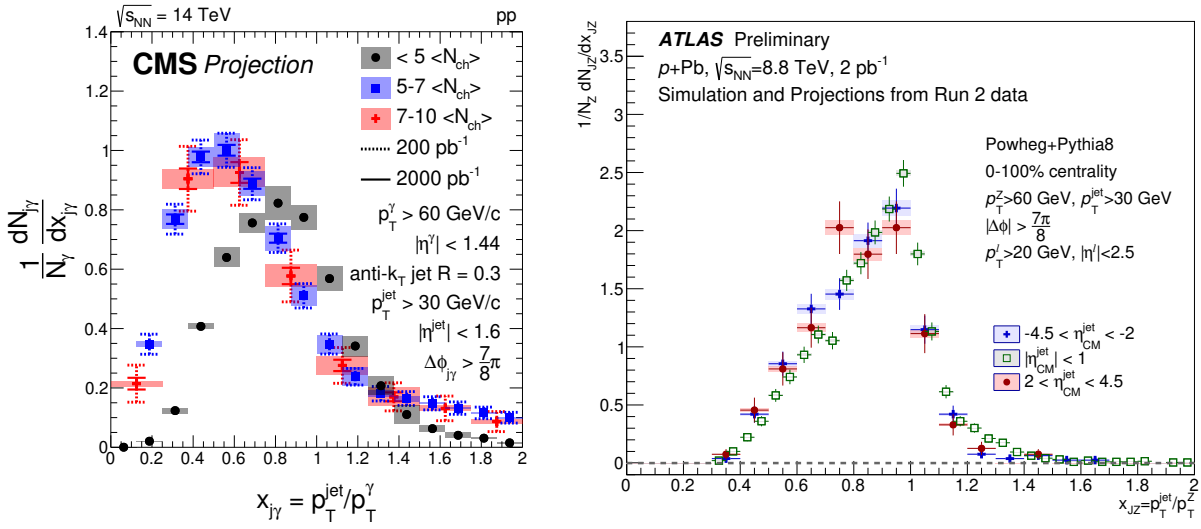

Fig. 73: Left panel: CMS projection of the measurement of the jet–γ momentum fraction $x_{j\gamma}$ in pp collisions for selected high-multiplicity bins. A jet with $p_{\mathrm{T}} > 30$ GeV/c is required to be back-to-back ($\Delta\varphi > 7/8\pi$) with a γ with $p_{\mathrm{T}} > 60$ GeV/c. The shape is based on Pythia and shifts due to selection biases as a function of multiplicity (see text). Figure from Ref. [10]. Right panel: ATLAS projection of the measurement of the Z–jet momentum fraction x_{jZ} in p–Pb collisions in different pseudorapidity intervals. The momentum requirements are also 30 GeV/c for the jet and at least 60 GeV/c for the Z, with the same back-to-back requirement ($\Delta\varphi > 7/8\pi$). The projection is based on Powheg + Pythia 8 Monte Carlo samples with the CT10 PDF set. Figure from Ref. [7].

the p and Pb hemisphere.

9.9 Thermal Radiation

The measurement of thermal radiation in p–Pb collisions can be considered as a smoking gun for the formation of a system with an energy scale above the phase-transition temperature, see Chapter 8. In order to estimate the sensitivity to the thermal radiation in p–Pb collisions, a similar strategy as in Sec. 8.1.2 was used. The combinatorial background was scaled from Pb–Pb collisions to the expected number of pairs in p–Pb collisions. The pair efficiency (including the efficiency for rejecting $\mathrm{e}^+\mathrm{e}^-$ pairs from semileptonic charm decays) is assumed to be the same as in Pb–Pb collisions. Subsequently, the temperature of the QGP is extracted in the same way as in Sec. 8.1.2. The minimum thermal photon to π^0 (both decaying into $\mathrm{e}^+\mathrm{e}^-$) ratio that is needed for a fit to the invariant mass spectrum with a statistical uncertainty $\sigma_{\mathrm{T,stat}} = 10\%$ as a function of L_{int} up to 2000 nb^{-1} is shown in Fig. 74. If the considered prediction is accurate, an integrated luminosity of about 50 nb^{-1} is sufficient for the measurement. In case the signal is 50% smaller about 4–5 times the statistics is needed.

9.10 Potential of O–O Collisions

A promising opportunity to study the emergence of collective phenomena further as well as the presence of possible parton energy loss in small collision systems, are collisions of smaller nuclei. In particular, collisions of oxygen are an efficient way of investigating the properties of low-multiplicity heavy-ion collisions, which in large A–A systems only occurs for peripheral geometries. The achieved multiplicities in O–O collisions are similar to p–Pb collisions with the significant advantage that the collision geometry is much better defined. This is demonstrated in Fig. 75, which shows the correlations between number of participants, multiplicities and impact parameter in O–O and p–Pb collisions. The correla-

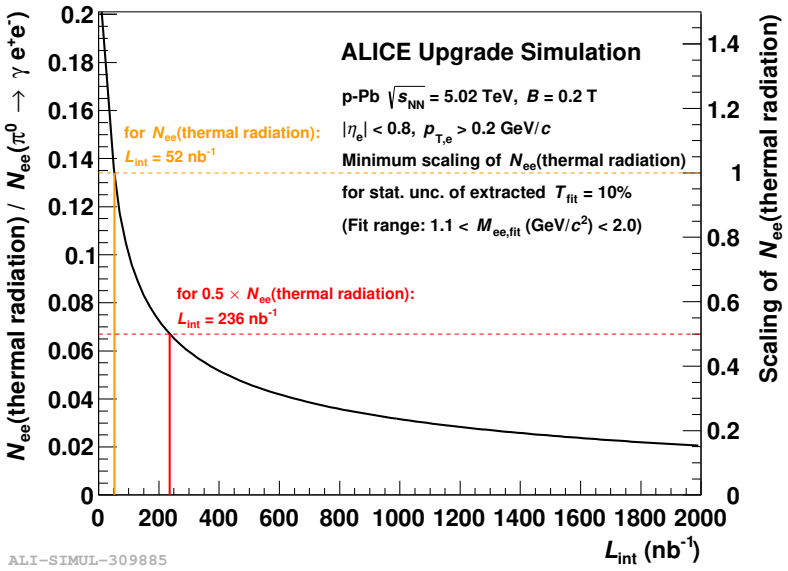

Fig. 74: Projection of the measurement of the medium temperature extracted from thermal dileptons in p–Pb collisions. As the expected signal is uncertain, the figure presents the required integrated luminosity relative to the prediction based on Ref. [558] denoted by $N_{\rm ee}$(thermal radiation). It is expressed as the minimum thermal photon $N_{\rm ee}$(thermal radiation) to π^0 ratio (left axis) and scaling of $N_{\rm ee}$(thermal radiation) (right axis) for achieving a 10% statistical uncertainty on the extracted temperature. Figure from Ref. [1].

tions between $N_{\rm part}$ and impact parameter as well as multiplicity and $N_{\rm part}$ is much narrower in O–O collisions as compared to p–Pb collisions. Consequently, highest multiplicities in p–Pb collisions are only accessible in the tail of the distribution while similar multiplicities are already reached in O–O collisions in the plateau region. This is shown in Fig. 76 illustrated for the 20–40% event class.

Scaling the measured nuclear-modification factor in Pb–Pb collisions at 5.02 TeV [327] at similar multiplicities as for central O–O collisions while roughly accounting for the artificial suppression caused by the multiplicity bias present in such peripheral Pb–Pb collisions [734], allows to estimate the expected effect on the $R_{\rm AA}$ in O–O collisions to about 20%. Out of this deviation from unity, about half can be attributed to biases due to the multiplicity selection in such small collision systems already in absence of nuclear effects [772]. An observable deviations from unity of about 10% caused by energy loss in the produced medium remains. While this expected suppression may seem small, it should be possible to measure it already with an $L_{\rm int}$ of a few 100 μb^{-1}. In case such a suppression was absent, the conclusion can be drawn that small collision systems do not exhibit measurable energy loss, while other collective features are present, challenging the role of significant final-state interactions as underlying mechanism. It should be noted that the absence of suppression can most likely not be taken as a proof against the formation of the QGP, as it may be that the fast partons are emerging without seeing the medium, either because they are emitted from the surface or because their formation time is longer than the time within the medium. On the contrary, as discussed in Sect. 9.8 the first observation of energy loss in small systems would clearly confirm models in which final-state interactions play an important role

The study of bulk particle production in O–O collisions has twofold interest: Firstly, the dependence of the pseudorapidity density of charged particles scaled by participant pairs on $\sqrt{s}$ is stronger in A–A collisions than in pp and p–A collisions [775]. The rise for p–Pb and d–Au collisions is simi-

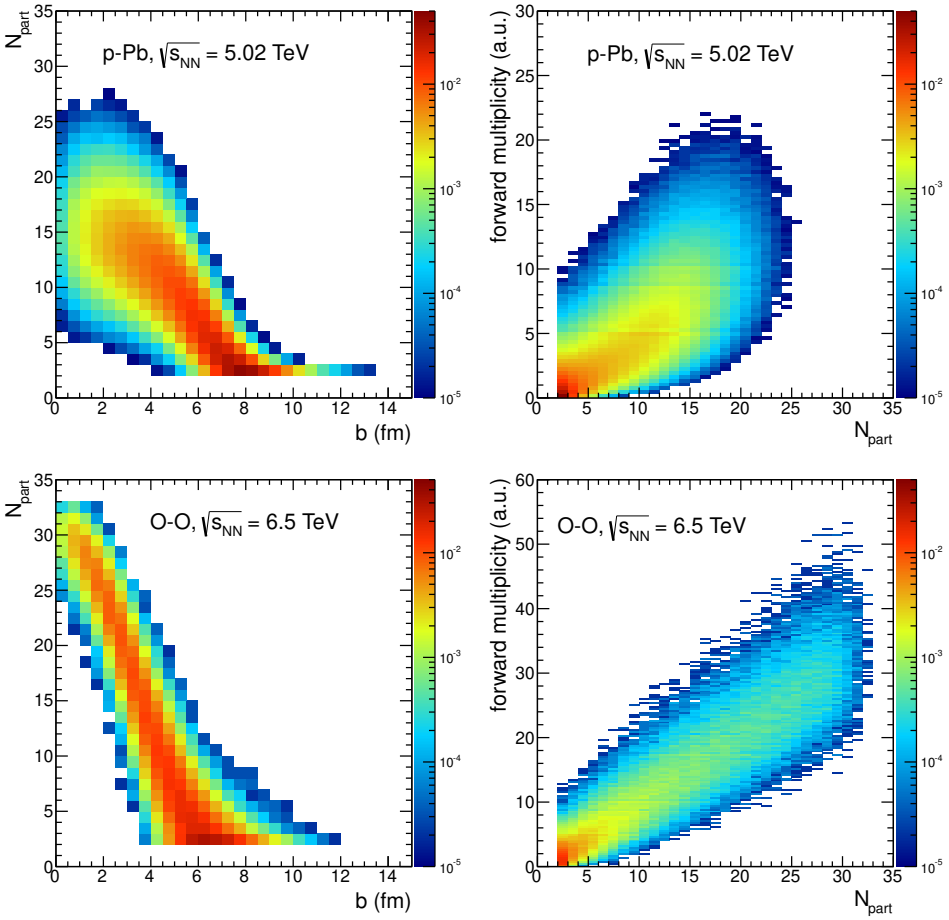

Fig. 75: Glauber MC calculations are presented for for p–Pb (top panels) and O–O collisions (bottom panels). Shown are N_{part} as a function of impact parameter (left panels) and forward multiplicity as a function of N_{part} (right panels).

lar to the one of inelastic pp collisions indicating that the stronger rise in A–A collisions might not be solely related to the multiple collisions undergone by the participants since the proton in p–A collisions also encounters multiple nucleons. High-energy O–O collisions promise to study this $\sqrt{s}$ dependence further in a regime of small number of participants. Secondly, a strong correlation between initial state geometry (collision eccentricity) and observed flow has been established since RHIC [776], and pertains at LHC, in Pb–Pb and Xe–Xe collisions [777]. As shown in Fig. 77, the eccentricity profiles of Xe–Xe and Pb–Pb collisions are, however, quite similar, and collision systems exhibiting a different geometry as O–O could therefore provide further insight into the connection between initial-state geometry and multi-particle correlations [778].

9.11 Summary

The discoveries made in recent years in small collision systems have challenged two paradigms, the modelling of heavy-ion collisions, as well as the modelling of the underlying event of elementary pp collisions. The experimental observations of strangeness enhancement and multi-particle correlations suggests that energy loss should also be present, as both are a consequence of significant final-state interactions. But up to this point no hint of energy loss in pp or p–Pb collisions has been seen. The increased luminosity will allow both for precision studies of the established signatures of small system

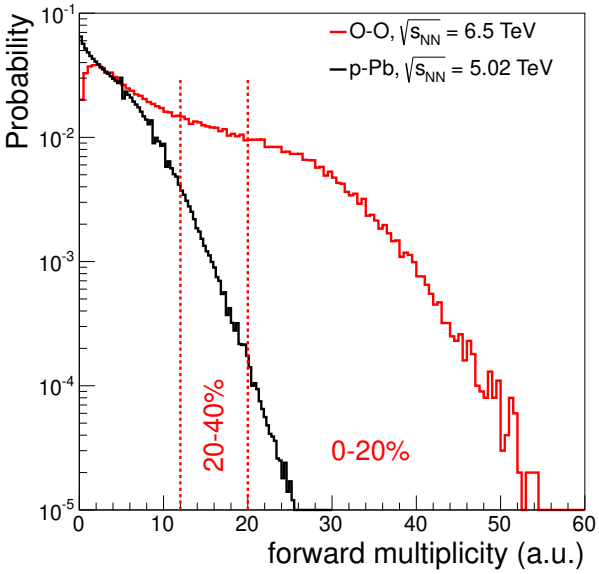

Fig. 76: Estimated multiplicity distributions in the forward region in O–O and p–Pb collisions. The event classes of highest multiplicity in O–O collisions are indicated with 0–20% and 20–40%. The O–O studies have been been performed for the 2018 beam configurations at $\sqrt{s_{\rm NN}} = 6.5$ TeV, while the Run 3 configuration would yield $\sqrt{s_{\rm NN}} = 7$ TeV, with the advantage that a large pp reference data set already exists from earlier LHC running (2010–11).

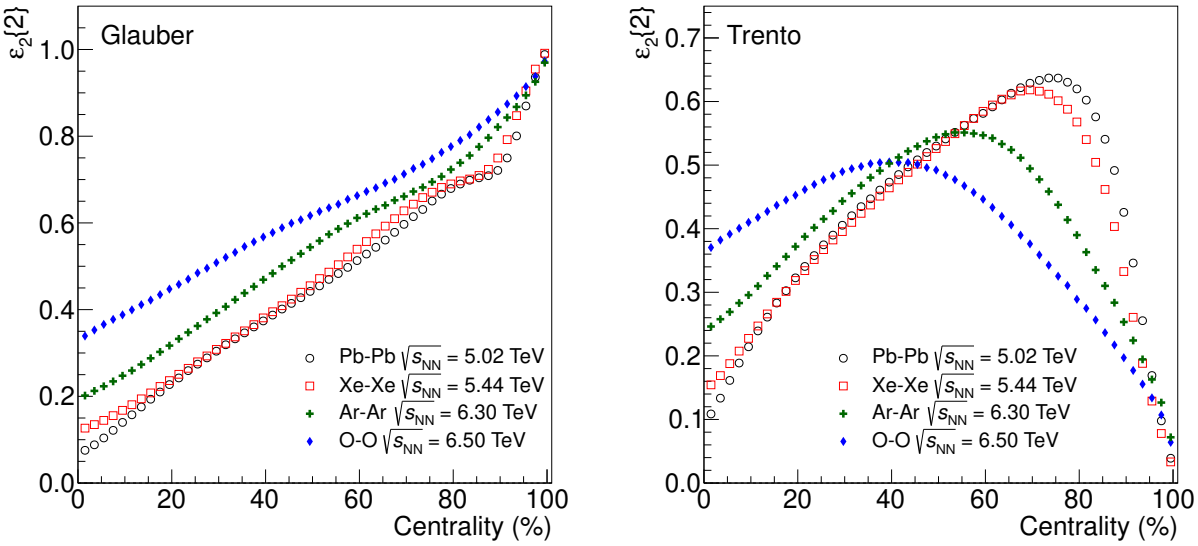

Fig. 77: Second-order eccentricity coefficient ϵ_2 as a function of centrality for O–O, Ar–Ar, Xe–Xe and Pb–Pb collisions from MC-Glauber (left panel) [767, 773] and Trento (right panel) [774] initial conditions.

collectivity, and to either establish evidence or place exclusion limits on the latter.

This chapter has presented a HL-LHC small system experimental program promising significant progress shown by the set of performance studies, ranging from largely non-flow suppressed high-order correlations, over measurement of strange-particle yields and thermal radiation, to energy-loss signals. In addition, new theoretical insights and phenomenological developments are also needed for developing

a unified picture of parton dynamics and particle production valid for both small and large systems. This working group encourages both investment in the necessary theoretical development, and facilitation of collaboration between theorists and experimentalists.

The physics community can look forward to a deepened understanding of hot and dense QCD and a universal description of small to large collision systems.

10 High energy QCD with proton-nucleus collisions and ultra-peripheral collisions

10.1 Introduction

Proton-nucleus [17] and ultraperipheral (UPC) [587] collisions offer the opportunity to study the behaviour of QCD at high energies and large partonic densities [779]. As the theory of the strong interaction, QCD is analytically well understood only in a perturbative regime of small coupling constant and where radiation of gluons and quarks is a linear process that can be described with linear evolution equations of the non-perturbative parton densities, i.e., hadrons and nuclei are considered as dilute partonic objects. However, non-linear effects are unavoidable in QCD, and they should in principle dominate at large densities reached at high collision energies and for large nuclei. It was proposed long ago [780,781] that at such large densities a resummation of powers of density scaled by the strong coupling constant is possible, resulting in a non-perturbative but weak coupling regime where parton densities saturate, and whose effective field theory incarnation is the Color Glass Condensate (CGC) [782]. Particle production in p–A collisions in the forward rapidity region is dominated by small$-x$ partons in the nucleus. Therefore, saturation effects are expected to be largest there. Furthermore, UPCs as a source of large fluxes of quasi-real photons, provide the opportunity to study the partonic structure of protons (in pp and p–A) and nuclei (in p–A and A–A).

The structure of nucleons and nuclei, and the mechanism of particle production at small x, are also key ingredients for a detailed description of heavy-ion collisions and for the characterisation of the produced hot and dense medium. For hard probes, the nuclear modification of standard collinear parton densities is one of the uncertainties in the extraction of medium characteristics [260, 385]. For soft and semihard observables, both the parton densities and the detailed transverse spatial structure of nucleons and nuclei are crucial ingredients for their description, e.g. for the initial conditions for hydrodynamical evolution [211, 212, 783].

In the collinear framework, parton densities inside nuclei (nPDFs) [784, 785] are poorly constrained due to two primary factors. On the one hand, data come from a large variety of nuclei and the number of data points for any of them is very small compared to the proton analysis. In particular, for the Pb nucleus, there are less than 50 points coming from fixed target Deep Inelastic Scattering (DIS) and Drell-Yan experiments and from p–Pb collisions at the LHC. The fit for a single nucleus is therefore impossible and the modeling of the A-dependence of the parameters in the initial conditions becomes mandatory [786, 787]. On the other hand, the kinematic coverage in Q^2 and x with existing data is very small compared to the requirements of present hadronic colliders, see Fig. 78. In spite of the

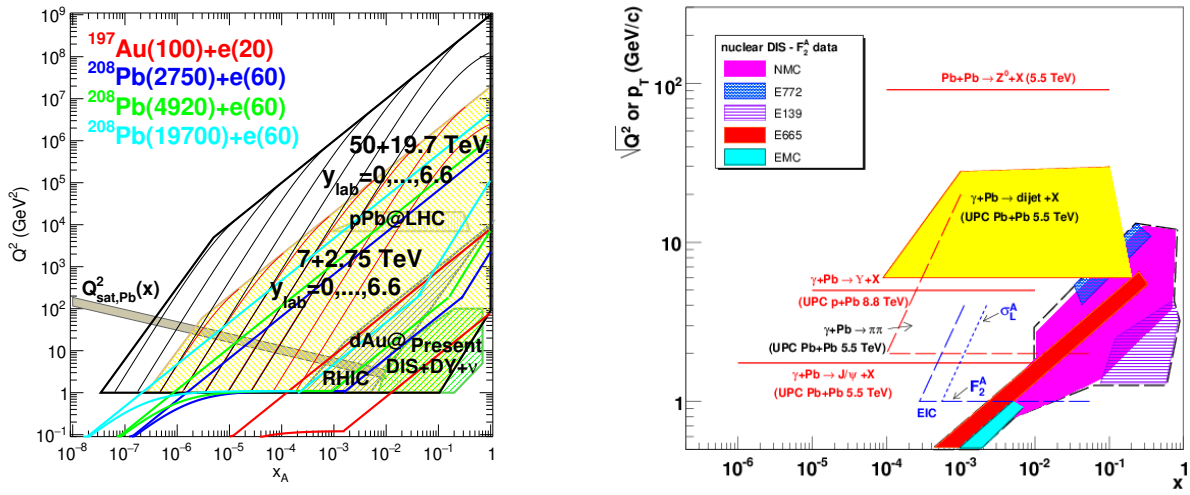

Fig. 78: Left: x-Q^2 plane to be explored in proton-nucleus at the LHC and the FCC, and in proposed electron-nucleus colliders, compared with the regions where the experimental data presently used in the EPPS16 analysis [786] lie. Right: x-Q^2 plane to be explored in UPCs, taken from [587].

uncertainties in the applicability of collinear factorisation, scale choices and other theoretical caveats for nPDFs extraction in hadronic collisions and UPCs, these are the only experimental collision systems where the nPDFs can be constrained before electron-ion colliders become available. The most up to date analyses include between 1000 and 2000 data points for 14 nuclei and are performed at next-to-leading accuracy [786–788], there even exists a first attempt at next-to-next-to-leading [789]. Differences between them mainly arise from the different sets of data included in the analysis and from the different functional forms employed for the initial conditions. All in all, all parton species are very weakly constrained at small $x < 10^{-2}$, gluons at large $x > 0.2$, and the flavour decomposition is largely unknown - a natural fact for u and d due to the approximate isospin symmetry in nuclei. The impact of presently available LHC data, studied in [786], is quite modest with some constrains on the gluon in the region $0.01 < x < 0.3$. On the other hand, theoretical predictions for nuclear shadowing of quark and gluon PDFs based on s-channel unitarity and diffractive nucleon PDFs are available down to $x \sim 10^{-4}$ –10^{-5} [790, 791].

In the context of phenomena beyond collinear factorisation and PDF evolution in $\ln(Q^2)$, there have been recent claims [792, 793] that resummation of logarithms of x may be required for a better description of DIS data from HERA at small x, and searches for long range azimuthal correlations are undergoing [794]. But no conclusive evidence of saturation, i.e., of non-linear dynamics, has been found in hadronic collisions. While the CGC provides a calculational framework for several observables in pp, p–A and A–A, see e.g. the reviews [795, 796], like the ridge, back-to-back hadron correlations in the forward region, multiplicities and transverse momentum distributions,. . . , there is no consensus in the field in the interpretation of these results, or they involve non-perturbative modeling, or they are affected by large theoretical uncertainties and, for some of them, higher-order calculations are missing, or the data lie at the border of phase space where extracting clear conclusions is very delicate. Therefore, high-energy p–A collisions and UPCs are two promising systems where data can offer clear evidences of non-linear effects.

In Fig. 78, the kinematic regions covered by proton-nucleus collisions at the LHC and the FCC (the left panel, [411]) and UPCs at the LHC (right) are shown and compared with the regions where data currently used to constrain nPDFs lie. A huge enlargement is evident with respect to the presently existing data at the LHC. The HL-LHC offers new improved detectors and larger statistics for some observables

like dijets or photon-jet correlations. The HE-LHC would enlarge the kinematic plane in a region intermediate between the LHC and the FCC. On the other hand, electron-nucleus collisions [797, 798], if they eventually happen in the 2030's, would be complementary. They offer measurements in a cleaner experimental environment (no pileup, full kinematic reconstruction) and under better theoretical control as first-principle calculations are easier in DIS albeit in a more restricted kinematical region. The comparison between the kinematic regions covered by the LHC and Future Circular Collider (FCC) in p–A mode, and the Electron-Ion Collider (EIC) [798] (10-20 GeVelectrons combined with the RHIC nuclear beams or with a new hadron machine at Jefferson Lab) and the LHeC [797] (60 GeVelectrons colliding with the HL-LHC, HE-LHC or FCC nuclear beams) is shown in Fig. 78 (left).

10.2 The physics of ultra-peripheral collisions

Ultra-peripheral collisions are interactions with impact parameter larger than the radial size of the colliding nuclei or protons. In these collisions, one nucleus acts as a source of quasi-real photons that interact with the crossing nucleus or proton. The electromagnetic field intensity and hence the photon flux scales with the charge number squared. At the LHC, these collisions occur abundantly and serve as a laboratory for strong and electromagnetic interactions [587]. After an experimental overview discussing the opportunities, the discussion focuses on vector meson production studies to probe nuclear gluons and dijet production in photonuclear or photon-proton interactions in LHC Run 3 and 4 as a direct access of nPDFs. A dedicated section 11.2 addresses the physics of $\gamma\gamma$ interactions as a probe of QED and beyond the standard model physics. The investigation of γ-proton interactions in pp collision allowed interesting measurements on vector meson production by LHCb [799–802] and will allow for interesting measurements with already recorded and future data. This possibility will not be discussed in detail because the standard running conditions in terms of pile-up and beam optics relevant for forward proton tagging in ATLAS/CMS and the pile-up in LHCb in Run 3 and Run 4 will make comparatively low Q^2 measurements primarily discussed here challenging and likely restricted to short special runs whereas in ALICE, the equivalent luminosity γ-proton luminosity will be smaller or similar than in p–Pb collisions but with the ambiguity which beam emitted the photon.

10.2.1 Experimental overview

An overview of the detector capabilities in Run 3 and Run 4 is given by the four collaborations ALICE,ATLAS,CMS and LHCb in the following. Subsequently, the expected statistics for vector meson observables is given in Tab. 13,14,15 followed by an estimate of the available precision for coherent heavy vector meson production and the theoretical assessment of vector mesons and dijet production in UPCs.

- **ALICE** [2] will take data in both in triggered and in continuous readout mode during Run 3 and Run 4 [70]. Using continuous readout [69] essentially the full delivered luminosity can be integrated without significant trigger and dead-time inefficiencies. Therefore the total acceptance-efficiency factor for UPC events is significantly larger than in LHC Runs 1 and 2; it is determined by the tracking efficiencies and the geometrical acceptances of the Inner Tracking System (ITS) [3], of the Time Projection Chamber (TPC) [68], and of the Muon Spectrometer [803]. The geometrical acceptances of these detectors correspond to the narrow central and forward acceptances defined in Tab. 12. Vector meson yields in the corresponding acceptance are given in Tab. 13,14,15. Final-state neutron emission in UPC events can be detected by the zero-degree calorimeters (ZDC) which will also take data in continuous readout mode, and vetoes can be imposed using the fast interaction trigger detector (FIT).
- **ATLAS** UPC measurements in Run 3 and Run 4 will continue to be an important part of the experiments heavy-ion programme and will benefit from several detector upgrades in that period.

Prior to Run 3, the Zero Degree Calorimeter (ZDC), which is key for UPC event identification by measuring forward neutrons, will be upgraded. At mid-rapidity, the Inner Tracker (ITk) upgrade [264] will increase the acceptance for charged particles to $|\eta| < 4$ for Run 4. The High Granularity Timing Detector (HGTD) [265] will complement the spatial information of the ITk with timing information in the region $2.4 < \eta < 4.0$, with a resolution of 30 ps. In addition, upgrades to the ATLAS trigger and data-acquisition system will take place prior to both Run 3 and Run 4 [804], and will enable advanced triggering capabilities. Together these will aid the study of low-mass resonances and the continuum as well as jets in UPC events.

- **CMS** UPC studies will benefit from the upgraded inner tracker for Run 4 which will provide a large acceptance for charged particles up to $|\eta| < 4$ [457]. The improved CMS level-1 trigger and data acquisition rate (up to 60 GB/s) will provide opportunities for more innovative and sophisticated triggers to capture a wide variety of processes. In addition, the proposed MIP Timing Detector [805], which is around 1.16 m away from the beam pipe could provide a time resolution around 30 ps. By combining it with other detectors, MIP will provide proton, pion, and kaon separation for p_{T} values between 0.7 to 2 GeV/$c$in the midrapidity region ($|\eta| < 1.5$). These detector upgrades and the increased trigger performance summarised in [806] will facilitate the study low-mass UPC resonant states and UPC heavy flavour studies. In addition, the reconstruction algorithms will be improved with the addition of the four-layer pixel system. The CMS-acceptance in Run 3 corresponds to the wide central range defined in Tab. 12. Yields in acceptance for vector mesons are provided in Tab. 13,14,15.
- **LHCb** is well suited for exclusive production studies in ultra-peripheral collisions. In particular, its optimisation for flavour physics within its acceptance $2 < \eta < 5$ provides an excellent resolution for typical momenta in quarkonium and heavy-flavour exclusive production as demonstrated in Ref. [807]. Its particle identification capabilities allow to measure final states with charged muons, pions, kaons and protons. The upgraded detector will be able to efficiently sample the full delivered luminosity for UPC final states based on a purely software based trigger scheme [808]. Exclusive diphoton analyses as pioneered in ATLAS [809] and CMS [810] are also conceivable with lower E_{T}-thresholds discussed in Section 11.2. The feasibility of inclusive γ-induced measurements in LHCb will require further studies. In Tab. 13,14,15 conceivable vector meson final states are given for LHCb represented by the wide forward acceptance defined in Tab. 12.

10.2.2 Vector meson production

10.2.2.1 Experimental reach

The number of vector mesons expected in the upcoming runs provides an estimate of the expected physics reach. Four toy-model experimental acceptances are shown in Tab. 12. The effects of cuts on the p_{T} of the final state daughter particles are not estimated, because this depends on the analysis and trigger conditions. In general, for two-prong decays, as long as the minimum detectable p_{T} is less than about 1/4 of the final state mass, the effect on the efficiency is limited. The acceptance cuts are applied to both the vector meson rapidity and the daughter particle pseudorapidities. These two selection types have similar effects on the production phase space, and the results would not be very different without the cut on the vector meson rapidity.

Table 13 shows the expected cross sections and rates for five representative vector meson decays, including the decay branching ratios. The rates are calculated using STARlight [598], which has been shown to predict the cross sections for all mesons on proton targets and for ρ photoproduction on heavy targets [811, 812]. Since the ρ vector resonance is broad, the mass range from $2m_{\pi}$ up to $M_{\rho} + 5\Gamma_{\rho}$ is considered. Non-resonant $\pi^{+}\pi^{-}$ production is not included which would lead to a 8% increase of the production rate. The ρ' state represents $\pi^{+}\pi^{-}\pi^{+}\pi^{-}$ states with masses in the range from $4m_{\pi}$ up to

2.5 GeV/c^2. In absence of other guidance and the possibility of more complex resonance structure, the calculation is anchored to the STAR measurement of the $\pi^+\pi^-\pi^+\pi^-$ final state in Au–Au collisions at $\sqrt{s_{\rm NN}} = 200$ Gev [813] and uses STARlight to extrapolate in collision energy and collision system.

Since STARlight does not include nuclear shadowing, a rapidity-dependent nuclear shadowing correction following Ref. [814] for the heavy quarkonium (J/ψ, ψ(2S) and Υ(1S) was applied. The cross sections and rates are hence reduced by factors of 0.42, 0.475 and 0.77 for the J/ψ, ψ(2S) and Υ(1S) respectively.

Table 12: Table of toy-model acceptance cuts for the different experiments.

Condition	Tot.	Central 1 Narrow	Central 2 Wide	Forward 1 Narrow	Forward 2 Wide
Rapidity	-	$\|y\| < 0.9$	$\|y\| < 2.4$	$2.5 < y < 4.0$	$2 < y < 5$
e/π/μ pseudorapidity	-	$\|\eta\| < 0.9$	$\|\eta\| < 2.4$	$2.5 < \eta < 4.0$	$2 < \eta < 5$

Table 13: Table of cross sections and numbers of events in 13 nb^{-1} integrated luminosity for the different mesons in Pb–Pb collisions. B, M and K denote 10^9, 10^6 and 10^3 respectively. Both the rates and cross sections include the relevant branching ratios. The cross sections and toy-model acceptances are determined using STARlight [598]. For the J/ψ, ψ(2S) and Υ(1S), rapidity-dependent nuclear shadowing cross sections have been applied following the approach in Ref. [814].

PbPb						
Meson	σ	All Total	Central 1 Total	Central 2 Total	Forward 1 Total l	Forward 2 Total
$\rho \to \pi^+\pi^-$	5.2b	68 B	5.5 B	21B	4.9 B	13 B
$\rho' \to \pi^+\pi^-\pi^+\pi^-$	730 mb	9.5 B	210 M	2.5 B	190 M	1.2 B
$\phi \to \mathrm{K}^+\mathrm{K}^-$	0.22b	2.9 B	82 M	490 M	15 M	330 M
J/$\psi \to \mu^+\mu^-$	1.0 mb	14 M	1.1 M	5.7 M	600 K	1.6 M
ψ(2S) $\to \mu^+\mu^-$	30μb	400 K	35 K	180 K	19 K	47 K
Υ(1S) $\to \mu^+\mu^-$	2.0 μb	26 K	2.8 K	14 K	880	2.0 K

The rates for light mesons are very large, enough to support billion-event samples of the ρ and ρ', and hundreds of millions of ϕ, allowing the studies discussed below. Beyond precise cross section measurements detailed below, the rates for J/ψ, ψ(2S) and Υ(1S) should allow tomographic measurements which can be used to infer information on the nuclear wave function and which is outlined in Section 10.2.2.3. In the $\pi^+\pi^-$ channel, the study of pairs with masses above 2 Gev/c^2 comes in reach.

In the hadronic decay $\phi \to K^+K^-$, the kaons have a momentum of only 135 MeV/c in the ϕ rest frame. Since the kaon momentum is dominated by the longitudinal momentum acquired from the ϕ-meson, the kaons are produced with large pseudorapidity. Therefore, the acceptance for this channel is low at around midrapidity even without a considering a minimal kaon-$p_{\rm T}$. Consequently, an observation is very difficult with the potential exception of the far forward region where the kaons are significantly Lorentz boosted. Alternately, measurements exploiting the leptonic decay channels $\phi \to \mu^+\mu^-$ore$^+$e$^-$ despite the small branching ratios. The feasibility can be conservatively estimated by scaling the $\phi \to \mathrm{K}^+\mathrm{K}^-$ rates down by Br ($\phi \to \mu^+\mu^-$)/Br($\phi \to \mathrm{K}^+\mathrm{K}^-$)$\approx 5.9 \times 10^{-4}$ neglecting the acceptance increase for leptons w.r.t. kaons.

The exploration of double vector mesons photoproduction by a single ion-ion pair by exchange of two independent photons becomes available. The expected ratio of $\rho\rho$ photoproduction to single ρ photoproduction is about $1:600$ while the predicted ratio of ρJ/ψ to ρ is about $1:160$ [815]. These

events should display significant quantum correlations.

In p–Pb collisions, the per-nucleon centre-of-mass system is boosted by 0.465 units of rapidity from the lab frame, and there are two possible directions for the beams, protons from the $+z$ direction, or from the $-z$ direction influencing strongly the available kinematics for the forward detectors. Furthermore, there are two possibilities for the photon emitter, 'lead-shine' (γp), the photon from the lead nucleus, or 'proton-shine' (γPb), the photon from the proton. These two vector meson production channels can be in principle separated by their different p_{T} scale corresponding to $\hbar/R_{\mathrm{proton}}$ for 'lead-shine' (γp) and $\hbar/R_{\mathrm{Pb}}$ for 'proton-shine' (γPb). The rates are calculated for these two possibilities in separate tables.

The total p–Pb luminosity of 2000 nb^{-1} assumed to be equally divided between the two possible proton beam directions. For the asymmetric (around $y = 0$) detectors, these two Runs are considered separately, listing them as 'forward' (in the proton-going hemisphere) and 'backward' (in the lead-going hemisphere).

Tables 14 and 15 show the cross sections and rates for the lead-shine and proton-shine cases respectively. Lead-shine is dominant, with proton-shine contributing less than 10% to the total rate. The extraction of the proton-shine component by fitting to the different p_{T} spectra for proton-shine and lead-shine will be challenging and the measurement precision depends strongly of the momentum resolution of the detector. Nuclear shadowing corrections are not applied, the reduction factors are similar for the proton-shine cross sections as for the lead-lead collisions. No attempt to calculate the rates for the ρ' on proton targets is undertaken due to the large rate uncertainties.

Table 14: Table of cross sections and numbers of events for the different mesons in p–Pb collisions for 'lead-shine' (a photon from the lead scattering from the proton). The rates are for the 2000 nb^{-1} integrated luminosity noted above, split evenly between the two possible proton directions. For the central regions, the net luminosity is 2000 nb^{-1} since both directions contribute, but for the forward (FW) and backward (BW) directions, the net luminosity is only 1000 nb^{-1} each. B, M and K denote 10^9, 10^6 and 10^3 respectively. Both the rates and cross sections include the relevant branching ratios.

$\Upsilon(1\mathrm{S}) \to \mu^+\mu^-$	5.74 nb	11 K	1.1 K	5.4 K	310	880	41	100

In case of coherent heavy vector meson production in UPC of lead nuclei, the expected experimental uncertainties are evaluated by the ALICE and CMS collaborations. The vector meson cross section in Pb–Pb UPC can be expressed as a sum of two terms reflecting the fact that either of the colliding ions can serve as a photon source:

$$\sigma(y) = n(+y)\sigma_{\gamma\mathrm{Pb}}(+y) + n(-y)\sigma_{\gamma\mathrm{Pb}}(-y) \tag{31}$$

The photoproduction cross sections $\sigma_{\gamma\mathrm{Pb}}(y)$ and $\sigma_{\gamma\mathrm{Pb}}(-y)$ are coupled and cannot be extracted unambiguously from the measured rapidity differential cross section. However, one can decouple them by measuring vector meson production in UPC with and without additional neutron activity in Zero Degree Calorimeters [816]. Measurement of $\sigma_{0\mathrm{N}0\mathrm{N}}(y)$ (no neutrons on both sides) and $\sigma_{0\mathrm{N}\mathrm{X}\mathrm{N}}(y)$ (at least one neutron on one of the sides) cross sections provides a system of two equations of two unknown

Table 15: Table of cross sections and rates for the different mesons in p–Pb collisions for 'proton-shine' (a photon from the proton scattering from the lead nucleus). The rates are for the 2000 nb^{-1} integrated luminosity noted above, split evenly between the two possible proton directions. For the central regions, the net luminosity is 2000 nb^{-1} since both directions contribute, but for the forward (FW) and backward (BW) directions, the net luminosity is only 1000 nb^{-1} each. B, M and K denote 10^9, 10^6 and 10^3 respectively. Both the rates and cross sections include the relevant branching ratios.

pPb - proton shine, γA								
Meson	σ	All Total	Ctl. 1 Total	Ctl. 2 Total	FW 1 Total	FW 2 Total	BW 1 Total	BW 2 Total
$\rho \to \pi^+\pi^-$	531μb	1.1 B	83 M	360 M	20 M	44 M	56 M	150 M
$\phi \to \mathrm{K}^+\mathrm{K}^-$	23 μb	46 M	1.3 M	8.0 M	120 K	1.7 M	210 K	3.9 M
$\mathrm{J}/\psi \to \mu^+\mu^-$	333 nb	670 K	55 K	290 K	14K	36 K	15 K	41 K
$\psi(2\mathrm{S}) \to \mu^+\mu^-$	8.9 nb	18 K	1.5 K	7.9 K	380	990	380	1.0 K
$\Upsilon(1\mathrm{S}) \to \mu^+\mu^-$	0.43 nb	860	93	460	14	34	14	30

photoproduction cross sections $\sigma_{\gamma\mathrm{Pb}}(\pm y)$:

$$\sigma_{0\mathrm{N}0\mathrm{N}}(y) = n_{0\mathrm{N}0\mathrm{N}}(+y)\sigma_{\gamma\mathrm{Pb}}(+y) + n_{0\mathrm{N}0\mathrm{N}}(-y)\sigma_{\gamma\mathrm{Pb}}(-y), \quad (32)$$

$$\sigma_{0\mathrm{N}\mathrm{X}\mathrm{N}}(y) = n_{0\mathrm{N}\mathrm{X}\mathrm{N}}(+y)\sigma_{\gamma\mathrm{Pb}}(+y) + n_{0\mathrm{N}\mathrm{X}\mathrm{N}}(-y)\sigma_{\gamma\mathrm{Pb}}(-y), \quad (33)$$

where $n_{0\mathrm{N}0\mathrm{N}}(\pm y)$ and $n_{0\mathrm{N}\mathrm{X}\mathrm{N}}(\pm y)$ are corresponding photon fluxes, calculable with high accuracy. Solutions of this system of equations can be used to extract photoproduction cross section $\sigma_{\gamma\mathrm{Pb}}$.

The expected experimental uncertainties are evaluated in terms of the nuclear suppression factor R_{Pb} which is defined as root square of the ratio of photoproduction cross section $\sigma_{\gamma\mathrm{Pb}}$ measured in Pb–Pb UPC and photoproduction cross section in the Impulse Approximation calculated as a reference photoproduction cross section off proton scaled by the integral over squared Pb form factor [817]:

$$R_{\mathrm{Pb}}(x) = \left(\frac{\sigma_{\gamma\mathrm{Pb}}(x)}{\sigma_{\mathrm{IA}}(x)}\right)^{1/2}, \qquad \text{where} \qquad x = \frac{m_V}{\sqrt{s_{\mathrm{NN}}}}\exp(-y). \quad (34)$$

Under the assumption that the coherent photoproduction cross section is proportional to the squared gluon density at the scale $Q = m_V/2$, where m_V is the mass of the produced vector meson, this nuclear suppression factor can be used to constrain nuclear shadowing at different scales Q. The theoretical discussion is given in the following Section 10.2.2.2.

The ALICE and CMS collaborations estimate that the uncertainties on luminosity (4%), reference cross section (5%) and photon flux (5%) result in $\sim$ 8% systematic uncertainty on the ratio $\sigma_{\gamma\mathrm{Pb}}(x)/\sigma_{\mathrm{IA}}(x)$ and $\sim$ 4% uncertainty on the nuclear suppression factor $R_{\mathrm{Pb}}(x)$. Detailed information about the uncertainty calculation can be found in existing publications [818–820]. The pseudodata projections for the nuclear suppression factor are shown in Fig. 79 at different scales corresponding to J/ψ, $\psi(2\mathrm{S})$ and $\Upsilon(1\mathrm{S})$ photoproduction measurements demonstrating that precision measurements with a range of different scales become available.

10.2.2.2 Coherent vector meson production off nuclei

Extensive data were produced in the previous LHC heavy ion Runs on coherent photoproduction of ρ mesons [811], J/ψ [818, 819, 821] and to a lesser extent $\psi(2\mathrm{S})$ [820]: $\gamma + A \to V + A$. Due to the presence of two photon sources, the x-range of these studies is largely limited to $x \geq m_V/\sqrt{s}$. For light mesons these measurements provide information on the pattern of interactions of extended

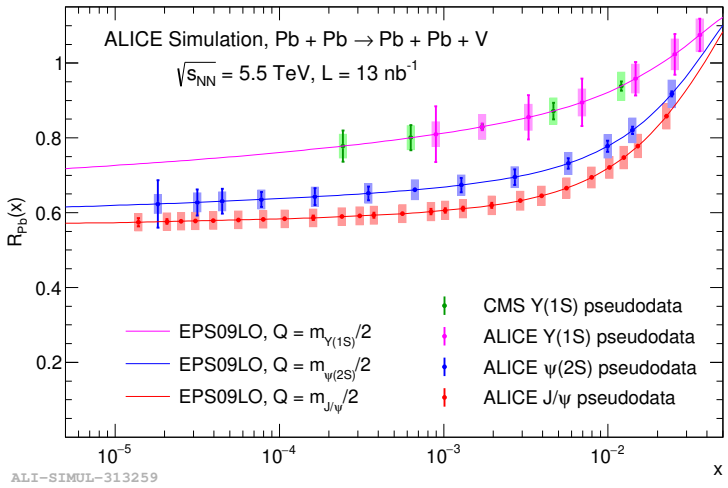

Fig. 79: Pseudodata projections for the nuclear suppression factor by ALICE [1] and CMS measured with the photoproduction of three heavy vector mesons in Pb–Pb ultra-peripheral collisions are shown. The pseudodata points are derived from EPS09-based photoproduction cross section projections following the method described in Ref. [817].

pion-size mesons and such phenomena as shadowing and color fluctuations. For small dipoles like J/ψ and $\Upsilon(1S)$, it provided information on the leading twist nuclear shadowing at moderate Q^2, which is difficult to obtain using other hard probes. The measured factor of $\sim$ 3 reduction of the J/ψ cross section compared to the γp case has significantly constrained the gluon distribution in leading twist approaches [817, 822–824]. In the dipole model framework, e.g., [825, 826], have had a tendency to predict less supression than seen in the data (in this case, the shape and normalisation of the rapidity distribution rather strongly depends on the form of the dipole cross section and charmonium wave function). The gluon nuclear shadowing in coherent J/ψ photoproduction in UPCs was also studied in the k_t-factorization approach [827] in terms of the unintegrated nuclear gluon distribution, which determines the initial condition for the non-linear evolution equation. In the case of ρ meson production, shadowing is a factor of $\sim$ 2 stronger [828] than in the approach based on the Glauber model and the vector meson dominance model.

The higher LHC luminosity and experimental upgrades will allow us to collect vastly improved samples of UPC events. In particular, the planned ALICE continuous readout [829], will eliminate many of the trigger-based constraints that have limited UPC data collection, allowing for high-efficiency collection of large samples of photoproduced light mesons. The increases in sample sizes should be considerably larger than one would expect from merely scaling the luminosity.

In order to conclude this section on the opportunities with vector meson production, we want to give a list of not yet exploited measurements that provide further insight into photonuclear interactions with heavy, light and multiple vector meson production:

– Extend substantially the x range for coherent J/ψ photoproduction on nuclei using information on the impact parameter distribution in peripheral and ultra-peripheral collisions provided by forward neutron production [816]. The impact parameter distribution can be accessed in the context of UPCs by exploiting the properties of additional photon or hadronic interactions in addition to the photon that produces the vector meson. The rates for the combined processed can be found in [830] and the relationship between impact parameter and additional photon interactions is discussed in [831]. The x-range can be also extended by using p–A collisions to probe the nucleus. In the latter case, one would have to separate coherent J/ψ production in γA and γp using a

much more narrow p_{T} distribution of J/ψ produced in coherent γA scattering and very good p_{T} resolution for the transverse momentum of the pair (LHCb).

- Measure with high enough statistics coherent $\Upsilon(1\mathrm{S})$ production in γp and γA scattering to check the expectation of the 20% reduction of the coherent cross section, which would allow one to probe gluon shadowing at a factor of ~ 10 higher Q^2 than in J/ψ production.
- Study coherent production of two pions with masses above 1 GeV/$c^2$to study an interplay of soft and hard dynamics as a function of $M_{\pi\pi}$ and $p_{\mathrm{T}}(\pi)$.
- Measure the production of heavier 2π [832], 4π and other resonances on ion targets, and search for the photoproduction of the observed exotic mesons. By using data from both proton targets (at HERA or the LHC) and ion targets, it is possible to separate the photon-meson coupling constant and the meson-nucleon interaction cross sections.
- Study the photoproduction of multiple vector mesons by a single ion pair [815]. Double photoproduction introduces many quantum correlations, including the possibility of observing stimulated decays of vector mesons. Since the two photons share the same linear polarisation, it will be possible to study photoproduction with polarised photons. In the discussed process, the charged particles from the vector meson decays are aligned (as $cos^2(\theta)$) with the plane of the linear polarization. If the two vector mesons are aligned along the same plane, then the planes formed by the decay particles will be correlated [831].

10.2.2.3 Nuclear imaging with coherent photoproduction

In coherent photoproduction, production amplitudes from each individual scattering site add with a phase factor $\exp i(\vec{x}\cdot\vec{k})$, where $\vec{x}$ is the location within the nucleus and $\vec{k}$ is the momentum transfer from the nucleus to the vector meson. So, one can Fourier transform the coherent photoproduction cross section, $\mathrm{d}\sigma_{\mathrm{coherent}}/\mathrm{d}t$ to find the location of the scattering sites within the nucleus. This can provide information on the spatial dependence of nuclear shadowing, allowing us to compare shadowing in the centre of nuclei vs. shadowing in the periphery through the transverse profile $F(b)$. Assuming azimuthal symmetry [833, 834]

$$F(b) \propto \frac{1}{2\pi}\int_0^\infty p_{\mathrm{T}} dp_{\mathrm{T}} J_0(bp_T)\sqrt{\frac{\mathrm{d}\sigma_{\mathrm{coherent}}}{\mathrm{d}t}}. \tag{35}$$

One complication is that it is necessary to flip the sign of $\sqrt{\mathrm{d}\sigma_{\mathrm{coherent}}/\mathrm{d}t}$ when crossing each diffractive minimum in the sample.

This calculation is data-hungry, and is subject to a number of theoretical uncertainties. It is also necessary to separate the cross section into its coherent and incoherent components. Nevertheless, the STAR Collaboration applied it to ρ^0 photoproduction in UPCs [835], finding a relatively boxy shape, inconsistent with a Woods-Saxon distribution, but seemingly consistent with expectations from nuclear shadowing. A follow-on study explored the Q^2 evolution of this transverse distribution by dividing the sample into three bins with different dipion mass [836]. That study also considered some of the uncertainties inherent in the analysis, including the finite experimental reach in p_{T} and the effects of the photon p_{T}, and the impact of the vector meson wave function.

Studies at the LHC could avoid many of these issues, by triggering on exclusive vector mesons (STAR required that the vector mesons be accompanied by neutrons from mutual Coulomb excitation). This would expand the p_{T} range where a meaningful $\mathrm{d}\sigma_{\mathrm{coherent}}/\mathrm{d}t$ can be extracted, increasing the accuracy of the transform. Also, because of the higher beam energies, the photon p_{T} is less important than it is at RHIC. More importantly, LHC Run 3 and 4 could also extend this study to a wider variety of mesons, including the ρ' (generically, 4π final states with a mass in the 1-2 GeV/c^2range) and the J/ψ. The latter is of particular interest because it is heavy enough to probe gluon shadowing, rather than just nuclear shadowing.

10.2.2.4 Incoherent vector meson production off nuclei

Incoherent diffractive processes provide information on nuclear dynamics, which is complementary to the information one can obtain from coherent scattering. In particular, incoherent J/ψ photoproduction probes quantum fluctuations of the target gluon density [837–842]. The corresponding cross section can be measured in a much larger range of $W_{\gamma N}$ than in the coherent case. This is possible since the activity in the nucleus fragmentation region, for example, neutrons in a ZDC can be used to determine which of two nuclei was a source of photons almost in each event.

One can distinguish two contributions to incoherent diffraction: quasielastic, when the nucleus involved in the strong interaction breaks down into nucleons and nuclear fragments, and inelastic, when hadrons are produced in the nucleus fragmentation region. At small t the second mechanism gives a $\sim 20\%$ contribution to the incoherent cross section [837, 843]. However, since the t-dependence of the inelastic mechanism is weaker, it dominates the nuclear incoherent cross section for $|t| \geq 0.5$ GeV/c^2.

While it is generally understood and accepted that J/ψ photoproduction with target dissociation is sensitive to fluctuations of the gluon density of the target, practical realisations of this notion require modeling. Notably, proton size fluctuations at $t = 0$ [837] should be contrasted with proton shape fluctuations [838–840], which in turn can be refined by including fluctuations of number of subnucleonic degrees of freedoms representing regions of high-gluon density, so-called hot spots [841,842]. The latter two approaches are assumed to be valid in an entire range of $|t|$. Hence, studies of incoherent diffraction in γp scattering via p–A UPCs and γA scattering via A–A UPCs would allow one to map variations of the gluon fluctuations with energy (x) including a possible approach to the black disk regime, where the fluctuations are strongly suppressed [841].

For very large $|t| \geq 1 - 2$ GeV/c^2one enters the regime of pQCD, which corresponds to elastic scattering of small-size dipoles off individual small-x partons of the nuclear target [844, 845].

Note also that for the proton target, one can use the process $\gamma + p \to VM(\mathrm{J}/\psi) + gap + Y$ at $-t \geq$ few GeV/c^2 to study the perturbative Pomeron. In the kinematics, where Δy is fixed, $\mathrm{d}\sigma/\mathrm{d}y_{VM} \propto (y_{VM} - \Delta y)^{2\alpha_{Pomeron}-2}$. In BFKL one expects $2\alpha_{Pomeron} - 2 \sim 0.4$ and, hence, a strong rapidity dependence of the corresponding cross section. A larger acceptance of the ATLAS and CMS detectors should allow for a more effective study of these processes than at HERA.

By studying the t-dependence and activity in the nucleus fragmentation region it would be possible to separate the two mechanisms of incoherent nuclear scattering as a function of t. For small $|t| \leq 0.3 - 0.5$ GeV^2, one can calculate nuclear shadowing for both mechanisms within the leading twist shadowing framework [816]. The shadowing turns out to be large and sensitive to the details of the leading twist shadowing dynamics. At large $|t|$, one can study the A dependence of the discussed reaction for different rapidity gap intervals to track propagation of a small dipole through the nuclear medium. By changing Δy it would be possible to vary strongly the relative role of the initial and final state interaction.

10.2.3 Inclusive and diffractive dijet production in UPC

Ultra-peripheral heavy-ion collisions provide an opportunity to study nuclear modifications of the PDFs in clean photon-nucleus interactions. One possible observable is dijet production as suggested in Ref. [846]. Compared to the dijet production in p–Pb collisions the photo-nuclear events have less underlying event activity since multiparton interactions are significantly suppressed. This enables jet reconstruction at lower transverse momenta allowing to study nPDFs at smaller scales Q^2 and x where the current PDF uncertainties are more pronounced. As the virtuality of the photons emitted by the nucleus is negligible, there are two components that need to be taken into account: the photons may interact as unresolved particles or the quasi-real photons may fluctuate into a hadronic state described with photon PDFs. The relative contribution of the direct and resolved components depends on the kinematics of the final state

jets. Hence, the uncertainty related to weakly-constrained photon PDFs can be reduced by focusing on the region where direct processes dominate the dijet production.

Here, the photoproduction framework is applied which has been recently implemented into the PYTHIA 8 Monte-Carlo event generator [516] and validated against HERA data [847], to study the potential of the Run 3 and Run 4 program to constrain nPDFs using photo-nuclear dijets. The relevant part of the photon flux is obtained by integrating the impact-parameter dependent flux from $b_{\mathrm{min}} = 2R_{\mathrm{Pb}} \approx 13.27$ fm. Two different jet kinematics are considered, one corresponding to the preliminary ATLAS measurement [848] with $p_{\mathrm{T}}^{\mathrm{lead}} > 20$ GeV/c and $m_{\mathrm{jets}} > 35$ GeV/$c^2$and one similar to HERA dijet photoproduction data [849, 850] with $p_{\mathrm{T}}^{\mathrm{lead}} > 8$ GeV/c and $m_{\mathrm{jets}} > 14$ GeV/c^2. In both cases the jets were reconstructed from the generated events using the anti-k_{T} algorithm with $R = 0.4$ implemented in the FASTJET package [409]. The differential cross sections are shown as a function of x_A in Fig. 80 using NNPDF2.3LO proton PDFs [851] with and without EPPS16 nuclear modifications [786]. The kinematic variables used in the ATLAS study [848] are defined as

$$\begin{aligned} x_A &= \frac{m_{\mathrm{jets}}}{\sqrt{s_{\mathrm{NN}}}} e^{-y_{\mathrm{jets}}}, \qquad z_\gamma = \frac{m_{\mathrm{jets}}}{\sqrt{s_{\mathrm{NN}}}} e^{y_{\mathrm{jets}}}, \\ m_{\mathrm{jets}} &= \left[\left(\sum_i E_i \right)^2 - \left| \sum_i \vec{p}_i \right|^2 \right]^{1/2}, \qquad y_{\mathrm{jets}} = \frac{1}{2} \ln \left(\frac{\sum_i E_i + p_{i,z}}{\sum_i E_i - p_{i,z}} \right). \end{aligned} \tag{36}$$

where the index i runs over all accepted jets; E_i and $\vec{p}_i$ denote the jet energy and momentum, respectively. Note that in a leading-order (LO) parton-level calculation, the definitions of x_A and z_γ would exactly match the momentum fractions probed in the PDFs of the nucleus and the photon. The parton-shower emissions and MPIs, and NLO corrections considered below, smear this connection but x_A and z_γ do serve as rather precise hadron-level estimators for the momentum fractions [852].

The uncertainty bands are derived from the EPPS16 error sets and reflect the uncertainties in the current nPDF analyses which are compared to the expected statistical uncertainties of the data in the ratio. Also the contributions from direct and resolved processes are separately plotted. Furthermore, results with the default CJKL photon PDFs [853] are compared to GRV [854] and SASGAM [855] analyses to study the underlying photon PDF uncertainty.

As shown in Figure 80(left), the contribution from resolved processes becomes dominant around $x_A > 0.02$ for $p_{\mathrm{T}}^{\mathrm{lead}} > 20$ GeV/c. This leads to a more pronounced dependence on the photon PDFs in this region, partly hindering the use of the data from this region in a global nPDF analysis. However, at small-x region, where the nPDF uncertainties are currently large and the dijets in p–Pb do not provide additional constraints, the direct processes dominate the dijet production and the dependence on the photon PDFs is negligible. The dijet cross sections fall off rapidly at small-x_A region which increases the expected statistical uncertainty limiting the small-x_A reach of the observable. With an integrated luminosity of $L_{\mathrm{int}} = 2$ nb^{-1} in Pb–Pb collisions and jet kinematics of the ATLAS preliminary study the expected statistical uncertainties become significant at $x_A \lesssim 2 \cdot 10^{-3}$. The increased luminosity of the LHC Run 3 and 4 increases the potential small-x_A reach only slightly but in the region where nPDF constraints are currently sparse. An effective way to extend the small-x_A reach is to consider jets with lower p_{T} as demonstrated in Figure 80(right). With a cut of $p_{\mathrm{T}}^{\mathrm{lead}} > 8$ GeV/c and an integrated luminosity $L_{\mathrm{int}} = \mathrm{nb}^{-1}13$ in Runs 3 and 4 it is possible to obtain nPDF constraints down to $x_A \approx 10^{-4}$. Also, the small-x nPDF uncertainties are more pronounced with a lower $p_{\mathrm{T}}^{\mathrm{lead}}$-cut since the nuclei are probed at smaller scales. The theoretical uncertainty related to the limited precision of the photon PDFs could be reduced by performing a similar measurement in p–Pb collisions where the photon flux would be dominantly provided by the Pb ion and the jets produced by γ-p system without any nuclear modifications. This measurement would constrain also the uncertainty related to the impact-parameter rejection that removes the events with hadronic interactions. However, as the minimum allowed impact

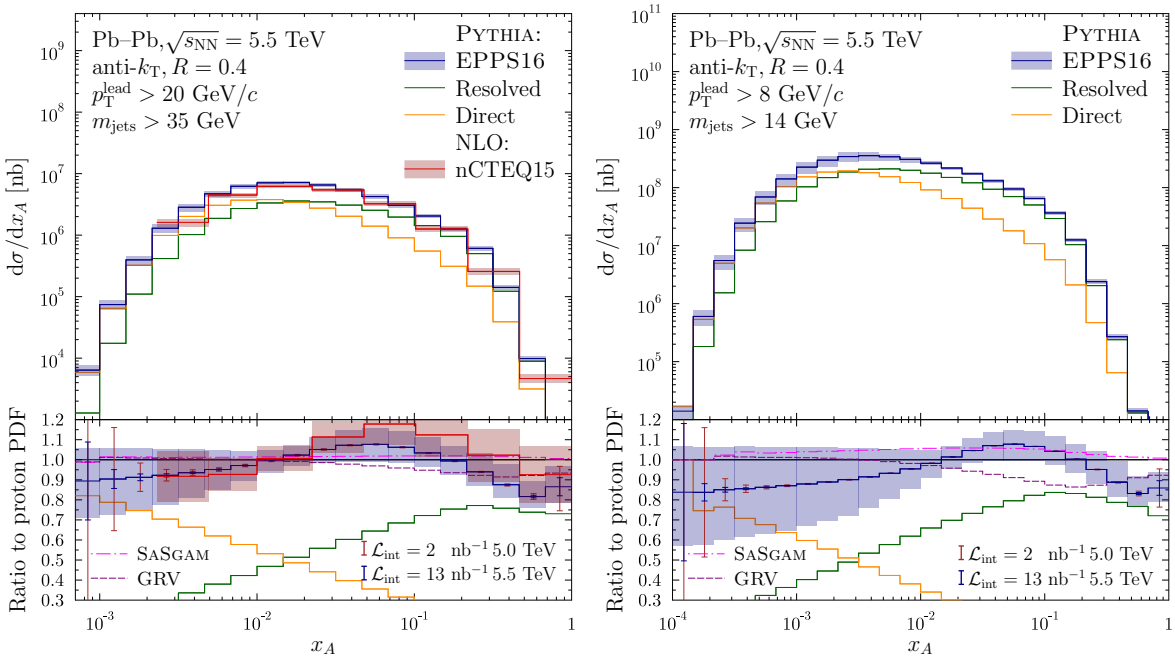

Fig. 80: Photo-nuclear dijet cross sections in ultra-peripheral Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.5$ TeV with leading jet $p_{\rm T}$ cut of 20 GeV/c (left) and 8 GeV/c (right). Results based on PYTHIA simulations are calculated with EPPS16 nuclear modification (blue) and the contributions from resolved (green) and direct (orange) photons are separately shown. Ratio plots show also results with different photon PDF sets and the expected statistical uncertainties corresponding to the LHC (brown) and the Run 3 and and Run 4 (dark blue) luminosities. Corresponding results based on NLO calculations for Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.02$ TeV with nCTEQ15 nPDFs [856] (red) are shown in case leading jet $p_{\rm T}$ cut of 20 GeV/c.

parameter is smaller in case of p–Pb compared to Pb–Pb and the spectrum of photons is correlated with the impact parameter cut, the kinematics would not be fully comparable preventing a full calibration of the photon flux. As the nPDFs mainly vary the shape of the x_A distributions, part of the theoretical and experimental uncertainties could also be reduced by considering x_A distributions normalized with the integrated cross section.

Inclusive dijet photoproduction in UPCs can also be evaluated to the next-to-leading order (NLO) accuracy of perturbative QCD. The corresponding cross section can be written in the following form [857]:

$$\mathrm{d}\sigma(AA \to A + 2\mathrm{jets} + X) = \tag{37}$$

$$\sum_{a,b} \int \mathrm{d}y \int \mathrm{d}x_\gamma \int \mathrm{d}x_b f_{\gamma/A}(y) f_{a/\gamma}(x_\gamma, \mu^2) f_{b/A}(x_A, \mu^2) \mathrm{d}\hat{\sigma}(ab \to \mathrm{jets}) \,, \tag{38}$$

where a, b are parton flavours; $f_{\gamma/A}(y)$ is the flux of equivalent photons emitted by one ion, which depends on the photon light-cone momentum fraction y; $f_{a/\gamma}(x_\gamma, \mu^2)$ is the PDF of the photon, which depends on the momentum fraction x_γ and the factorisation scale μ; $f_{b/A}(x_A, \mu^2)$ is the nPDF with x_A being the corresponding parton momentum fraction; $\mathrm{d}\hat{\sigma}(ab \to \mathrm{jets})$ is the elementary cross section for production of two- and three-parton final states emerging as jets in the interaction of partons a and b. The sum over a involves quarks and gluons for the resolved photon contribution and the photon for the direct photon contribution dominating at $x_\gamma \approx 1$.

Figure 80 (left) presents predictions of Eq. (38) for the cross section of dijet photoproduction in Pb–Pb UPCs at $\sqrt{s_{\rm NN}} = 5.02$ TeV in the ATLAS kinematics as a function of x_A. The red solid lines and the associated shaded band correspond to the central fit of nCTEQ15 nPDFs and their uncertainty,

respectively. The top panel of this figure demonstrates that NLO pQCD correctly reproduces the shape and, at least semi-quantitatively, the normalisation of the preliminary ATLAS data. The lower panel of Fig. 80 shows the ratio of the curves from the upper panel to the result of the calculation, where nCTEQ15 nPDFs are substituted by free proton and neutron PDFs. One can see from this panel that the central value of the ratio of the two cross sections reveals the expected trend of nuclear modifications of nPDFs: $\sim 10\%$ shadowing for small $x_A < 0.01$, which is followed by $\sim 20\%$ antishadowing (enhancement) around $x = 0.1$ and then $\sim 10\%$ suppression for $x_A > 0.3$. Note that since the uncertainties of nCTEQ15 nPDFs are of the same magnitude as the effect of nuclear modifications, inclusion of this dijet data if global QCD fits of nPDFs should in principle reduce the existing uncertainty.

It is also important to study diffractive dijet photoproduction in UPCs in the reaction $A + A \to A{+}jet1{+}jet2{+}X{+}A$. NLO pQCD predictions for the cross section of this process in pp, p–A, and A–A UPCs in the LHC kinematics were made in [858]. It was shown that studies of this process on nuclei may shed some light on the mechanism of QCD factorisation breaking in diffractive photoproduction and, for the first time, give access to nuclear diffractive PDFs and test their models.

10.2.4 Photoproduction of heavy quarks

Photoproduction of open charm and bottom is a direct probe of the gluon content of the target nucleus [859, 860]. The lowest order process, $\gamma + gluon \to c\bar{c}$ (or $b\bar{b}$) dominates over higher order, resolved processes, in which the photon radiates before it interacts with the target gluon [859]. This process type is a subset of flavour untagged dijets, discussed above. However, open charm and bottom offer some advantages, including very high rates. Based on the leading order calculations in Ref. [859] with the EKS nPDF [861], a total number of 22 billion (10 million) $c\bar{c}$ ($b\bar{b}$) pairs are produced in γPb interactions in a 13 nb^{-1} PbPb data set at $\sqrt{s_{NN}}$=5.5 TeV. In pPb collisions at $\sqrt{s_{NN}}$ =8.8 TeV with a luminosity of 2 pb^{-1}, 18 billion (100 million) $c\bar{c}$ ($b\bar{b}$) pairs are produced. The measurement of both of these processes should be well feasible despite the small experimental acceptances and branching ratios.

Vertex detectors can detect separated vertices from charm production if the charm is moderately relativistic [862], so it should be possible to study pairs with an invariant mass of $M_{c\bar{c}} \approx 4m_c \approx 6$ GeV/c^2. This will enable to study gluon distributions down to Bjorken$-x$ values of around: $x \approx M_{Q\overline{Q}}/(4\gamma m_p)\exp(y)$, where the relativistic boost of the nucleus γ, the rapidity y of the $Q\overline{Q}$ and the proton mass m_p appear. The corresponding scale is $Q^2 \approx M_{Q\overline{Q}}$. Assuming scales down to $M_{c\bar{c}} \approx 6$ GeV/c^2, a Bjorken$-x$ lower by a factor 6 can be reached compared to the kinematic selection in the preliminary inclusive dijet ATLAS analysis [848] for which the Bjorken-x reach is depicted in Fig. 80(left). By comparing results from proton targets (in p–A collisions) and heavy-ion targets (in A–A collisions), it is possible to make a direct measurement of nuclear shadowing.

The clear experimental signature for this process consists of a pair of separated vertices each corresponding to a D-meson decay in an event with one large rapidity gap. The ion moving in the same direction as the rapidity gap should remain intact. The full reconstruction of both D-mesons, the cleanest channel, the in specific decay channels requires large large event statistics and might be complemented by an analysis with one D-meson decaying semileptonically. However, the charm production rates are high enough that the low efficiency should be affordable for a precise measurement.

In addition to charm and bottom, it may also be possible to study the photoproduction of top [863, 864]. The rates are small for lead-lead collisions at the LHC (7 pairs in 13 nb^{-1}), but for pPb collisions at $\sqrt{s_{NN}}$ =8.8 TeV, the calculation of Ref. [863] finds that an integrated luminosity of 2 pb^{-1} corresponds to a production of 110 pairs. These pairs are mostly at fairly central rapidities and the large top semileptonic branching ratio should provide a clear experimental tag. This process could provide a separate probe of gluon distributions at larger x, and very high Q^2. It would also allow a direct measurement of the electric charge of the top quark.

10.3 The physics of inelastic p-Pb collisions

10.3.1 Experimental overview

Proton-lead collisions are an integral part of the LHC program since the 2012 pilot run. Within collinear factorisation, constraints on our knowledge of the nuclear wave functions could be extended at high Q^2 by dijets and heavy gauge boson available for the first time in nuclear collisions [786]. Insights have been gained at lower Q^2 with heavy-flavour production based on the assumption that their nuclear production modification is dominated by nPDFs [329]. In Run 3 and 4, the increased luminosities and detector upgrades will allow to improve the statistical precision, to extent the kinematic reach and the available processes. The detector capabilities and observables are outlined in view of high-energy QCD studies in p–Pb collisions and experimental measurement projections on selected observables are shown. One upgrade dedicated to low-x physics is separately discussed. In all cases, the statistical and point-by-point uncorrelated systematic uncertainties are not taking into account to place the central point. After this introduction, two theory contributions zoom in on specific aspects of Run 3-4 data.

- **ALICE** will measure heavy flavour and charged particle production at mid-rapidity in p–Pb collisions during Run 3 and Run 4. These measurements will constrain the parton densities in the nucleus at moderate x. At forward and backward rapidity, measurements of W and Z-boson production, as well as a range of quarkonia (J/ψ, $\psi(2S)$, and the Υ(nS) family) will be performed. In particular the W and Z boson measurements will constrain the nuclear PDFs, while the quarkonia are also sensitive to final state effects. An example is given for the Z boson in Fig. 83 on the right.
- **ATLAS** will measure heavy electro-weak bosons, W and Z, with the larger p–Pb dataset which will be available in Run 3-4. The much larger luminosity will allow precision in these measurements significantly surpassing the one currently available. Projected W and Z boson cross sections published in Ref. [7] are shown in Figure 81. Previous results have suggested that the modification of EW boson cross sections that is described with nPDFs, appears to be stronger in more central collisions [865, 866]. Figure 82 (left) shows the projected boson yield ratio of central to peripheral collisions, $R_{\rm CP}$, for different centrality bins from Ref. [7]. Figure 82(right) shows the yield of Z bosons scaled by the nuclear overlap function, $\rm T_{AB}$, as a function of centrality. It indicates that the Z boson yield uncertainties will be considerably smaller than the $\rm T_{AB}$ uncertainty.
- **CMS** will exploit the larger p–Pb dataset available during Run 3–4 and it will hence further improve the precision on differential measurements of W and Z bosons (constraining quark and antiquark nPDFs) [867, 868], as well as dijet and top quark pair ($t\bar{t}$) production (gluon nPDFs) [869, 870]. While first Run 2 results on W boson production already feature experimental uncertainties smaller than the nPDF ones [871], the larger luminosity by a factor 5 to 10 expected in Runs 3–4 will allow for another large jump in the constraints on nPDFs from data. The CMS dijet capabilities with Run 3–4 data [12] are shown in Fig. 84. In addition, novel studies will become possible, such as the measurement of differential cross sections for $t\bar{t}$ production, for an improved constraining power on nPDFs, as well as the mass dependence of Drell-Yan production down to the Υ meson mass region. The projection for $t\bar{t}$ production [12] is shown together with the precise W boson asymmetry measurement in Run 3–4 [8] in Fig. 85. Heavy flavour meson cross sections will also be measured, which are sensitive to low-x gluon nPDFs: D mesons ($p_{\rm T} > 0.5$ GeV/c), B mesons ($p_{\rm T} > 5$ GeV/c), prompt and non-prompt J/ψ ($p_{\rm T} > 3$ GeV/c), and Υ(nS) down to $p_{\rm T} = 0$. These measurements will benefit from the improved detector and trigger performance in Run 4 [806].
- **LHCb** will operate during Run 3 and Run 4 with the average charged particle multiplicity in p–Pb and Pb–p collisions that are smaller than the nominal conditions in pp running with an average pile-up of 5 interactions. All p–Pb collisions will be processed in the software trigger. Hence, LHCb can fully profit from the luminosity increase including $p_{\rm T} = 0$ heavy-flavour production.

A natural focus is the study of open and hidden beauty and charm production with improved precision. A novel measurement in the p–Pb collision system is discussed in detail in view of saturation physics in section 10.3.3 and is shown in Fig. 87. A new focus of LHCb, profitting from the increased ion in one of the considered rapidity range is shown in Fig. 83 down to 5 GeV/c^2. Direct photon studies in the conversion channel will strongly profit from the increased luminosity. The projections of the LHCb collaboration for p–Pb collisions are discussed in detail in Ref. [13].

10.3.2 Forward calorimeter upgrade of ALICE

The ALICE collaboration is considering to add a high-granularity forward calorimeter (FOCAL) to the experiment to measure direct photon production in the rapidity range 3.0–5.0 and at low p_{T}, to probe the gluon density in protons and nuclei at $x \sim 10^{-5}$ where gluon saturation and non-linear effects in the gluon density may become apparent. The FOCAL design is based on the Si-W calorimeter technology, with two or three high-granularity layers with silicon pixel sensors that allow to separate electromagnetic showers with only a few mm distance between them. This unique high granularity makes it possible to reconstruct neutral pions in the forward direction and to reject the decay photon background for the direct photon measurement.

Figure 86 shows the expected performance of the FOCAL detector for the direct photon measurement in p–Pb collisions. The left panel shows the projected uncertainties, which are 7-8% at high p_T and increase at lower momentum due to the combinatorial background. The right panel shows the impact of the measurement on our knowledge of the nuclear modification of the gluon distribution; the red lines show the current uncertainty, based on the EPS09 nPDFs, but using a broader set of parametrisations for the nuclear PDFs at the initial scale Q_0, similar to [873]. The grey band shows the uncertainty after including the FOCAL pseudo-data. The improvement in the uncertainty is about a factor 2, but it should be noted that the direct photon measurements probes the gluon distribution at low x directly, while the most of the existing data only probe $x \gtrsim 10^{-3}$ (see Fig. 78). At present, the only measurements that probe the very low x region for nuclear PDFs are forward heavy flavour measurements from LHCb [754, 874] and ALICE [875]; theoretical developments are under way to use these data to constrain the PDFs [329, 876]. The FOCAL program will probe small x in different production channels (quark-gluon Compton scattering vs gluon fusion) and therefore also further test universality and factorisation in this regime [877]. Future measurements of Drell-Yan production in LHCb, as shown in Fig. 91, will also probe this region, but will have a weaker impact for gluons at small Q^2 according to current experimental uncertainty estimates.

In addition to the inclusive direct photon measurement, the FOCAL program will measure forward π^0 production in pp, p–Pb and Pb–Pb collisions, which also provides important constraints for the nuclear PDFs and parton energy loss in Pb–Pb collisions at large rapidity. Correlation measurements of neutral pions and photons will be used to further probe the gluon density and to search for evidence of multiple-gluon interactions which are expected to be important in the high gluon density of the Color Glass Condensate [878, 879].

10.3.3 Transverse momentum dependent and low-x phenomena sensitive observables in $c\bar{c}$ and $b\bar{b}$ production

In recent years, many efforts have been devoted to elucidate the properties of transverse-momentum-dependent gluon distributions in the high-energy or small-x limit, and in particular to determine how non-linear saturation effects impact the various distributions. A process which is particularly interesting in this regard is the forward production of a heavy quark-antiquark pair, in high-energy proton-proton or proton-nucleus collisions. For kinematical reasons, in the proton-nucleus case, the proton side of the collision involves large-x partons, while on the nucleus side, small-x gluons participate. Hence,

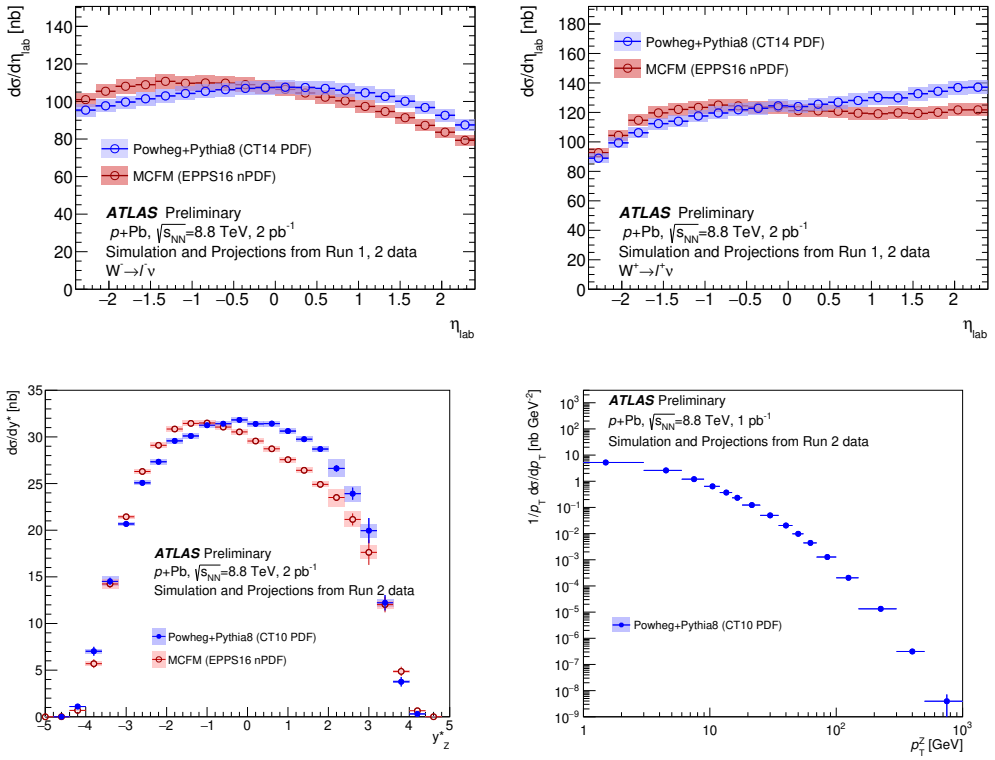

Fig. 81: Top row: Fiducial cross sections for W^+ (left) and W^- (right) boson production in p–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 8.8$ TeV differential in the charged lepton pseudorapidity measured in the laboratory frame η_{lab} [7]. The cross sections are projected with nuclear effects described by the EPPS16 nPDF set and without any nuclear effects. The boxes represent the projected total uncertainties (quadratic sum of statistical and systematic uncertainties), while vertical bars represent statistical uncertainties (smaller than the marker size). Botton row: Z boson rapidity (left) and transverse momentum (right) differential cross sections [7].

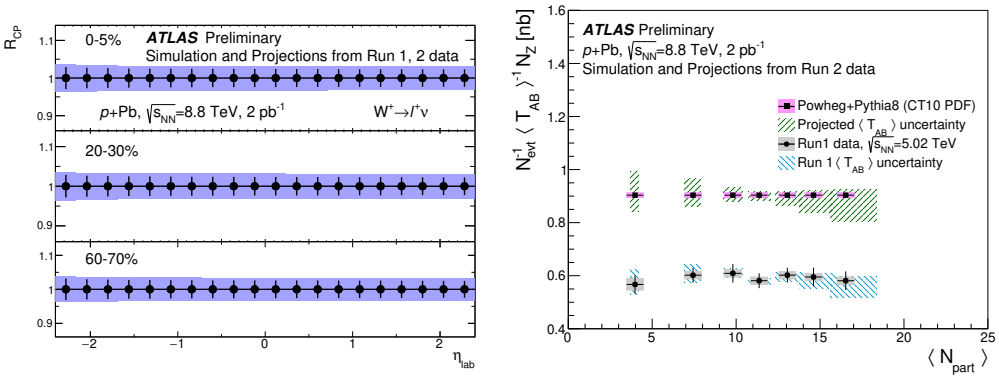

Fig. 82: Left: Uncertainties on measurments of the W^+ (left) and W^- (right) boson yield ratio of central to peripheral collisions R_{CP}. The boxes represent the projected total uncertainties (quadratic sum of statistical and systematic uncertainties), while vertical bars represent statistical uncertainties [7]. Right: Projected Z boson yields scaled by $\mathrm{T_{AB}}$ as a function of the number of nucleon participants [7]. Statistical uncertainties are everywhere smaller than the marker size, and projected systematic uncertainties (green) are described in the text. The projections are compared with a previous run 1 analysis [865].

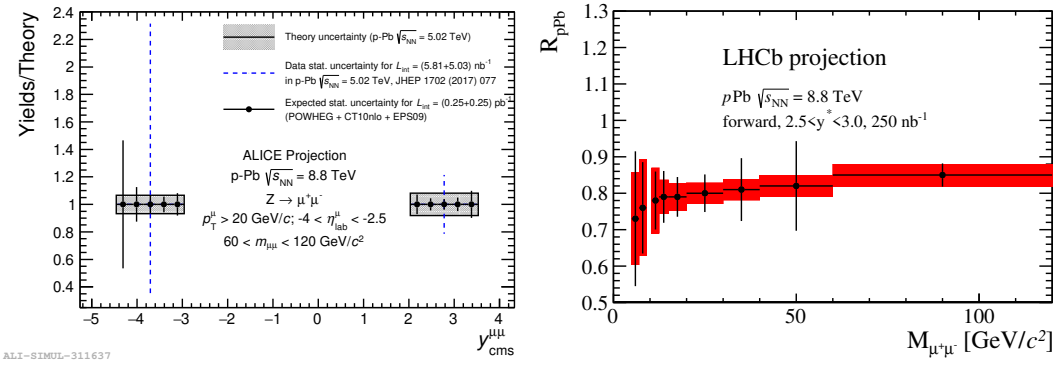

Fig. 83: Left: Expected statistical significance of the Z boson rapidity distribution for p–Pb collisions at $\sqrt{s_{\rm NN}} = 8.8$ TeV in Run 3-4 assuming an integrated luminosity of 0.25/pb (0.25/pb) obtained with the proton (Pb ion) going toward the ALICE muon spectrometer [1]. The results are compared with the statistical significance of the published data collected in p–Pb collisions in 2013. Right: $R_{\rm pPb}$ of inclusive Drell-Yan production in $2.5 < y_{cms} < 3.0$, one of five rapidity bins accessible with LHCb. The projection is detailed in Ref. [13].

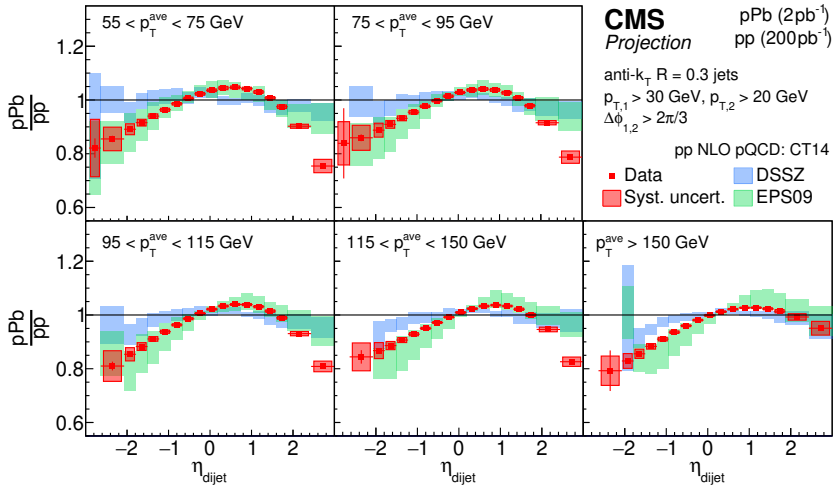

Fig. 84: Projected dijet η measurements in p–Pb collisions with combined Run 3 and Run 4 data [12].

this process can be described in a hybrid approach in which the proton content is described by regular, integrated PDFs, while the small-x dynamics in the nuclear wave function is dealt with using the Color Glass Condensate (CGC) effective theory, from which the gluon transverse momentum dependent distributions (TMDs) naturally emerge [880, 881].

In terms of sensitivity to the QCD saturation regime, the same manifestations are expected than with light quarks [882], although smaller values of x can be reached in the latter case. From the point of view of the TMD content however, heavy quarks are interesting because their production involves linearly-polarized gluons TMDs [883], in addition to the usual unpolarized gluon TMDs, and because, due to non-linear effects, the linearly-polarized TMDs generally differ from their unpolarized partners [884]. The LHCb detector is well-suited to measure heavy hadrons in the forward rapidity region, and given large-enough statistics, one could potentially try and extract information about the linearly-polarized gluons in protons and lead nuclei, from data obtained with LHC unpolarized beams. Before giving cross section estimates, let us briefly give a bit more details about the process and the physics involved.

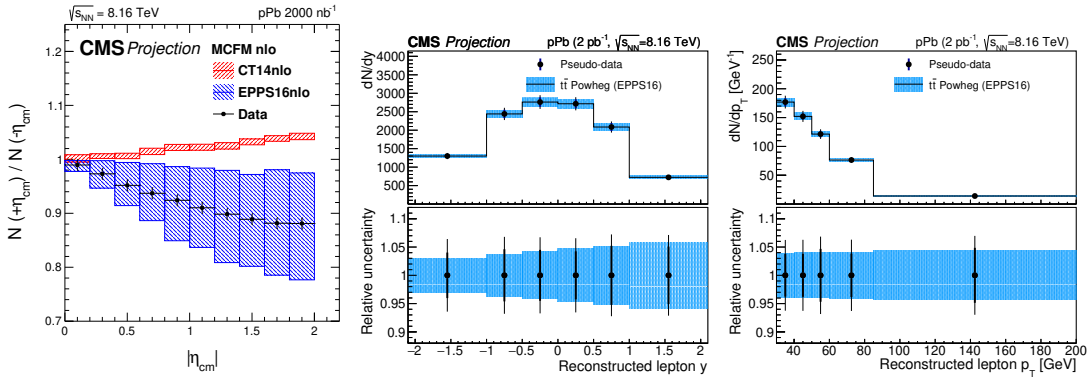

Fig. 85: Left: W boson asymmetry measurement with Run 3 and Run 4 with CMS [8]. Middle and right: CMS projected differential $t\bar{t}$ production cross section as a function of the reconstructed lepton p_{T} (middle) and rapidity (right) [12]. The total and statistical uncertainties are represented by the outer and inner error bars, respectively. The bottom panels represent the relative uncertainties (68 confidence-level error bands) in the projected data and theory predictions employing the CT14NLO [872] free proton and EPPS16NLO [786] bound nucleon PDF sets.

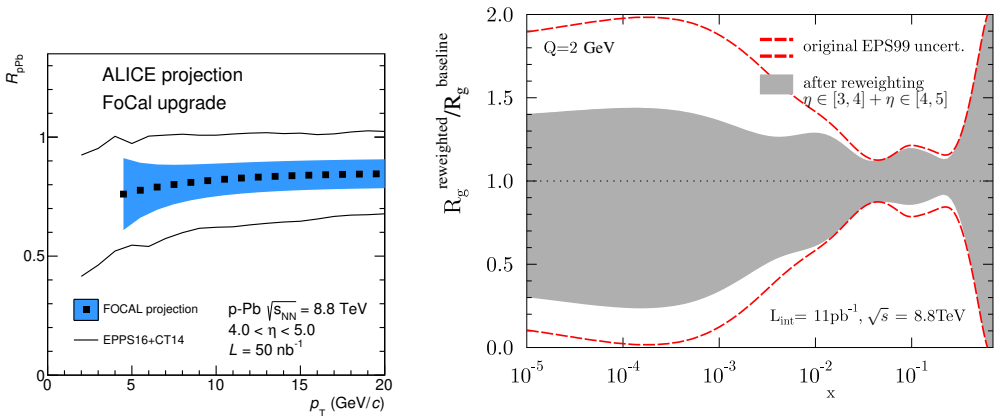

Fig. 86: Left: Projected uncertainties on the nuclear modification factor for the forward direct photon measurement in p–Pb collisions with the ALICE FOCAL upgrade. Right: Uncertainty on the modification ratio of the gluon density in the Pb nucleus from a fit to FOCAL pseudo-data. The red lines show the current uncertainty and the grey band shows the uncertainty after including the FOCAL pseudo-data. Figures from Ref. [1].

Forward quark-antiquark pair production in dilute-dense collisions is characterized by three momentum scales: P_t, the typical transverse momentum of a single quark, and always one of the largest scales; k_t, the total transverse momentum of the pair, which is a measure of the transverse momentum of the small-x gluons coming from the target; and Q_s, the saturation scale of the target, which is always one of the softest scales. The value of k_t with respect to Q_s and P_t governs which factorisation scheme is relevant. Indeed, when $k_t \sim Q_s \ll P_t$ (the quark and the antiquark are almost back-to-back), there are effectively two strongly ordered scales k_t and P_t in the problem and TMD factorisation applies [880], implying the involvement of several gluon TMDs that differ significantly from each other, especially in the saturation regime, when $k_t \leq Q_s$ [881]. In the other regime which shall not be discussed here (away from back-to-back production), k_t and P_t are of the same order and far above the saturation scale, only the linear small-x dynamics is important and the various TMDs differ no more.

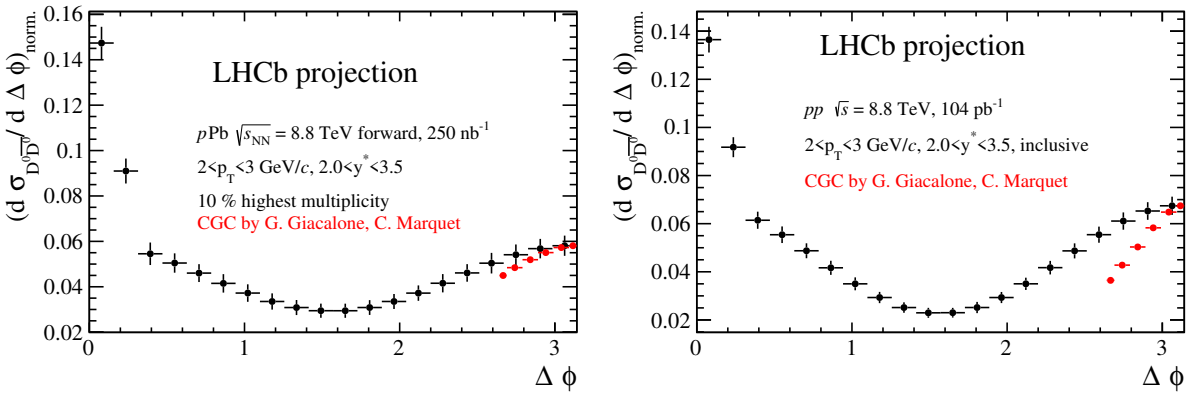

Fig. 87: LHCb projections [13] for $D^0\overline{D^0}$ in LHC Run 3 and Run 4 compared with theoretical calculations decribed in section 10.3.3 in 10 % largest multiplicity p–Pb collisions (left panel) and minimum bias, i.e., inclusive, pp collisions (right panel). The D-mesons are both reconstructed in the πK-decay channel.

In [880, 885], the cross section for forward di-jet production in proton-nucleus collisions was calculated within the CGC. It was then shown that, in the back-to-back limit, a TMD factorisation formula could be extracted, the result being the same as in a direct TMD approach (i.e., without resorting to the CGC). However, in contrast to the direct TMD approach, the calculation in the CGC yields explicit expressions for the TMDs in terms of Wilson lines, which can be evolved in rapidity through the non-linear Jalilian-Marian-Iancu-McLerran-Weigert-Leonidov-Kovner (JIMWLK) equation. In [884], those results were extended to the case of a forward heavy quark-antiquark pair. As already observed earlier (see for instance [883, 886–890]), by keeping a non-zero quark mass, the cross section becomes sensitive to additional TMDs, which describe the linearly-polarized gluon content of the unpolarized target.

The three unpolarized gluon TMDs which describe the quark-antiquark pair production are the adjoint-dipole TMD, the Weizsäcker-Williams TMD, and a third one which is roughly a convolution of two fundamental-dipole TMDs. They are accompanied by three 'polarized' partners, which couple through the quark mass and via azimuthal-angle modulation. This is analogous to what happens in the $\gamma^* A \to q\bar{q}$ process (in that case not only a non-zero quark mass but also a non-zero photon virtuality brings sensitivity to linearly-polarized gluons) described in Section 10.2.4,10.2.3, although there, only one unpolarized gluon TMD is involved (the Weizsäcker-Williams distribution), along with its polarized partner [889, 890].

Predictions for D mesons are presented in Figure 87 as a function of their relative azimuthal angle near π, along with projections from the LHCb experiment. In the p–Pb kinematical range that is investigated here, roughly 2.800 raw counts are expected over the full azimuthal range for the specified decay channel that can be complemented with other channels as in pp collisions in Ref. [891].

10.3.4 Fully coherent energy loss effects on different final states

The multiple scattering of quarks and gluons traveling in a QCD medium induces the radiation of gluons which carry away some energy of the propagating parton, leading for instance to the jet quenching phenomenon. Therefore, a key ingredient of any parton energy loss calculation is the medium-induced gluon spectrum radiated by the fast propagating color charge. It is of course of crucial importance to know the correct parametric dependence of the induced spectrum, which in general depends on the parton properties (in particular its energy and mass) and those of the medium, since it has a direct impact on the phenomenology of particle production in p–A and A–A collisions. The emission of a gluon

radiated by an energetic parton experiencing multiple scattering in a medium takes a typical formation time, t_f, which needs to be compared to the length of the medium, L.

Over the last few years, it has been realized that in a hard process involving incoming and outgoing energetic color charges (which do not have to be identical) being quasi-collinear in the rest frame of the medium, the associated medium-induced gluon spectrum is dominated by *large* gluon formation times, $t_f \gg L$ [489, 892, 893]. In this so-called fully coherent (FC) region, the medium-induced radiated energy is similar to the energy loss of an asymptotic charge. In particular it scales as the energy, and thus exceeds at high energy the average parton energy loss in the Landau–Pomeranchuk–Migdal (LPM) regime, $t_f \lesssim L$, for which the energy dependence is at most logarithmic. This different parametric behavior has important consequences on the phenomenology of hadron production in p–A collisions. In particular, a model based on the fully coherent induced gluon spectrum was shown to describe accurately the quarkonium suppression observed in p–A collisions at all centre-of-mass energies, from the SPS fixed-target experiments ($\sqrt{s} \simeq 20$ GeV) to the LHC ($\sqrt{s} = 5.02$ TeVand $\sqrt{s} = 8.16$ TeV) [894–896]. It is therefore necessary to investigate further the role of fully coherent energy loss on other processes. Because the fully coherent induced gluon spectrum arises from the interference between the emission amplitudes off the initial charge and that off the final state, the effects of FC energy loss are process dependent. Let us review, at a qualitative level, the expected nuclear dependence of different processes which could be measured at the LHC with a high luminosity.

In the absence of color charge in the partonic final state, the energy loss in Drell-Yan (DY) production at leading order is expected to be that of a suddenly decelerated parton, that is, independent of its energy (LPM regime). The effects of parton energy loss in nuclei should therefore play almost no role on DY production in high-energy p–A collisions, since $\Delta E/E \to 0$ in the high-energy limit. The inclusive production of DY lepton pairs in p–A collisions at the LHC should therefore be free of any parton energy loss effect. As a result, this process might be used advantageously in order to probe possible nuclear PDF effects at small values of x, see e.g., Fig. 83 and Ref. [500] for more details. Assuming a luminosity of $L_{\text{int}} = 250$ nb^{-1} and taking the conservative value for the cross section in p–Pb collisions at $\sqrt{s} = 5$ TeV, $\mathrm{d}\sigma/\mathrm{d}y = 40$ nb [500], the number of forward DY lepton pairs, which could be measured by the LHCb experiment is typically 10^4 per rapidity unit. Also interesting, and accessible with a high luminosity, would be the production of diphotons in p–A collisions. This process would be free of energy loss effects, for the same reasons as the DY process, while being sensitive to nPDF in the quark sector, $q\bar{q} \to \gamma\gamma$, and in the gluon sector through the 'box diagram', $gg \to \gamma\gamma$.

Note that the energy loss scaling as E (FC regime) would come into play only if *another* energetic charged particle is produced in the final-state in association with the virtual photon (or the diphoton), such that the final state carries a global color charge. Such a situation typically occurs in DY+jet production in p–A collisions. Consider for instance the Compton scattering process, $qg \to q\gamma^\star$. At forward rapidity, an incoming quark from the proton projectile scatters in the medium to produce the final state in a color triplet representation. In this peculiar case of quark to a color triplet final state, one would expect a negative *medium-induced* gluon spectrum (i.e., with stronger gluon radiation in pp than in p–A collisions), leading to an energy *gain* (with respect to pp collisions), $\Delta E \propto (-1/2N_c) \times E$ [893]. Such an unusual dependence would manifest by a slight *enhancement* of DY+jet production in p–A collisions with respect to pp collisions [500], although a quantitative study would be needed to answer whether this effect could be visible in the experiment. Similarly, should this enhancement be small or negligible, the associate production of a prompt photon with a heavy-quark jet might be sensitive to the nPDF of heavy quarks and gluons, as emphasized in Ref. [897]. Using $\sigma_{\gamma c} = 1.2 \times 10^5$ pb in the acceptance of the ALICE calorimeter [897] leads to 2.4×10^5 $\gamma + c$-jet events in p–Pb collisions at $\sqrt{s} = 8.8$ TeV assuming $\mathcal{L} = 2$ pb^{-1}. This observable should be also accessible in ATLAS, CMS and LHCb acceptances as well.

More pronounced effects of fully coherent energy loss are expected when the final state is in a

color octet state, or possibly in higher color representations. An example is the production of a jet pair with not too large transverse momenta (ideally only a few times the saturation scale of the target nucleus). In the case of di-gluon production, the final state can be produced in the 27-plet color representation (with Casimir $C_{27} = 8$) that would lead to an average coherent energy loss proportional to $(N_c + C_{27})/2 = 11/2$, that is almost twice larger that expected if the final state is in a color octet state. Such higher color representations could also be probed in the production of B_c mesons (or in the associate production of a D and a B meson), with a complex final state $\mathrm{c\,\bar{c}\,b\,\bar{b}}$. From the number of fitted signal candidates $\mathcal{N} = 10^4$ B_c mesons extracted at LHCb in the semileptonic decay channel in pp collisions at $\sqrt{s} = 8$ TeV with $\mathcal{L} = 2$ fb^{-1} [898], the expected $\mathrm{B_c}$ rate in the LHCb acceptance using $\mathcal{L} = 0.5$ pb^{-1} in p–Pb collisions at the same energy is $\mathcal{N} = 5 \times 10^2$ $\mathrm{B_c}$ mesons.

10.4 Constraints on nuclear PDFs

10.4.1 Overview

As previously discussed in Sec. 10.1, the nuclear Parton Distribution Functions (nPDFs) are poorly constrained as compared to the proton PDFs. This is mainly due to the lack of high statistics data across the very large nuclear mass number (A) range. In fact, even the precision of the proton PDFs rely crucially on nuclear target data [872, 899, 900]; for example, the neutrino-nucleon deep-inelastic-scattering (DIS) structure functions are essential for decomposing the flavour components of the proton [901–905]. Consequently, improved determinations of the nuclear PDFs and nuclear correction factors could improve the proton PDF precision. Thus, the future LHC Runs 3 and 4 could provide the opportunity to precisely constrain the nPDFs for the Pb-nucleus and, in Run 5 and later, one or more lighter nuclei, and thereby disentangle the nuclear effects from the individual flavour components.

In Fig. 88 selected nPDFs from the literature are displayed.

10.4.2 W and Z boson production

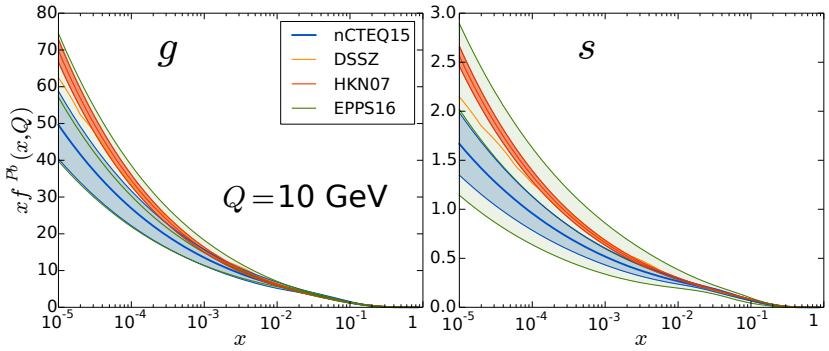

Fig. 88: Comparison of the gluon (left) and strange (right) quark nPDF for a lead nucleus as a function of x for a selection of nuclear PDF sets: HKN07 [906], DSSZ [788], EPPS16 [786], and nCTEQ15 [787].

Inclusive W and Z boson production: Inclusive production of W and Z bosons in pp collisions at the LHC can provide new information on the strange, charm and beauty quark PDFs. Additionally, heavy-ion W and Z production data from p–Pb and Pb–Pb can provide insight on the nuclear corrections, and this complements other data on nuclear targets as it is at large A (lead) and high energy (and thus, smaller x) [865–868, 871, 910, 911]. For example, ATLAS used inclusive W/Z production data to extract the strange quark component of the proton as displayed in Fig. 89 (left). This yielded a larger strange quark PDF than commonly expected [907, 912]. A recent analysis of the ATLAS and CMS inclusive W and Z differential cross section data at 7 and 8 TeV [913] and the combined HERA inclusive data indicates that while there is no tension between the data sets, the LHC data does support unsuppressed

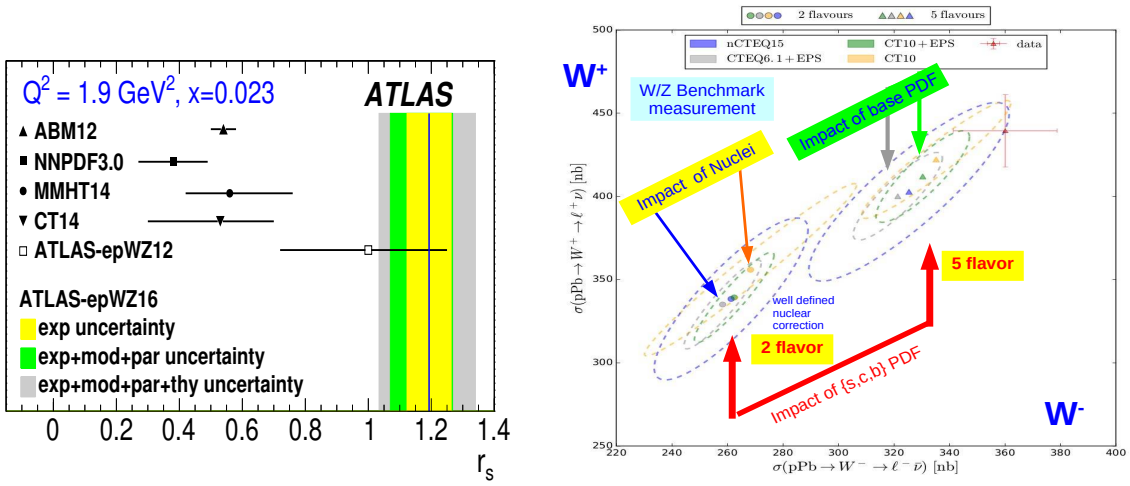

Fig. 89: Left: The relative strange-to-down sea quark fractions $r_s = 0.5(s + \bar{s})/\bar{d}$ as compared with predictions from different NNLO PDF sets; figure from Ref. [907]. Right: correlations between W^+ and W^- p–Pb cross sections calculated with different input PDFs and assumptions to illustrate the separate impact of the i) nuclear corrections, ii) heavy flavour components, and iii) base PDFs [908,909].

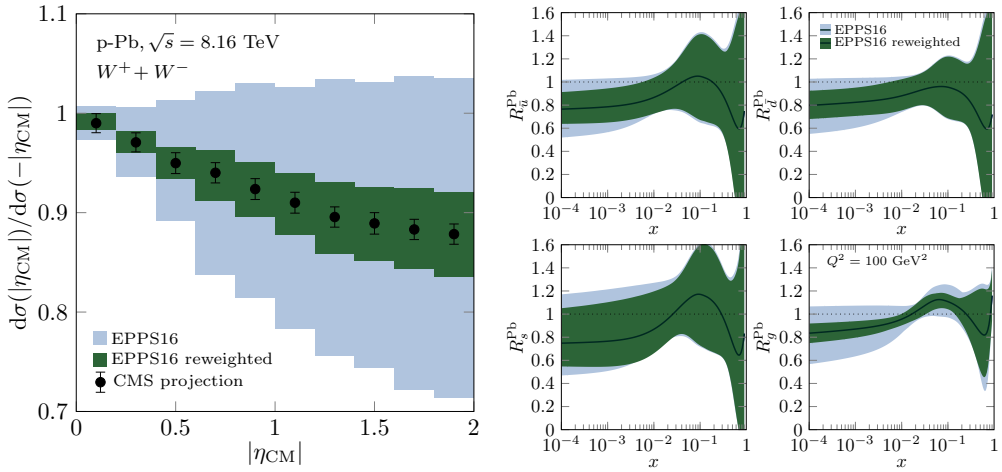
strangeness in the proton at low x at both low and high scales. Certainly this is an area that warrants further study.

To highlight the sensitivity of the heavy ion W/Z production to both the heavy flavour components and the nuclear corrections, in Fig. 89 (right), the correlations between W^+ and W^- cross sections for proton-lead interactions calculated with different input PDFs and assumptions [908] are shown. By comparing the results with and without the strange, charm, beauty quark flavours, it can be observed that these quarks do have a large impact on this observable; hence, this process can provide incisive information about the corresponding PDFs. To see the effect of the nuclear corrections, the CT10 proton result is compared with the other calculations. For the case that only two flavours are considered, the separation of the proton result (CT10) and the nuclear results are quite distinct. In this case, the effect of the specific nuclear correction (nCTEQ15 or EPS09) or the effect of the underling base PDF (CTEQ6.1 or CT10) is minimal. In contrast, when this picture is compared to the five flavour results, the division between the proton and nuclear result is not as simple as the different nuclear corrections and proton baseline PDFs yield a broader range of results. In particular, the strange quark PDFs in the CTEQ6.1 and CT10 proton baseline PDFs are quite different, and this will contribute to the spread of results. Thus, proton-lead production of W/Z is an ideal "laboratory" as this process is sensitive to i) the heavy flavour components, ii) the nuclear corrections, and iii) the underlying "baseline" proton PDF. Thus, high-statistics heavy-ion run data during Run 3 and Run 4 has the potential to reduce the current uncertainties and improve the nuclear PDF determination as illustrated by the projections from ATLAS in Fig. 81 and CMS 85.

$W^{\pm}$ asymmetries: A way to disentangle the nuclear effects from proton PDF and other theory uncertainties like higher-order corrections even in the absence of a pp reference, is the forward-to-backward ratio [914]. To showcase the potential in the case of $W^{\pm}$ projections (shown in Fig. 85), Fig. 90 presents the effect that PDF reweighting [915] analysis with these data has on EPPS16 nuclear PDFs and the corresponding theory predictions for the asymmetry. The most notable effect is the dramatic reduction in the uncertainties of the gluon PDF. Indeed, $W^{\pm}$ production takes place at a high scale $Q^2 \sim M_W^2$ and even though it is mostly $q_i\bar{q}_j$ processes that make the W bosons, the $\bar{q}_j$ PDFs probed at $\eta_{CM} \gtrsim 0$ are, in practice, dominated by the evolution effects at small x. Thus, it is not that surprising that it is predominantly the gluon component that gets tightly constrained by the W data. The improvement for the light

Fig. 90: Left: The CMS projections [8] for the forward-backward asymmetry in $W^{\pm}$ production (Fig. 85) compared to the original EPPS16 90% confidence-level error bands and those after reweighting with these $W^{\pm}$ data. Right: The change in EPPS16 nuclear PDF modifications for sea quarks and gluons at $Q^2 = 100$ GeV^2 upon reweighting with the data shown in the left-hand panel.



sea quarks (d,u,s) is merely a consequence of better constrained gluons, through QCD dynamics. The large-x ($x \gtrsim 0.1$) part is not really affected by the $W^{\pm}$ data.

Another $W^{\pm}$ observable that would benefit from a high luminosity is an asymmetry

$$[\sigma^{W^+}(y_{\mathrm{CM}}) - \sigma^{W^+}(-y_{\mathrm{CM}})]/[\sigma^{W^-}(y_{\mathrm{CM}}) - \sigma^{W^-}(-y_{\mathrm{CM}})]$$

proposed in Ref. [914]. In order to measure such a quantity involving four cross sections and subtractions among them (particularly in the denominator which may fluctuate between positive and negative), an excellent statistical precision — like that achievable during Run 3 and 4 at the LHC would be advantageous. With the present Run 2 luminosity it appears that the data [871] are still not accurate enough to measure this across the full rapidity acceptance.

Low-mass Drell-Yan: The Drell-Yan process at low invariant masses is a luminosity-hungry process where LHC Run 3 and Run 4 can make a difference. It would be very much advantageous to reach this low-mass region experimentally as it offers a possibility to constrain the nuclear PDFs at lower factorisation scale where the nuclear effects are larger. The estimated impact is shown in Fig. 91 where the LHCb estimates for R_{pPb} are compared to the reduction of EPPS16 uncertainties upon performing a PDF reweighting [915] with these data described in detail in Ref. [13]. In the calculation, a full decay-lepton phase space has been assumed, but this has a feeble effect on R_{pPb}. Although the Drell-Yan process occurs predominantly via $q\bar{q}$ annihilation, the scale-evolution effects are large and these data mostly constrain the gluon PDFs. Here, it should be noted that the probed x values are already so small, that the parametrisation bias which is prominent at small x [873, 916] is probably significant and understates the "true" effect of these measurements. This kind of scan over a wide range of invariant masses with the LHC Run 3 and 4 precision would offer a possibility to test the Q^2 evolution of nuclear PDFs – whether there are corrections to standard DGLAP – much more systematically than only on-shell $W^{\pm}$- and Z-production measurements do (involving only one scale).

10.4.3 Heavy quark production

Inclusive Heavy Quark Production: A recent study of inclusive heavy quark production in proton–lead collisions at the LHC demonstrates this can also help constrain the gluon distribution in nuclei.

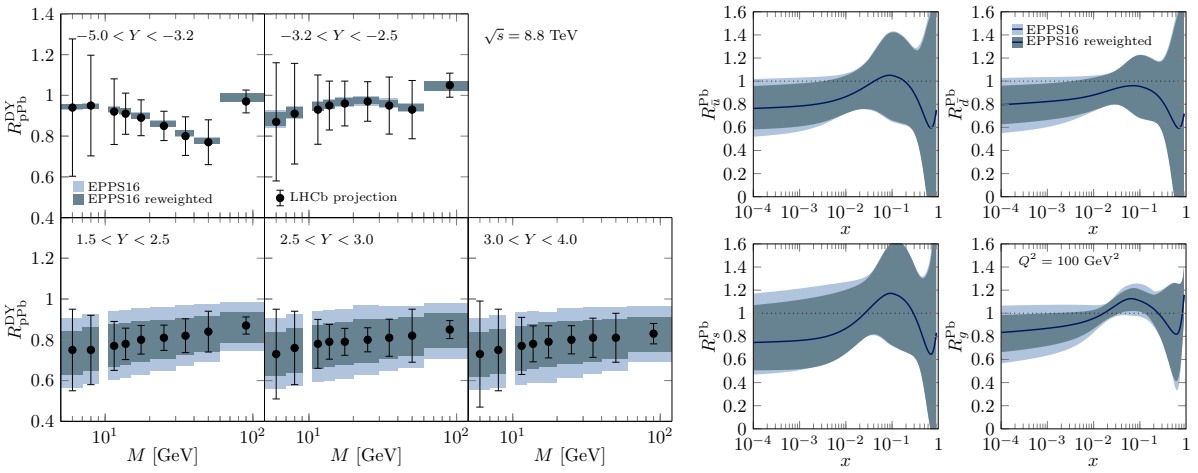


Fig. 91: Left: The LHCb projections [13] on R_{pPb} in Drell-Yan process compared to the original EPPS16 error bands and those after reweighting with these data. Right: The improvement in EPPS16 nuclear PDFs for sea quarks and gluons at $Q^2 = 100$ GeV^2 upon reweighting with the data shown in the left-hand panel.

Specifically, Ref. [917] makes use of LHC p–Pb data on $\mathrm{D}^0, \mathrm{J}/\psi, \mathrm{B} \to \mathrm{J}/\psi, \Upsilon(1\mathrm{S})$ meson production [496, 506, 754, 874, 918–929]. They obtain a consistent description of these data assuming nPDF modifications are the dominant source of nuclear modifications in p–Pb collisions. Under this assumption, a clear confirmation of gluon shadowing at small x is found. Additionally, they demonstrate that the inclusion of such heavy-flavour data in a global fit can significantly reduce the uncertainty on the gluon density down to $x \simeq 7 \times 10^{-6}$ while keeping an agreement with the other data of the global fits. A reweighting of the current nPDFs sets with the LHC heavy-flavour data was performed for the nCTEQ15 and EPPS16 sets. In a recent analysis of beauty hadrons by the LHCb collaboration [754, 922, 923] excellent agreement between the reweighted predictions and the measured data for the nuclear modification factor R_{pPb} was found. Furthermore, the precision of these data will allow to further reduce the uncertainty of the low-x nuclear gluon distribution. Due to the lower production rates for beauty hadrons, this kind of observables would clearly profit from a higher luminosity as shown in Fig. 25 in the heavy-flavour chapter. Note that heavy flavour measurements from LHCb extending to larger transverse momenta have also the potential to constrain the intrinsic heavy quark component [930–932].

Prompt Diphoton Production: As discussed in Sec. 10.3.4, other nuclear effects such as coherent small angle gluon radiation may explain the heavy-flavour data without a strong shadowing of the small-x gluon. A way to contrast parton shadowing against effects from coherent energy loss discussed in section 10.3.4, will be to study hard processes with color neutral final states in the context of a global analysis in order to see whether a coherent description of all the data remains possible. The case of vector boson production has already been discussed above which is rather sensitive to the quark distributions. Interesting processes (with more or less color neutral final states) which are sensitive to the gluon distribution are inclusive prompt photon production and diphoton production. The prompt photon observable has been discussed in Section 10.3.2 in the context of the ALICE upgrade. The diphoton production is rather clean with an essentially color neutral final state assuming that the contribution from the fragmentation of quarks and gluons into photons can be strongly suppressed by photon isolation criteria [725, 933]. Due to the small diphoton cross section, this measurement requires high luminosities. Based on the available calculations at next-to-leading order [934, 935], about 6000 events within the fiducial experimental acceptance used in pp collisions by ATLAS can be expected with 2 pb^{-1} p–Pb collisions.

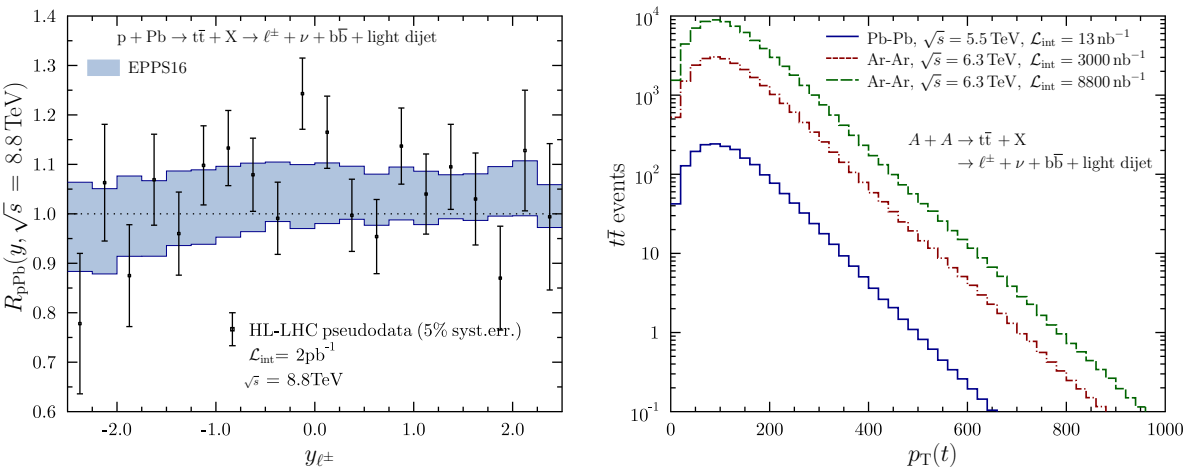

Fig. 92: Left: Projected data for $t\bar{t}$ production during Run 3 and 4 compared with uncertanties of the EPPS16 pdf-set. Right: Number of expected $t\bar{t}$ events in Ar–Ar collisions and in Pb–Pb as a function of the top-quark transverse momentum. the used luminosities are discussed in the text.

Heavy Quark Associated Production: The associated production of a heavy quark Q and a vector boson $\gamma/Z/W^{\pm}$ also provides incisive information about the PDFs. For all these processes, the LO contribution comes from the gluon–heavy-quark (gQ) initiated subprocess, making this process very sensitive to the gluon and the heavy quark nuclear parton densities. For the neutral current processes, a prompt photon γ or Z together with a c or b quark can be considered to obtain information of the c and b PDFs, respectively; for the charged current process, the Wc and Wb final states are sensitive to the strange and charm quark, respectively. These channels have been analysed for the LHC pp data [936–941] and the Wc channel is a key input for the ATLAS/CMS comparison of the strange sea quark content of the proton [913]. The event statistics in 2 pb^{-1} p–Pb collisions can be expected to be a factor 10 smaller than in the Run 1 CMS [940] and ATLAS [941] allowing for a first measurement in p–Pb collisions.

Additionally, the γ/Z transverse momentum can be used to gauge the initial energy of the massive parton propagating through the dense QCD medium produced in those collisions, making γ/Z+ Q production a powerful process in order to probe energy loss dynamics in the heavy-quark sector. Furthermore, the comparison of the photon-jet pair momentum, from pp to Pb–Pb collisions, is sensitive to the amount of energy lost by the heavy-quarks and could therefore be used in order to better understand parton energy loss processes in the heavy quark sector.

10.4.4 Top production

The $t\bar{t}$ production provides a complementary observable to the dijets for probing high-x gluons [870, 942]. For the very short t-quark life time, they decay, in practice exclusively, to W boson and b quarks. Although, the cleanest channel is the one where both W bosons decay leptonically, it has been recently demonstrated [870] that it is possible to get a clear signal when one of the two W bosons decays leptonically and the other one goes to light-quark jets. This is the preferred observable as the yields are 3 times higher than when both W bosons decay leptonically. The cross sections using the MCFM code [943], process 146 (where the leptonically decaying W comes from top quark) have been estimated at NLO level. The following fiducial cuts have been applied:

$$p_{\rm T}^{\ell^\pm} > 30\ \text{GeV/c},\ |y^{\ell^\pm}| < 2.5,\ p_{\rm T}^{\rm missing} > 30\ \text{GeV/c},$$

$$p_{\mathrm{T}}^{\mathrm{jets}} > 30 \text{ GeV/c}, \ |y^{\mathrm{jets}}| < 2.5, R_{\mathrm{isolation}}^{\mathrm{jets}} = 0.5.$$

In this setup, the NLO calculation with the factorisation and renormalisation scales set to the top-quark mass yields, per-nucleon, $\sigma_{\mathrm{n-n}} \approx 4200\,\mathrm{fb}$ in p–Pb collisions at $\sqrt{s} = 8.8\,\mathrm{TeV}$, with CT14NLO [872] proton PDFs and EPPS16 [786] nuclear corrections. This is to be multiplied by a factor two to account for the electron and muon final states and by a factor of two to account for the process where the antitop is the one from which the leptonically decaying W originates from. Since this is the nucleon-nucleon cross section, a factor of 208 has to be still multiplied to get the p–Pb cross section. This yields $\sigma_{\mathrm{pPb}} \approx 3.5\,\mathrm{nb}$. Considering the $2000\,\mathrm{nb}^{-1}$ scenario, and efficiency of 0.75 [942] in b-jet tagging, around 5200 events are expected. Based on this number, the expected nuclear modification factor R_{pPb} following the steps of Ref. [942] has been estimated, assigning each data point a 5% uncorrelated systematic uncertainty (in the current p–Pb measurement of CMS [870] the systematic uncertainty is ∼20%). Dividing the $|y^{\ell^{\pm}}| < 2.5$ interval to 20 bins, the statistical uncertainty varies from 5% ($|y^{\ell^{\pm}}| < 1$) to 10% (most forward/backward). The resulting R_{pPb} is compared in Fig. 92 with the EPPS16 uncertainty band. In the considered kinematic configuration the expected R_{pPb} is typically a bit above unity for the gluon antishadowing in EPPS16. As can be seen from the left-hand panel of Fig. 92, the expected precision of the measurement is not enough to give significant constraints on nuclear PDFs. In particular, the dijets considered in Section 11.4.3 will probe the same kinematic configuration with a clearly higher precision. However, here much depends on the expected systematic error (taken here to be 5% for each data point separately) and how large are the bin-to-bin correlations. In the p-Ar mode, the higher c.m. energy of $\sqrt{s} \approx 9.4\,\mathrm{TeV}$ increases the yields around 50% and would also benefit from the higher luminosities, see the next subsection and Sec. 2.4.

This, plus a higher achievable nucleon-nucleon luminosity would render the above case almost completely systematics dominated.

Using the same framework and assumptions as above, the fiducial $t\bar{t}$ yields in A-A collisions have been estimated. Here, the Pb–Pb and Ar–Ar cases have been considered. In Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.5\,\mathrm{TeV}$, the per-nucleon cross section is $\sigma_{\mathrm{n-n}} \approx 1200\,\mathrm{fb}$ which translates to around 2000 reconstructed events for $13\,\mathrm{nb}^{-1}$ ion-ion luminosity. In the Ar–Ar option, the c.m. energy is slightly higher, $\sqrt{s} = 6.3\,\mathrm{TeV}$, which increases the cross section by some 50%. In addition, the achievable ion-ion luminosity is much higher, $3000\,\mathrm{nb}^{-1}$-$8800\,\mathrm{nb}^{-1}$ within 2.75 months of running, see Tables in Chapter 2.4. Thus, the estimated amount of $t\bar{t}$ events is clearly larger, around 30000. The right-hand panel of Fig. 92 shows the event distributions as a function of top-quark transverse momentum $p_{\mathrm{T}}(t)$. This shows that, the HL-LHC may allow to probe the space-time picture of heavy-ion collisions using top quarks [944] up to $p_{\mathrm{T}}(t) \approx 400$ GeV/c in the Pb–Pb case, and up to $p_{\mathrm{T}}(t) \approx 700$ GeV/c in the Ar–Ar alternative.

10.5 Perspectives with lighter ions

Lighter ions, with the possibility to achieve large integrated luminosities in modest running times, see Sect. 2.4 in the accelerator chapter, offer several interesting opportunities for the study of the initial stage of ion collisions, for small-x physics and for the determination of nuclear parton densities, see Section 10.1.

First, concerning nPDFs, it should be noted that due to the scarcity of nuclear data, a PDF fit or a single nucleus is impossible as discussed in Section 10.1. The different groups [786–788] have adopted different strategies but, generically, they give the parameters in the initial condition to be fitted a dependence on the nuclear mass number. Such dependence acquires different functional forms and, therefore, it constitutes part of the parametrisation bias in the nPDF set. Data on lighter nuclei may help to constrain such parametrisations, see the discussions for UPCs and p–A collisions in Section 10.4. To highlight the current unknowns, Fig. 93 compares the nuclear modifications for Argon and Lead, as

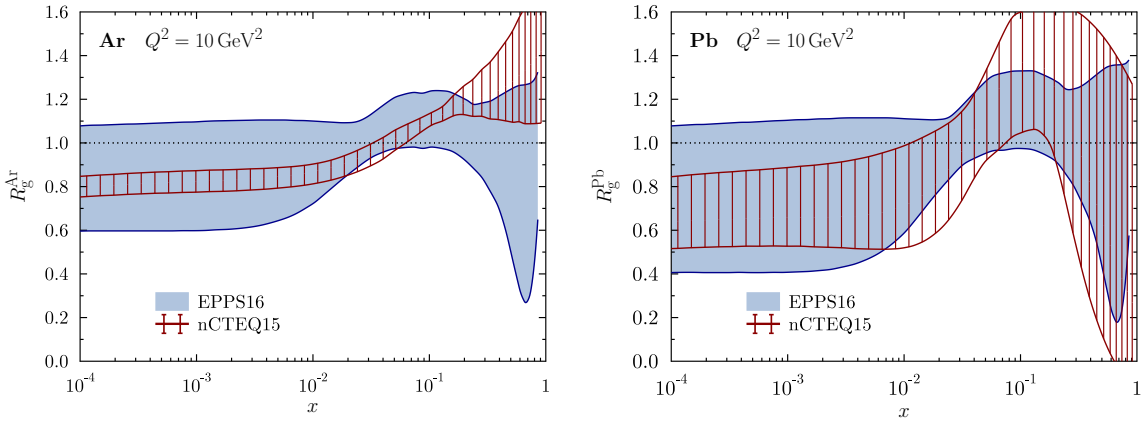

Fig. 93: The EPPS16 and nCTEQ15 nuclear PDF modifications for gluons at $Q^2 = 10\,\mathrm{GeV}^2$. Left-hand panel corresponds to the Argon nucleus and the right-hand panel to the Lead nucleus. From Ref. [945]

given by the EPPS16 and nCTEQ15 global analyses. In particular, the nCTEQ15 prediction varies, even qualitatively, quite significantly between Argon and Lead. This underscores the usefulness of e.g. a p-Ar run at the LHC.

On the other hand, the impact parameter dependence of nPDFs is linked to their dependence on nuclear size. Several models exist (see e.g. [946, 947]), and even less model-dependent approaches like the EPS09s analysis [948] where the dependence on nuclear size was used to constrain the impact parameter dependence. First-principle calculations combining the Gribov theory of inelastic shadowing and factorisation theorems for hard diffraction and DIS relate diffraction in electron-proton collisions with nuclear shadowing. This has been used to predict nuclear shadowing [790, 791], including its nuclear size and impact parameter dependence. While such relation is exact for the deuteron, its extension to larger nuclei has some degree of model dependence. Lighter ions are the ideal place to test the nuclear size dependence without resorting to centrality selection, whose relation with impact parameter is doomed to be as problematic - at least - as found in p–Pb collisions at the LHC.

Lighter ions also offer large luminosities that are important for several aspects:

- Data on beauty mesons and bottomonium in p–A collisions can be used to constrain nPDFs [329] better than their charm counterparts, because of the larger scale given by the mass and by the opportunity that they are less affected by collective effects. But they demand large statistics that can be achieved with lighter ions.
- Larger luminosities will benefit measurements in p–A collisions for observables with large scales, like high-mass DY or dijets, for precise determination of nPDFs.
- UPCs and photon-photon studies [587] in A–A collisions will greatly benefit in spite of the $Z^{2(4)}$ factor for the photon luminosities that can be overcompensated by the larger nucleon-nucleon luminosity.
- Larger luminosities can also benefit small-x forward observables that, like dijets [411], aim to reach quite large transverse momenta in p–A collisions.

Lighter ions offer a bridge between small systems and Pb–Pb without requiring centrality selection that is problematic both in pp, p–A and peripheral A–A. In the framework of saturation models [782] that aim to describe collective effects in small systems without requiring final state interactions (see e.g. [949] and references therein), the extension from the proton to the nuclear case in some of the phenomenological realisations is done by a simple rescaling of the squared saturation momentum

$Q_s^2 \propto A^{1/3}$. And the centrality dependence is assumed to be proportional to the nuclear profile, which leads to strong problems in the nuclear periphery where a dilute situation is restored. Lighter ions offer a check of our ideas on the nuclear size versus energy leading the density that determines saturation, and the use of minimum bias observables instead of centrality-sliced ones that would greatly simplify the phenomenology.

To conclude, lighter ions offer several advantages and disadvantages for initial stage studies. The main disadvantage is the fact that theory calculations usually assume the limit of scattering of a dilute projectile (proton) on a dense target (nucleus). Lighter ion-ion collisions are further from this limit. On the other hand, they offer: (i) a bridge between small and large systems without resorting to centrality selection that would be useful for constraining the nuclear wave function, the collision dynamics and the interpretation of collectivity; (ii) the possibility of larger luminosities for UPCs and forward observables for nPDFs determination and small-x studies; and (iii) a more affordable setup for microscopic calculations of nuclear corrections.

11 Other opportunities with ion and proton beams at the LHC

11.1 Physics motivation for collisions of light ions

Coordinator: Zvi Citron (Ben-Gurion University of the Negev)

Loizides (Oak Ridge National Laboratory), G. Milhano (LIP and IST Lisbon, CERN), A. Milov (Weizmann Institute of Science), J. Pires (CFTP and IST Lisbon), A.M. Sickles (U. Illinois, Urbana-Champaign), U. Wiedemann (CERN), M. Winn (LAL, Orsay and IRFU/DPhN, Saclay)

The collision of ion species with $A \ll A_{\mathrm{Pb}}$ is an appealing opportunity to expand the physics programme presented in this document. The recent Xe–Xe run of only eight hours has provided valuable input for the physics performance of ion collisions lighter than Pb at the LHC. Broadly, the advantages of using $A \ll A_{\mathrm{Pb}}$ collisions are twofold: smaller collision systems sample key physical parameters beyond what can be probed with Pb–Pb and p–Pb collisions, and they allow higher luminosity running to maximize the accumulation of rare events in heavy-ion collisions. This higher luminosity would enable high-precision measurements for currently rare observables in Pb–Pb collisions as well as the study of observables totally inaccessible in Pb–Pb collisions.

A scenario is envisioned in which the programme is extended in two directions: a) a short run of O–O ($A = 16$) to study system-size dependence and b) longer running of a species of intermediate A to achieve a large luminosity increase. The choice of the intermediate species will be dictated by the competition of increased luminosity with lower A against the goal of studying the properties of an extended QGP system. Optimizing the choice of species will require further study from the accelerator, experimental, and theoretical communities; in this document Ar–Ar ($A = 40$) collisions are considered as a test-case for the choice of intermediate ion. It is understood that any choice of collision species will likely require a pilot run prior to beginning dedicated collisions.

Section 2.4 describes the technical capabilities of the LHC to provide lighter-ion collisions, as well as the expected performance for several ion species. For example, for Ar–Ar the expectation for one month of collisions is $1080\,\mathrm{nb}^{-1}$ ($p = 1.5$). In order to compare across different collisions species we consider the nucleon–nucleon integrated luminosity per month of running, which could be larger by a factor 8–25 (for $p = 1.5$–1.9) with respect to Pb–Pb collisions, i.e. one month of Ar–Ar collisions would be equivalent to ~ 25–$80\,\mathrm{nb}^{-1}$ of Pb–Pb collisions. This gain would be the same in all centrality classes (defined in terms of percentiles of the hadronic cross section). Jet quenching estimates for light ion (Ar–Ar) collisions are presented in Sect. 6.5. Section 4.3.2 discusses flow measurements with light ions. A discussion of the role that light ion collisions can play for small-x and nPDF studies is reported in Sect. 10.5. Finally, the implications of Ar–Ar collisions for the study of light-by-light scattering are discussed in Sect. 11.2.

Even a short O–O run can help clarify the uncertainty concerning the onset of QGP or QGP-like phenomena in high-multiplicity pA and pp collisions, as discussed in section 9.10. The search for signals associated with the QGP in O–O collisions should complement the searches in pp and p–Pb collisions.In particular, the O–O system has well-understood collision geometry as described in detail in Sect. 9.10, enabling the study of collisions with low values of $\langle N_{\mathrm{part}} \rangle$ that are difficult to select and study in Pb–Pb collisions and that are similar to those associated to high-multiplicity p–Pb events. Colliding O–O at the LHC naturally dovetails with p–O collisions whose significance for cosmic-ray physics is detailed in Sect. 11.3.

Complementing Pb–Pb collisions, the possibility of high-luminosity extended LHC runs with intermediate-A nuclei (e.g. Ar–Ar or Kr–Kr) is an appealing long-term option. The chief promise of these collisions is the possibility of reaching much higher luminosity than Pb–Pb collisions while still producing a QGP over an extended volume of ~ 1000 fm^3 in central events. Based on a Glauber Monte

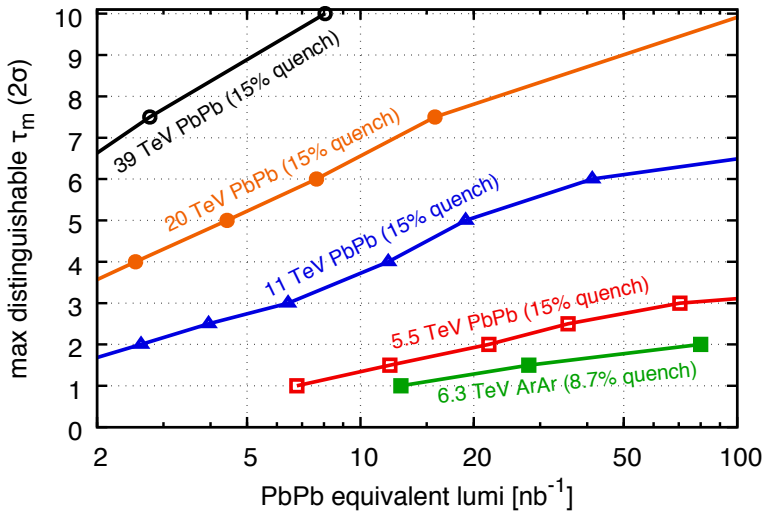

Fig. 94: Maximum medium lifetime that can be distinguished from a full quenching baseline with a statistical significance of two standard deviations ($2\,\sigma$), as a function of luminosity (shown in terms of equivalent Pb–Pb luminosity) for different species and collider energies. A single Ar–Ar run is expected to provide $\sim$ 25–80 nb^{-1} of Pb–Pb equivalent luminosity. Adapted from [944].

Carlo simulation [767], the mean number of participants for Ar–Ar ranges from $\langle N_{\mathrm{part}} \rangle \sim 7$ for 60–80% centrality to $\sim$ 70 for 0–5% centrality collisions. QGP effects are observed in Pb–Pb collisions with similar number of participants (see e.g. [950, 951]). In addition, the much lower underlying event multiplicity in Ar–Ar relative to central Pb–Pb collisions is expected to lead to reduced systematic uncertainties for several observables, from reconstructed jets to all signal affected by large combinatorial backgrounds. These features, combined with the possibility to increase the nucleon–nucleon luminosity by more than one order of magnitude, make Ar–Ar collisions an extremely attractive option for hard-probe measurements that in Pb–Pb collisions are limited or impossible, such as boosted top-quark decay chains for QGP studies [944]. Figure 94 extends the analysis to lighter nuclei and shows that one month of Ar–Ar collisions, with nucleon–nucleon luminosity equivalent to 25–80 nb^{-1} for Pb–Pb, allows a similar physics reach as the entire Pb–Pb future programme (13 nb^{-1}), namely to probe the QGP density evolution up to a time of about 1.5–2 fm/c. Top quark studies in Ar–Ar collisions in the context of constraints on nPDFs are discussed in Sect. 10.4.4.

Studies with Z bosons are representative examples of the types of measurements that may be undertaken in a lighter ion rare-probes programme. In Fig. 95 the expected number of Z boson candidates (assuming a selection similar to that used by ATLAS and CMS in previous studies) for one month of heavy-ion running as a function of $\langle N_{\mathrm{part}} \rangle$ is shown for several colliding ion species, and compared with the expectation for the full Pb–Pb and p–Pb programmes of Runs 3 and 4. The figure demonstrates that the overall yield of Z bosons would be considerably higher for one Ar–Ar run than for several years of Pb–Pb running including both a sufficient number of candidates to study low $\langle N_{\mathrm{part}} \rangle$ collisions unreachable with Pb–Pb collisions as well as moderate $\langle N_{\mathrm{part}} \rangle$ values in which QGP formation is expected. Z bosons are a powerful tool to probe the properties of the QGP in particular in Z+jet events. In these studies the energy of the Z is a direct measurement of the energy of parton that initiated the recoil jet. Therefore, the coverage of a broad range in Z momentum gives access to a jet-energy differential study of jet quenching. the The expected number of Z+jet events from the 0–10% centrality class above a given p_{T} of the Z boson is calculated at NLO (and without including jet suppression) and shown in Fig. 96 as a function of Pb–Pb equivalent luminosity. The Pb–Pb programme in Runs 3 and 4 (13 nb^{-1}) gives 1000 events with Z $p_{\mathrm{T}} > 120$ GeV/c, while a single Ar–Ar one-month run extends the coverage

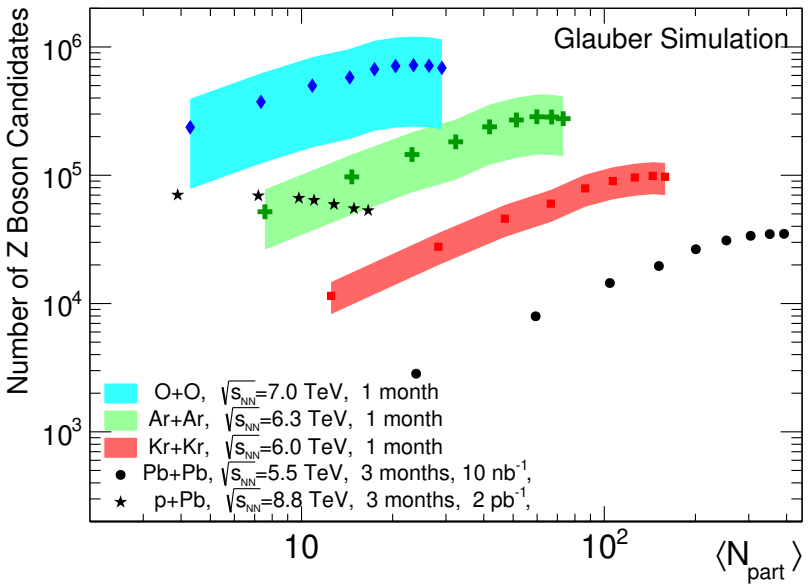

Fig. 95: The number of Z bosons as a function of $\langle N_{\mathrm{part}} \rangle$ expected for one month of O–O,Ar–Ar, and Kr–Kr collisions at the LHC and for the full expected Pb–Pb and p–Pb programmes. The Z bosons are reconstructed via the di-lepton decay channel with leptonic $p_{\mathrm{T}} > 20$ GeV/c and $|\eta| < 2.5$, and a mass selection of $66 < M_{\ell\ell} < 116$ GeV. The bands shown indicate the range of the expected luminosity ranging from $p = 1.5$ to $p = 1.9$, as discussed in section 2.4.

with the same number of events to 140–180 GeV/c. A three-months Ar–Ar programme extends well above 200 GeV/c.

For further study, Z+jet events were simulated in the 10% most central events in Ar–Ar collisions using Jewel [952] to estimate the expected jet-quenching effects. Details of the use of and limitations of JEWEL for this purpose are discussed in Sect. 6.5. Figure 97 shows the distribution of x_{jZ}, the ratio of the jet transverse momentum to that of the Z boson for 0–10% centrality Ar–Ar events, as well as pp collisions and 0–10% centrality Pb–Pb events ($N_{\mathrm{part}} = 356$, $T = 260$ MeV at thermalization time $\tau = 0.6$ fm/c for $\sqrt{s} = 5.02$ TeV). The Z boson must have $p_{\mathrm{T}} > 60$ GeV/c and be back-to-back ($|\Delta\varphi| > 7/8\pi$) to a jet with $p_{\mathrm{T}} > 30$ GeV/c. The Figure clearly shows that for this observable the jet-quenching phenomena observed in Pb–Pb collisions as modelled by JEWEL are present also in Ar–Ar collisions. More studies are needed to refine modelling of more dilute systems and optimize the choice of colliding species, but taken together the available information suggests the potential of light ion collision systems like Ar–Ar for a heavy-ion rare-probes programme.

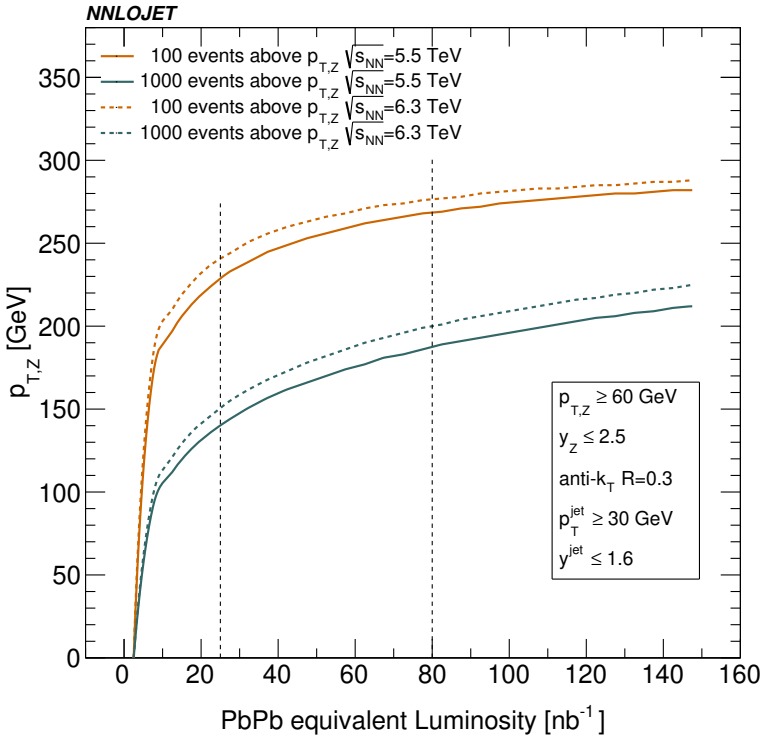

Fig. 96: The kinematic reach of Z+jet events as a function of Pb–Pb equivalent luminosity. The curves indicate the maximum p_{T} of the Z boson for which 100 (or 1000) events are expected from 0–10% centrality collisions for a given Pb–Pb equivalent luminosity. 25 and $80\,\mathrm{nb}^{-1}$, corresponding to the upper and lower expectations for one month of Ar–Ar collisions, are indicated by the vertical lines.

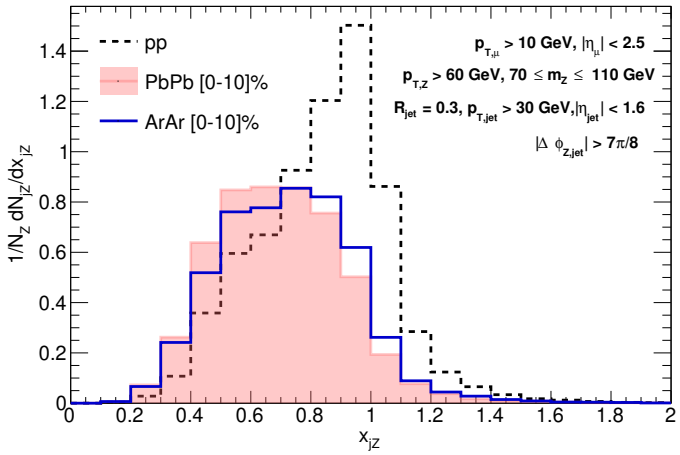

Fig. 97: The x_{jZ} distribution for pp, Pb–Pb, and Ar–Ar collisions calculated with JEWEL. The 10% most central events are shown for Pb–Pb and Ar–Ar. Ar–Ar collisions are calculated as $N_{\mathrm{part}} = 60$, $T = 318\,\mathrm{MeV}$ at thermalization time $\tau = 0.63$ fm/c for $\sqrt{s} = 6.3$ TeV. The Z boson must have $p_{\mathrm{T}} > 60$ GeV/c and be back-to-back ($|\Delta\varphi| > 7/8\pi$) to a jet with $p_{\mathrm{T}} > 30$ GeV/c.

11.2 Physics of $\gamma\gamma$ interactions in heavy-ion collisions

Coordinators: Iwona Grabowska-Bold (AGH University of Science and Technology)

Contributors: M. Dyndal (DESY), S. Hassani (Université Paris-Saclay), M. Klusek-Gawenda (IFJ PAN, PL-31342 Kraków, Poland), L. Schoeffel (Université Paris-Saclay), Peter Steinberg (BNL)

Heavy-ion beams are composed of nuclei which carry electric charge Ze (e is the electron charge and Z is the atomic number). They are accelerated to nearly the speed of light, thus they generate large electromagnetic (EM) fields. The EM fields generated by the relativistic ion can interact with the other nucleus or its EM fields. Therefore, besides nuclear hadronic interactions, EM interactions also occur in ultra-relativistic heavy-ion collisions. These EM interactions can be studied in so-called ultra-peripheral collisions (UPC) which occur when the distance between two nuclei in the transverse plane is larger than two times the nuclear radius, and hadronic interactions are thus suppressed [582].

A broad range of processes can be studied with $\gamma\gamma$ interactions in UPC. In the following, a few examples of photon-induced processes are considered at the HL-LHC: exclusive production of $\mu^+\mu^-$ or $p\bar{p}$ pairs, a rare process of light-by-light (LbyL) scattering and a potential of searches for axion-like particles (ALP).

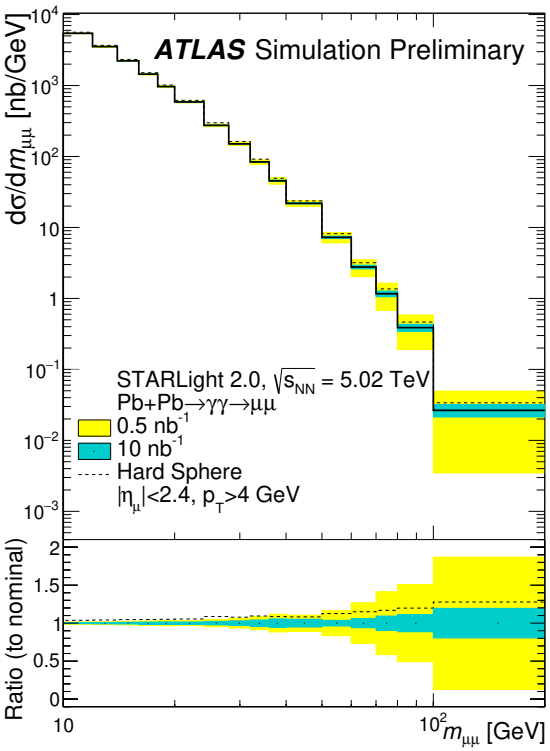

Fig. 98: (Upper) Differential cross section for exclusive production of the di-muon pairs as a function of the di-muon mass for $10 < m_{\mu\mu} < 200$ GeV extracted from STARLight. Two scenarios are considered for the nuclear geometry: a realistic skin depth of the nucleus (solid line) or a hard sphere (dashed line). (Bottom) Ratio to nominal as a function of the di-muon mass, where "nominal" stands for the realistic skin depth of the nucleus. Shaded bands represent expected statistical uncertainties associated with a number of signal events in each bin for integrated luminosity of $0.5\ \mathrm{nb}^{-1}$ (yellow), and $10\ \mathrm{nb}^{-1}$ (cyan).

Exclusive production of di-muon pairs ($\gamma\gamma \to \mu^+\mu^-$) in UPC can offer a precision measurement of photon fluxes associated with ion beams, and as such can be used to constrain predictions for the

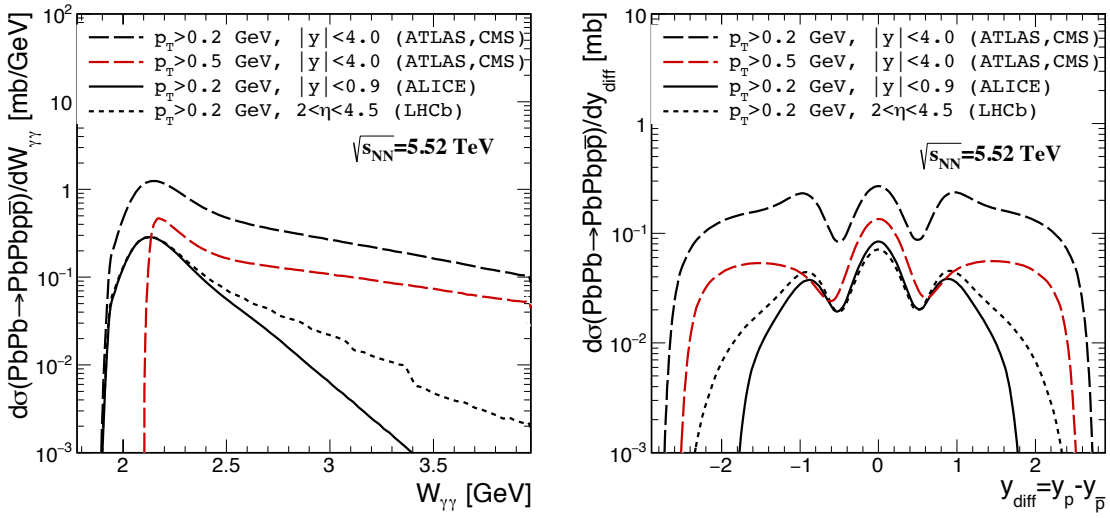

Fig. 99: Differential cross sections as a function of $\mathrm{p\bar{p}}$ invariant mass (left) and rapidity distance between proton and anti-proton (right) in Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 5.52$ TeV for four experimental acceptance requirements. For ATLAS and CMS experiments two requirements for proton $p_{\mathrm{T}} > 0.2$ GeV/c or $p_{\mathrm{T}} > 0.5$ GeV/c are considered.

other processes covered in this section. The cross section at high pair mass is also sensitive to the nuclear geometry assumed in the calculations. Figure 98 presents a differential cross section as a function of the invariant mass of the di-muon system in the range of 10–200 GeV with expected statistical uncertainties represented by two bands corresponding to integrated luminosities of $0.5\ \mathrm{nb}^{-1}$ and $10\ \mathrm{nb}^{-1}$. Two scenarios are considered for the nuclear geometry: a realistic skin depth of the nucleus or a hard sphere [953]. For the $10\ \mathrm{nb}^{-1}$ scenario, a significant reduction of the statistical uncertainty is expected. This will help in reducing uncertainties from the modelling of the nuclear geometry. The expected upgrades of the ATLAS Zero Degree Calorimeters (ZDC) in the LHC Run 3 will also be important for isolating the contributions to the cross section stemming from dissociative processes.

Exclusive production of $\mathrm{p\bar{p}}$ pairs ($\gamma\gamma \to \mathrm{p\bar{p}}$) in heavy-ion collisions is considered as a process which can help verify the existing theoretical approaches. It has been demonstrated that the $\gamma\gamma \to \mathrm{p\bar{p}}$ experimental data [954] from the Belle Collaboration can be successfully described by implementation of several components [955]: the non-resonant proton exchange, s-channel tensor meson exchange and the hand-bag model [956]. Figure 99 shows the calculated distributions of invariant mass of the $\mathrm{p\bar{p}}$ system, $W_{\gamma\gamma} = M_{\mathrm{p\bar{p}}}$ (left panel) and of the difference of rapidities for protons and anti-protons, $y_{\mathrm{diff}} = y_{\mathrm{p}} - y_{\bar{\mathrm{p}}}$ (right panel). The ALICE Collaboration can measure $\mathrm{p\bar{p}}$ pairs in Pb–Pb collisions at mid-rapidity ($|y| < 0.9$). The LHCb Collaboration could also provide a complementary measurement of $\mathrm{p\bar{p}}$ production in the forward region ($2 < \eta < 4.5$). The upgraded charged particle tracking capabilities of ATLAS and CMS experiments for Run 4 will measure in $|y| < 4.0$. Corresponding kinematic requirements on transverse momenta and rapidity or pseudorapidity specific for each experiment are presented in the figure legend. The calculations are made for Pb–Pb collisions with $\sqrt{s_{\mathrm{NN}}} = 5.52$ TeV. The total cross section predicted for the ATLAS and CMS acceptances for $p_{\mathrm{T}} > 0.2$ GeV/c ($p_{\mathrm{T}} > 0.5$ GeV/c) is $\sigma = 793$ μb (248 μb), while LHCb and ALICE requirements lead to $\sigma = 125$ and 105 μb, respectively.

From the left panel of Fig. 99 one can deduce that the dependence on invariant mass of the $\mathrm{p\bar{p}}$ pair is sensitive to the rapidity/pseudorapidity of the outgoing particle. The cut-off at the minimal value of $W_{\gamma\gamma}$ is determined by the minimum p_{T} requirement. The y_{diff} distribution shown in the right panel of Fig. 99 is of particular interest. The broad maximum at $y_{\mathrm{diff}} = 0$ corresponds to the region with $|\cos\theta| <$

0.6, where θ denotes the angle of the outgoing nucleon relative to the beam direction in the centre-of-mass frame. An observation of peaks at $y_{\rm diff} = \pm 1$ could be a good test to constraint the theoretical models which predict the elementary cross section. The proposed model has a few parameters (i.e. vertex form factors for the proton exchange, tensor meson s-channel exchanges and a form factor in the hand-bag contribution) which could be constrained with the help of the $y_{\rm diff}$ distributions. The fiducial acceptance requirements imposed on $p_{\rm T}$ do not distort the maxima. If the structures in the $y_{\rm diff}$ distributions indeed exist, the study of $\rm p\bar{p}$ production in UPC can provide an important complimentary information to the existing $\gamma\gamma \to \ell^+\ell^-$ and $\rm J/\psi \to \ell^+\ell^-$ data with $\ell = e, \mu$ [819, 957].

Evidence of the rare process of LbyL scattering has been established by the ATLAS and CMS Collaborations using Pb–Pb data obtained in 2015 [809, 958] with an integrated luminosity of about $0.4\ \rm nb^{-1}$. That process can be studied with higher precision using heavy-ion data collected at the HL-LHC. The left panel of Fig. 100 presents a differential cross section as a function of the di-photon rapidity for LbyL scattering for photons with $|\eta^\gamma| < 4$ with two photon $p_{\rm T}^\gamma$ thresholds: 2.0 and 2.5 GeV/c. The LbyL scattering occurs in the central region: 91% of the integrated cross section resides within $|\eta^\gamma| < 2.37$. A strong dependence on the $p_{\rm T}^\gamma$ requirement is observed. The cross section increases by a factor of two when the single photon $p_{\rm T}^\gamma$ threshold is lowered by half a GeV/c from 2.5 to 2.0 GeV/c. The corresponding integrated cross sections in the fiducial region are 112 nb for $p_{\rm T}^\gamma > 2.5$ GeV/c and 221 nb for $p_{\rm T}^\gamma > 2.0$ GeV/c.

The right panel of Fig. 100 shows a detector-level acoplanarity (=$1 - |\varphi_1^\gamma - \varphi_2^\gamma|/\pi$) distribution for the di-photon system from LbyL signal and two background processes originating from exclusive production of di-electron pairs ($\gamma\gamma \to \rm e^+e^-$) and di-photons produced in central exclusive production ($\rm gg \to \gamma\gamma$). The distributions depict simulated events which passed a full simulation of the ATLAS detector with the extended acceptance in pseudorapidity. About 640 LbyL events pass the selection requirements for acoplanarity below 0.01 and $p_{\rm T}^\gamma > 2.5$ GeV/c in 5.02 TeV Pb–Pb collisions with an integrated luminosity of $10\,\rm nb^{-1}$, in comparison to about 13 events observed in the 2015 data set with the $p_{\rm T}^\gamma > 3.0$ GeV/c requirement. The signal events are peaked at acoplanarities close to zero, while the background processes are distributed either uniformly (di-photons from central exclusive production) or even grow with acoplanarity ($\rm e^+e^-$ pairs from exclusive di-electron production). The latter originates from $\rm e^+e^-$ pairs which trajectories have been bent in the magnetic field before emitting hard-bremsstrahlung photons. A limitation of the current analysis is lack of simulation of the trigger response. Based on experience from the analyses of 2015 Pb–Pb data, triggering on photons with $p_{\rm T}^\gamma < 3.0$ GeV/c is challenging, and therefore a dedicated trigger strategy needs to be developed for LbyL event candidates exploiting new features of the upgraded trigger system [959, 960].

The LbyL process can also be studied at lower di-photon masses. The differential cross sections as a function of the di-photon mass can be evaluated taking into account acceptance of the ALICE experiment, i.e. pseudorapidity limited to $|\eta^\gamma| < 0.9$ or in the forward region defined by $2 < \eta^\gamma < 4.5$ in the LHCb experiment, and relatively low energies of outgoing photons [962]. At lower energies ($W_{\gamma\gamma} < 4$ GeV) meson resonances [963] may play an important role in addition to the Standard Model box diagrams [964, 965] or double photon fluctuations into light vector mesons [965] or two-gluon exchanges [966]. Figure 101 shows predictions for LbyL and background processes in the ALICE and LHCb experiments with photon acceptance in $|\eta^\gamma| < 0.9$ and E_γ > 200 MeV (top panel) or $2 < \eta^\gamma < 4.5$ and $E_{{\rm T},\gamma}$ > 200 MeV (bottom panel), respectively, for two systems: Pb–Pb collisions at 5.52 TeV (left panel) and Ar–Ar collisions at 6.3 TeV (right panel). Presented results include the effect of the experimental energy resolution [967, 968]. The black-solid lines depict the LO QED fermionic box mechanism with leptons and quarks. Presented results for the $\gamma\gamma \to \gamma\gamma$ process are in agreement with calculations from Refs. [969–971]. The green-solid lines show results for the s-channel $\gamma\gamma \to$pseudoscalar/scalar/tensor resonances that contribute to the LbyL process. In the present analysis, η, $\eta'(958)$, $\eta_c(1S)$, $\eta_c(2S)$, $\chi_{c0}(1P)$ mesons are considered. Their masses, total widths and branching

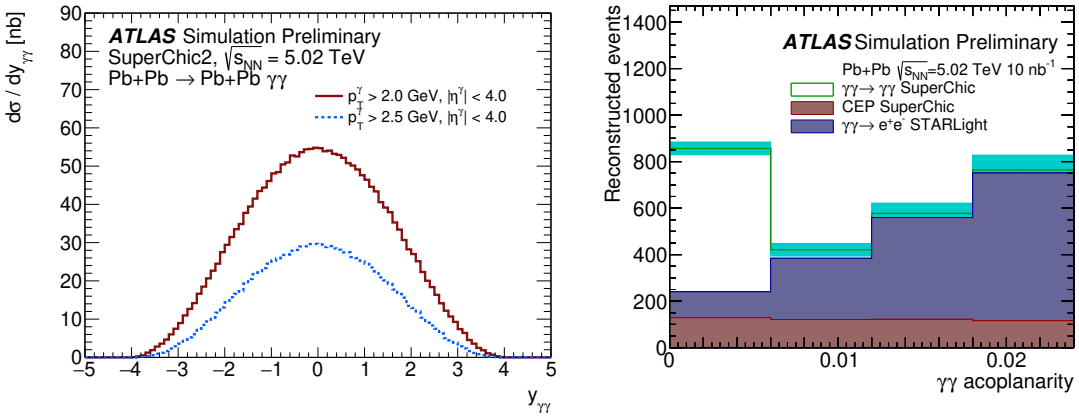

Fig. 100: (Left) Predicted differential cross section as a function of the di-photon rapidity for LbyL scattering for photons with $p_{\mathrm{T}}^{\gamma} > 2.5$ GeV/c (dashed) or $p_{\mathrm{T}}^{\gamma} > 2.0$ GeV/c (solid), and $|\eta^{\gamma}| < 4$ extracted from SuperChic [961]. (Right) Detector-level acoplanarity distribution of the di-photon system for photons from the LbyL signal and background processes in 5.02 TeV Pb–Pb collisions with an integrated luminosity of 10 nb^{-1}. The shaded band in cyan represents expected statistical uncertainties.

ratios are taken from the PDG [972]. The contributions of pseudoscalar mesons from radiative decays of a coherently-produced vector meson could be sizeable [973] and should be quantified in future studies. The dominant background from the $\gamma\gamma \to \pi^0\pi^0$ process is shown by the blue lines. It becomes non-negligible only when one photon from each $\pi^0 \to \gamma\gamma$ decay is reconstructed in the detector. Two scenarios with and without the acoplanarity requirement of 0.01 are considered. The acoplanarity requirement reduces this background contribution by a factor of 5 in the full $W_{\gamma\gamma}$ region. The experimental data for the $\gamma\gamma \to \pi\pi$ elementary cross section were very well described in Ref. [974]. There simultaneously the total cross section and angular distributions for both charged and neutral pions are shown. Following Ref. [974], here nine resonances, $\gamma\gamma \to \rho^{\pm} \to \pi^0\pi^0$ continuum, Brodsky-Lepage and hand-bag mechanism are included. Figure 101 shows that pionic background dominates at low invariant di-photon mass (below 2 GeV). In the same energy region, one can observe a very clear dominance of η, $\eta'(958)$ mesons over other processes. The inclusion of energy resolution introduces mainly smearing of the contribution from $\gamma\gamma \to \eta, \eta' \to \gamma\gamma$ resonance scattering. This contribution is supposed to be measured with good precision. These results suggest that both ALICE and LHCb Collaborations could measure LbyL scattering for $W_{\gamma\gamma} > 2$ GeV in Pb–Pb collisions.

In the case of Ar–Ar collisions, the cross sections are about two orders of magnitude lower, because of the smaller electric charge of Ar nulcei with respect to Pb nuclei. Assuming integrated luminosities of $3.0 - 8.8$ pb^{-1} in a dedicated Ar–Ar run, the LbyL production cross section leads to 1460–4280 signal events for ALICE and 11–34 events for LHCb in a range of $W_{\gamma\gamma} > 2$ GeV. A background contribution from $\gamma\gamma \to \pi^0\pi^0$ is at the level of 20% for ALICE and 134% for LHCb in this region.

Axions and axion-like particles (ALP) are fundamental components of extensions of the Standard Model, occurring in most solutions of the strong CP problem [975,976]. Recently an increasing interest has been paid to ALP masses above 1 GeV [977–981]. In particular the Higgs discovery has set spin zero particles in the spotlight of searches for new physics, with scalar and pseudo-scalar particles (elementary or not) as heralds of new phenomena. An interesting feature is that ALP (generically labelled as a in the following) in this mass range would induce an anomalous contribution to the LbyL, via the reaction: $\gamma\gamma \to \mathrm{a} \to \gamma\gamma$, under the condition that the magnitudes of the EM fields associated with the incident photon are large enough, typically $|\vec{E}| > 10^{18}$ V/m. This has triggered the study presented

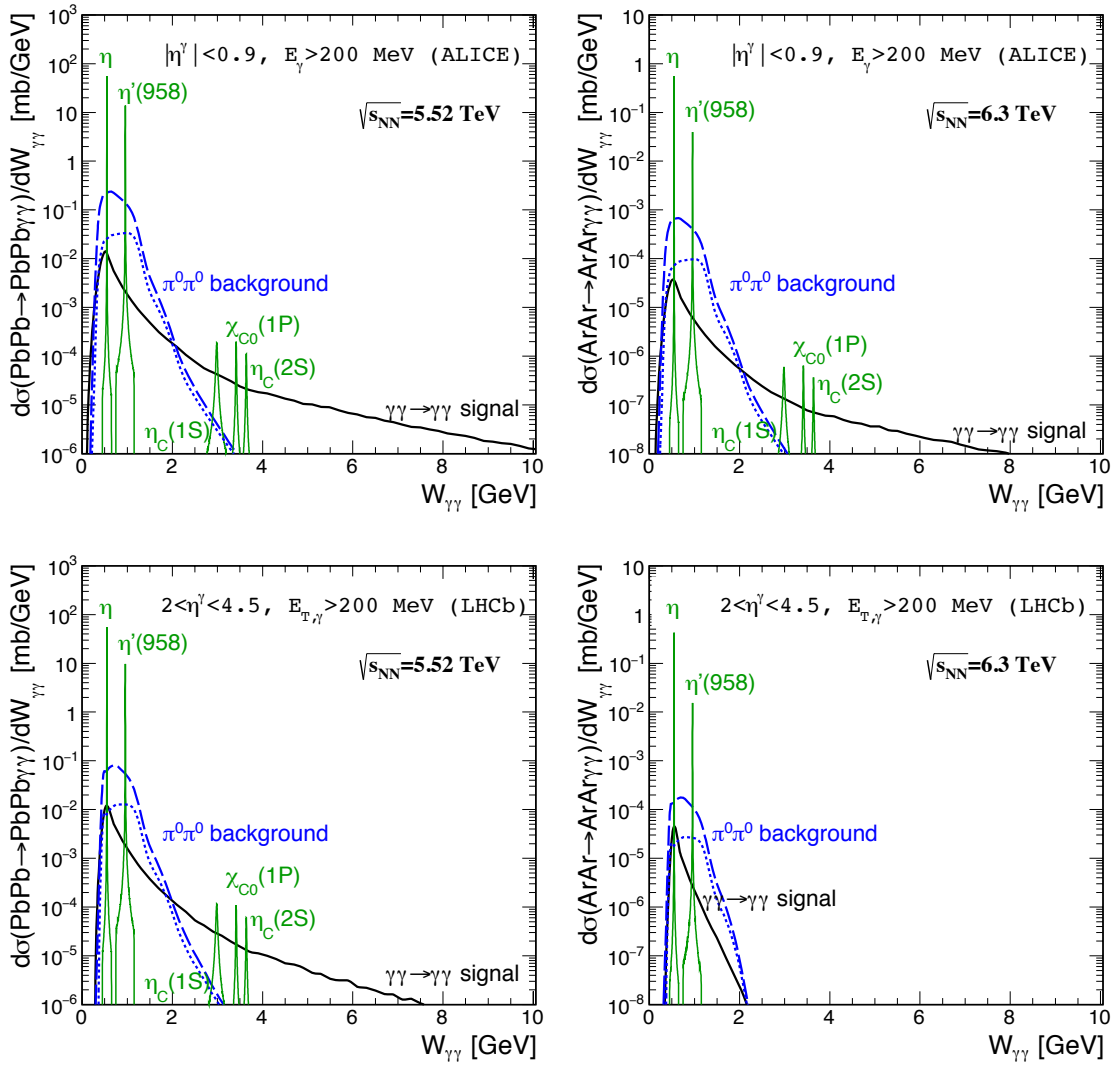

Fig. 101: Di-photon invariant mass distributions for Pb–Pb collisions at $\sqrt{s_{\rm NN}} = 5.52\,\text{TeV}$ (left) and Ar–Ar collisions at $\sqrt{s_{\rm NN}} = 6.3\,\text{TeV}$ (right) for ALICE at mid-rapidity (top) and LHCb at forward pseudorapidity (bottom). The $\pi^0\pi^0$ background is shown with the acoplanarity requirement of 0.01 (dotted line) and also without it (dashed line).

in Ref. [980], and then in Ref. [982] using the recent observation of LbyL scattering published by the ATLAS experiment in Pb–Pb collisions [809], where the electric field produced by the ultra-relativistic Pb is of the order of 10^{25} V/m (thus satisfying the above condition).

The potential of ALP searches in UPC Pb–Pb collisions is studied using detector-level quantities after the LbyL selection requirements are imposed. The overall selection efficiency (times acceptance) relative to generated events increases from about 40% to 65% for ALP masses ranging from 7 GeV to 80 GeV. Also, the mass resolution varies from 0.5 GeV at low masses (below 15 GeV) up to 1 GeV for larger masses. In the left panel of Fig. 102 the expected mass distributions for three ALP signal mass values, and the main background from LbyL normalised to integrated luminosity of 10 nb^{-1} are shown. In this study, other sources of backgrounds are neglected, since they have been found to be small in the LbyL measurement [809]. The invariant mass distribution is used as the discriminating variable, with bin widths comparable to the expected resolution of a narrow resonant signal. Upper limits are set on

the product of the production cross section of new resonances and their decay branching ratio into $\gamma\gamma$. Exclusion intervals are derived using the CLs method [983] in the asymptotic approximation. The limit set on the signal strength μ is then translated into a limit on the signal cross section times branching ratio as presented in the right panel of Fig. 102.

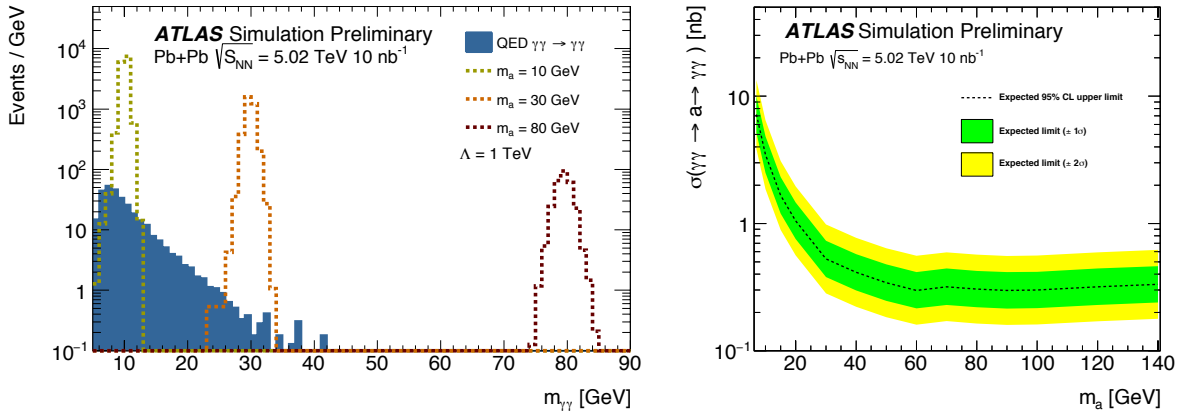

Fig. 102: (Left) Mass distribution for the ALP signal shown for three values of the ALP mass: $m_{\mathrm{a}} = 10, 30$ and 80 GeV (in red). Also shown (in blue) the LbyL background (see text). All ALP mass points are generated with $\Lambda = 1$ TeV ($1/\Lambda$ is the coupling of the interaction) which follows a convention defined in Ref. [980]. (Right) Expected 95% CLs upper limits on $\sigma_{\mathrm{a}\to\gamma\gamma}$.

In Fig. 103 exclusion limits on the coupling, $1/\Lambda$, as a function of m_{a} are presented along with the existing results from the compilation discussed in Ref. [984]. The ATLAS 20 nb^{-1} limit is derived using Pb–Pb collisions at 5.52 TeV. These results demonstrate that heavy-ion collisions have unique sensitivity to ALP searches in the range of $m_{\mathrm{a}} = 7 - 140$ GeV, where the previous results based on available Pb–Pb data by ATLAS and CMS [958, 980] are also shown (labelled as ATLAS $\gamma\gamma \to \gamma\gamma$ and CMS $\gamma\gamma \to \gamma\gamma$ in the figure).

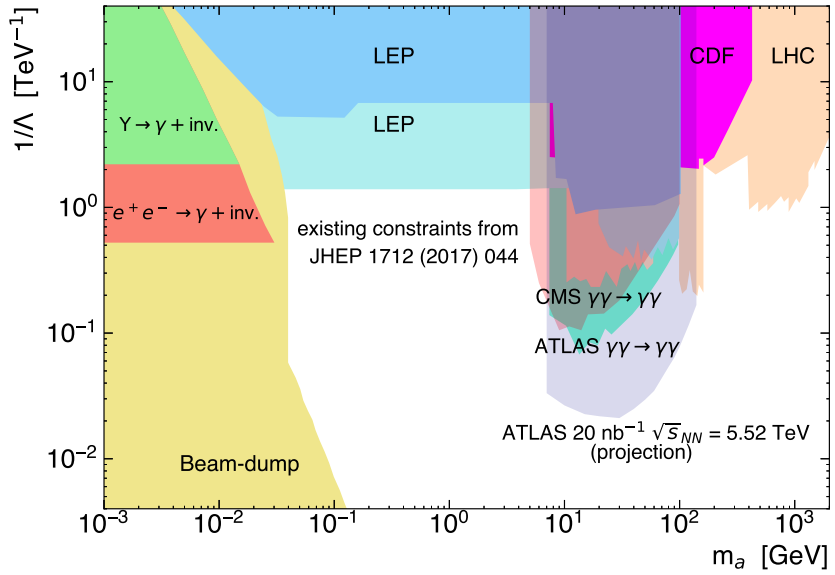

Fig. 103: Compilation of exclusion limits obtained by different experiments (see text). In light grey, the ATLAS 20 nb^{-1} limit at $\sqrt{s_{\mathrm{NN}}} = 5.52$ TeV is presented. The ATLAS $\gamma\gamma \to \gamma\gamma$ represents the exclusion limit derived from the LbyL cross section measured in Pb—Pb collisions by ATLAS [809], while the CMS $\gamma\gamma \to \gamma\gamma$ limit comes from the recent analysis described in Ref. [958]. A more complete version of the existing constraints on ALPs masses versus coupling, including the constraints in the sub meV range from astrophysical observations and from dedicated experiments such as CAST can be found in Ref. [977].

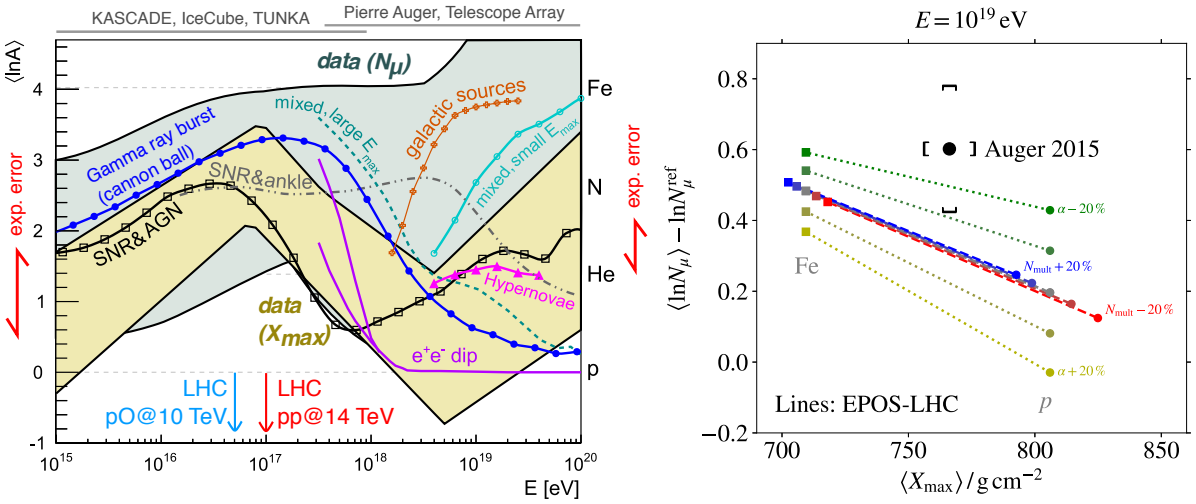

Fig. 104: Left: Mass composition of cosmic rays quantified by $\langle \ln A \rangle$ as a function of cosmic ray energy E. See Ref. [985] for references to data (bands) and model predictions (markers and lines), and the text for a discussion. Right: Impact of changes of the hadron multiplicity $N_{\rm mult}$ (dashed lines) and the energy fraction α (dotted lines) which goes into neutral pions in collisions at the LHC energy scale on EPOS-LHC predictions for $X_{\rm max}$ and $\ln N_\mu$ in 10^{19} eV air showers, compared to Auger data [986]. The model lines represent all values that can be obtained for any mixture of cosmic nuclei from proton (bottom right) to iron (top left). The dashed and dotted lines represent modifications of $N_{\rm mult}$ and α in steps of $\pm 10\%$ from their nominal values.

11.3 Proton-oxygen collisions for cosmic ray research

Coordinators: Hans Dembinski (MPI for Nuclear Physics, Heidelberg)

Contributors: T. Pierog (Karlsruhe Institute of Technology), R. Ulrich (Karlsruhe Institute of Technology)

The recent coincident observations of gamma rays and neutrinos from the flaring blazar TXS 0506+056 confirmed that active galactic nuclei produce high-energy cosmic rays [987]. This long awaited finding demonstrates that sources of cosmic rays are linked to the most violent places in our universe. Measurements of cosmic rays contribute to the understanding of the high-energy universe. Since cosmic rays are charged and bent by magnetic fields in space onto chaotic paths, their arrival directions at Earth are highly isotropic, but their mass composition carries an imprint of the source physics. Precision measurements of minimum-bias events in proton-oxygen collisions have the unique power to resolve current ambiguities in the mass composition measured with atmospheric air-shower techniques.

Cosmic rays are nuclei from protons to iron (heavier elements are negligible). The energy-dependent mass composition of cosmic rays is characteristic for different source scenarios, as shown in Fig. 104, left-hand-side, which displays predictions (lines and markers) of the mean-logarithmic-mass $\langle \ln A \rangle$ of cosmic rays. Above particle energies of 10^{15} eV, $\langle \ln A \rangle$ can only be indirectly inferred from extensive air showers, huge secondary particle cascades produced by collisions between cosmic rays and nuclei in the atmosphere. The two leading observables to infer $\langle \ln A \rangle$ are the depth $X_{\rm max}$ of the shower maximum in the atmosphere (yellow band in Fig. 104), and the number N_μ of muons produced in the shower (green band in Fig. 104). The width of those bands has two main contributions: the experimental uncertainties, and the hadronic model uncertainties inherent in converting the air shower observables into $\langle \ln A \rangle$.

Leading experiments achieve an instrumental accuracy of 10 % of the proton-iron difference, which would strongly discriminate between source scenarios, but air shower simulations are required

to convert N_μ and X_{max} to $\langle \ln A \rangle$ and this adds a large model uncertainty. The simulations use the multi-purpose heavy-ion event generator EPOS-LHC [988], or specialized hadronic interaction models such as QGSJet-II.04 [989] and SIBYLL-2.3c [990]. All are designed to describe nucleus-nucleus and soft-QCD interactions by extrapolating combinations of Regge field theory tuned to available data and perturbative QCD. Uncertainties in these models arise from a lack of data on multiparticle production in the very forward phase-space in hadron-nucleus interactions at the TeV scale.

LHC measurements have already reduced the spread of model predictions for X_{max} in the latest generation of models. This big improvement was due to high-precision measurements of the inelastic cross-section (see e.g. [991] and references therein). Further measurements now have the potential to make the spread negligible. The model spread for N_μ is still large and predictions are not consistent with X_{max} for cosmic rays with the same mass. There is overwhelming evidence from air shower experiments [986, 992–995] that the muon number N_μ is underestimated in simulations starting at about 10^{16} eV. This corresponds to a cms energy of 4.3 TeV, well accessible by the LHC. Shown in Fig. 104, right-hand-side, is a representative data point from the Pierre Auger Observatory, which is well above EPOS-LHC predictions – and EPOS-LHC and SIBYLL-2.3c are already models which produce the highest muon number of all hadronic interaction models models. This is called the *Muon Puzzle*.

Two aspects of multi-particle production with a strong effect on N_μ have been identified [996], the hadron multiplicity N_{mult} and the energy fraction α that goes into neutral pions. The impact of changing these variables in EPOS-LHC at 13 TeV cms energy and extrapolating upward in energy is also shown in Fig.104, right-hand-side. A combined measurement to 5 % accuracy of both variables at the LHC would reduce the model uncertainty for the conversion of X_{max} to $\langle \ln A \rangle$ well below the experimental uncertainty of 10 %, and has the clear potential to resolve the discrepancy in the muon number N_μ. To reach the accuracy goal, the following minimum-bias measurements are desired:

- Double-differential production cross-section for charged pions, kaons, and protons:
  ALICE $|\eta| < 0.9$, LHCb $2 < \eta < 5$
- Production cross-section for neutral pions and neutrons: LHCf $\eta > 8.4$.
- Energy flow over pseudo-rapidity, separated for hadrons and gammas:
  CMS+CASTOR $-6.6 < \eta < 5.2$, ATLAS $-4.5 < \eta < 4.5$.

Energy flow measurements separated by hadronic and electromagnetic energy deposit constrain both N_{mult} and α, and can be done further forward than direct measurements of charged tracks. The particle identification provided by the ALICE and LHCb experiments provides important additional information, needed to tune and test internal parameters of hadronic interaction models. In particular, the number of produced baryons was found to strongly affect the number of muons in air showers at ground, despite their small number compared to pions [997].

To meet the accuracy goal, N_{mult} and α need to be measured in proton-oxygen collisions at the LHC, which directly mimic interactions of cosmic rays with the atmosphere. Constraining α and N_{mult} to 5 % with existing and future pp and p–Pb data is very challenging [999], since forward-produced hadrons experience strong nuclear modification [327, 754, 1000]. A sufficiently accurate theory to predict nuclear modification in the p–O system based on pp and p–Pb data is not yet available, and a simple interpolation is not reliable since both systems are far away in $\ln A$. The difficulty of predicting hadron production in ion collisions is demonstrated in Fig. 105. EPOS-LHC predictions for Xe–Xe collisions significantly underestimate the observed yields in the central region, despite a satisfactory description of pp, p–Pb, and Pb–Pb collisions. The deviations in Xe–Xe are much larger than what is expected from a simple interpolation [998]. The dominant nuclear effects are expected to be different for light and heavy collision partners. Light nuclei are described by the shell model and nucleon correlations are important. Lead nuclei can be described by a simpler model, essentially a Wood-Saxon potential with reduced nucleon correlations that cannot be probed well in experiments.

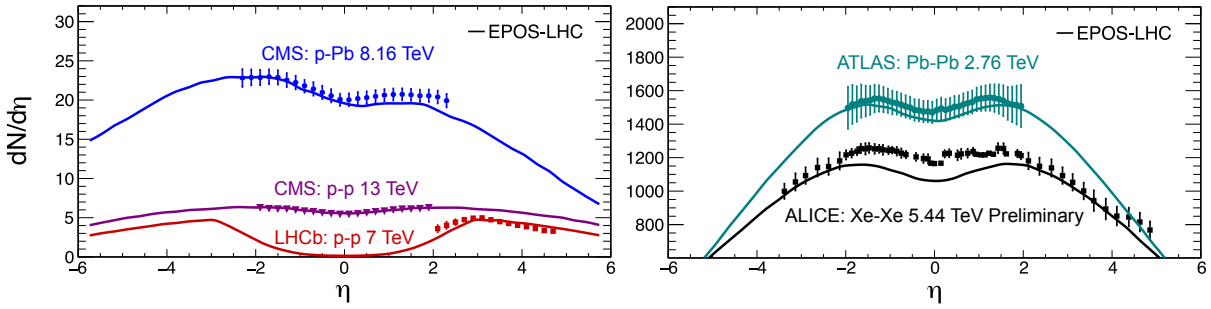

Fig. 105: Comparison of charged particle multiplicity measurements at different center-of-mass energies and in different colliding systems with the EPOS-LHC model [998]. Shown in both plots is $\mathrm{d}N/\mathrm{d}\eta$.

Selecting peripheral p–Pb collisions to mimic p-air collisions with the same number of binary collisions was considered as an alternative to direct p–O measurements, but this option also increases the uncertainty too much. Centrality in p–Pb collisions is extracted from the data using various centrality estimators with different selection biases. These biases would increase the uncertainty of the proposed measurements well beyond the target of 5 % [772]. However, p–O measurements could provide a sensitive test of centrality estimators since the thickness of the oxygen nucleus and hence the average number of wounded nucleons is about a factor of two smaller. The advantages of estimating centrality in a small ion system are discussed in Sect. 9.10.

In conclusion, collisions of p–O at the LHC are highly desirable to solve the outlined questions. The corresponding measurements would be a crucial input to cosmic ray physics and have the potential to result in significant advances in the century-long ridde of the origin of cosmic rays. The luminosity requirements to reach the physics goals are moderate. A statistical accuracy better than 5 % can be achieved with 100 M minimum-bias events. Luminosity calculations for light ion systems are given in Sect. 2.4. The setup of p–O collisions would follow the successful rapid set-up procedure previously used in the 2012 p–Pb run and the 2017 Xe–Xe run, as described in Sect. 2.5.

It is worthwhile noting that a period of oxygen acceleration in the SPS would also provide the opportunity to complement cosmic-ray related measurements of nuclear fragmentation at NA61/SHINE [1001, 1002] at beam momenta of $150\,A\,\mathrm{GeV}/c$. These measurements aim at improving our understanding of the cosmic-ray propagation in the Galaxy and to evaluate the cosmic-ray background for signatures of astrophysical dark matter [1003]. Another opportunity is the study of very forward production of hadrons in the p–O system at $\sqrt{s_{\mathrm{NN}}} \sim 100\,\mathrm{GeV}$ at the LHCb experiment, by colliding the oxygen beam with proton gas provided by an upgraded SMOG system, as described in Sect. 11.4.

11.4 Fixed-target prospects with LHC beams

Contributors: F. Fleuret (LLLR, Palaiseau), G. Graziani (INFN, Firenze), C. Hadjidakis (IPNO, Orsay), E. Maurice (LLR, Palaiseau), L. Massacrier (IPNO, Orsay), P. Di Nezza (INFN, Frascati), L. Pappalardo (University and INFN Ferrara), P. Robbe (LAL, Orsay), B. Trzeciak (Institute for Subatomic Physics, Utrecht)

Fixed target experiments present many advantages having the versatility of polarised and nuclear targets and allowing one to reach high luminosities with dense and long targets. The 7 TeV proton and 2.76 A.TeV lead beams allow one to reach a centre-of-mass energy per nucleon pair of $\sqrt{s_{\rm NN}} = 115$ GeV and $\sqrt{s_{\rm NN}} = 72$ GeV with a centre-of-mass rapidity boost of 4.8 and 4.2 units, respectively. These energies correspond to an energy domain between the SPS and nominal RHIC energies. The large rapidity boost implies that the backward rapidity region ($y_{\rm cms} \leq 0$) is easily accessible by using standard experimental techniques or existing LHC experiments such as ALICE or LHCb.

The physics opportunities offered by a fixed-target programme at the LHC have been developed in several publications of the AFTER@LHC study group [503, 507, 1004] and can be summarised as follows:

- advance our understanding of the large-x gluon, sea quark and heavy-quark content in the nucleon and nucleus,
- advance our understanding of the dynamics and spin of gluons inside polarised nucleons (if a polarised target were used),
- advance our understanding of the properties of the Quark-Gluon Plasma formed in heavy-ion collisions between SPS and RHIC energies.

11.4.1 Status and future plans in LHCb

The LHCb experiment has pioneered fixed target physics at the LHC since Run 2, using noble-gas targets (helium, neon and argon) obtained by injecting the gas directly in the LHC vacuum pipe in the proximity of the LHCb collision point through the SMOG device [1005]. The nominal target gas pressure of 2×10^{-7} mbar corresponds, for a typical LHC beam of 10^{14} protons, to a luminosity of $6 \times 10^{29} \mathrm{cm}^{-2}\mathrm{s}^{-1}$ for collisions occurring in one meter of gas along the beam direction, which is roughly the acceptance of the LHCb vertex detector.

The forward geometry of the detector is particularly well suited for this configuration. It provides three units of pseudorapidity corresponding to mid and backward rapidities ($-2.8 < y_{cms} < 0.2$ for a beam energy of 6.5 TeV), fully equipped with tracking and particle identification. Proton-nucleus and Pb-nucleus collisions using fixed targets of different nuclear size can be studied at the energy scale of $\sqrt{s_{\rm NN}} \sim 100$ GeV with unique coverage of the high-x regime in the target nucleon.

The samples collected during Run 2, corresponding to integrated luminosities up to about $100\ \mathrm{nb}^{-1}$, allowed to perform studies of particle production which are of particular relevance to cosmic ray physics [100 and to collect unprecedented samples of charmed hadrons in fixed-target collisions at this energy scale [506]. These data can provide unique inputs to discriminate cold nuclear matter effects in heavy-flavour production from the effect of deconfinement, and to study nuclear PDFs at large x. The physics reach of heavy-flavour studies is presently limited by the size of these samples. Measurements of absolute cross-sections are also limited in accuracy by the determination of the luminosity, since the gas pressure can be controlled only within $\pm 50\%$ with the SMOG device. For the first fixed-target physics results, the integrated luminosity has been determined from the rate of elastically scattered atomic electrons with a precision of 6% [1006].

An upgraded gas target device, named SMOG2, is currently being developed, and expected to be operational already during Run 3. In the new setup, the gas is contained in a storage cell, consisting of a 20-cm-long open-ended tube with a diameter of 1 cm, fed by a capillary. It allows to increase the gas

Table 16: Expected yields of reconstructed events for some benchmark channels using the largest fixed-target data sample acquired with SMOG during the LHC Run 2, and possible with SMOG2, using as example a p–Ar sample of 0.1 fb^{-1}.

	SMOG largest sample p–Ne@68 GeV	SMOG2 example p–Ar@115 GeV
Integrated luminosity	~ 100 nb^{-1}	100 pb^{-1}
syst. error on J/ψ x-sec.	6–7%	2–3 %
J/ψ yield	15k	35M
D^0 yield	100k	350M
Λ_c yield	1k	3.5M
ψ(2S) yield	150	400k
$\Upsilon(1S)$ yield	4	15k
Low-mass ($5 < M_{\mu\mu} < 9$ GeV/c^2) Drell-Yan yield	5	20k

density in the target by at least one order of magnitude with respect to SMOG, reaching luminosities of order 10^{31} cm^{-2}s^{-1} with proton beams. The target is placed upstream, from -50 to -30 cm, the nominal LHCb collision point and is thus not overlapping the luminous pp region. This opens the possibility to acquire fixed target events simultaneously with collision events with negligible impact to the pp physics program. The new setup would also allow other gases to be injected, notably hydrogen and deuterium, providing pp collisions in fixed-target mode as a reference for all pA collision samples, and extending the physics case to the study of the three-dimensional structure functions of the nucleon through spin-independent observables [1007]. Heavy noble gases as Kr and Xe would also be usable. The device will be equipped with a gas feed system, allowing to know the target gas density at 1% level.

Assuming that about 10% of the beam intensity can be exploited for fixed-target physics, either in synergy with pp data taking or through dedicated runs, samples corresponding to integrated luminosities of order 0.1 fb^{-1} (using proton beams) and 0.1 pb^{-1} (using Pb beams) can be collected per year, also profiting from the increased beam intensity provided by the HL-LHC.

Samples of this size would allow copious production of Drell-Yan and heavy flavour states, including $b\bar{b}$ mesons. As an example, rough estimates are provided in Table 16 for the yields of reconstructed events in an assumed sample of p–Ar collisions corresponding to 0.1 fb^{-1}. Substantial advancements in the understanding of parton distributions for gluons, antiquark and heavy-quarks at large x, where PDFs are now poorly constrained, are foreseeable [507, 1004]. The precise determination of heavy hadron production at large x is expected to clarify the extent of the intrinsic heavy quark content in the nucleon [931, 1008], and to constrain modifications of the nuclear PDFs due to initial state effects (anti-shadowing and EMC effect [1009], saturation effects [1010]). Sequential quarkonia suppression is a main signature for deconfinement [427], but is also affected by final state effects as break-up of the heavy quark pair [1011] and statistical recombination [428]. The rich samples of different quarkonia states reconstructed in fixed target data will allow to investigate sequential suppression at an energy scale between the SPS and RHIC/LHC, for collision systems ranging from pp to Pb–Xe. The study of collisions of Pb beams on heavy nuclei has been limited in Run 2 by the detector tracking capabilities and would greatly profit from the higher detector granularity offered by the LHCb upgrade 1 and upgrade 2 detectors.

The fixed-target program also presents a very good testbed for the hydrodynamic description of the QCD medium produced in heavy-ion collisions down to the energy of $\sqrt{s_{\rm NN}} \sim 100$ GeV, thanks to the considerable pseudorapidity coverage, with particle identification capability for pions, kaons and protons as well as neutral particles ϕ, K^0_S and Λ^0. Measurements of flow observables and correlations

can contribute in particular to shed light on the extension of the hydrodynamic description [1012, 1013] successful at top RHIC energy and at the LHC towards lower beam energies requiring an appropriate treatment of baryon density [1014], and a fully 3 dimensional initial state [1015]. This can provide important inputs to the search for the critical point in the QCD phase diagram [155, 1016]. In addition, the extension of the fluid dynamical paradigm towards smaller collision systems as an explanation of the experimental findings in proton(deuteron)-nucleus and pp collisions at the LHC [315–318, 720] and at RHIC [1017] can be probed in a novel kinematic regime.

The study of ultra-peripheral collisions in the fixed target configuration also offers a complementary kinematic regime to the similar studies in beam-beam collisions discussed in Section 10. An intriguing possibility would be the observation of η_c photoproduction in the PbAr sample, where the cross section is estimated to be of order 1 nb [1018] provided that the signal can be cleanly separated from the background due to radiative J/ψ decays. This would constitute a confirmation for the existence of the odderon, since the η_c state cannot be produced in the γ-pomeron process and would be under threshold for the γ-γ process in fixed-target PbA collisions. Large samples of exclusively produced ρ^0 and ω are also expected [1019].

Studies of proton collisions on light nuclei provide crucial inputs to the understanding of cosmic ray propagation in the interstellar medium (using H and He targets) and in the atmosphere (using N and O targets). The interpretation of the precise measurements of the antiproton component in cosmic rays, performed in the last decade by the PAMELA [1020] and AMS-02 [1021] space-based missions, is presently limited by the knowledge of the antiproton production in the interstellar medium. The first measurement of antiproton production in pHe collisions has been performed by LHCb with Run 2 data [1006] and has been used to improve the sensitivity to a possible dark matter contribution to the cosmic antiproton flux [1022, 1023]. During Run 3, it is planned to extend these studies with a hydrogen target. The production of antineutrons can also be inferred indirectly by evaluating isospin violation in antiproton production from proton-hydrogen and proton-deuterium collisions.

A better understanding of the bulk of particle production in high-energy hadronic collisions is also crucial to the modeling of atmospheric showers induced by ultra-high-energy cosmic rays. Despite the moderate energy scale, fixed target data offer the unique possibility to use a wide range of nuclear targets, including nitrogen and oxygen, and to study production at large x. The main background for the observation of the astrophysical high-energy neutrino flux, recently established by the IceCube collaboration [1024], originates from neutrinos of PeV energy produced from decays of charmed hadrons in atmospheric showers. A relevant uncertainty on this background is related to the possible intrisic charm contribution to the charm PDF at large x [1025]. Knowledge of light hadron production, notably baryons, at large x will allow to improve the modeling of the number of muons produced in the lateral development of the showers, which is a key observable to infer the mass composition of ultra-high-energy cosmic rays, as discussed in Sect. 11.3.

More ambitious projects for future target upgrades have also been proposed for a possible installation in LHCb on the time scale of HL-LHC. These are beyond the baseline LHCb Upgrade 2. A polarised gas target similar to that used in HERMES [1026], installed upstream of the LHCb vertex detector, would make LHCb a key contributor to spin physics. With this option, LHCb would have access to single spin asymmetries in an unique kinematic range for a variety of final states, including unique measurements with quarkonium and Drell-Yan lepton pairs [1027]. Measurements of the three-dimensional structure of nucleons from hadron collisions would be highly complementary to the program at the electron-ion collider, which is proposed on a comparable time scale.

11.4.2 Opportunities with ALICE

The ALICE detector provides many physics opportunities if running in the fixed-target mode with the LHC proton and lead beams. One of the main strengths of ALICE in the fixed-target mode would be

its large rapidity coverage. Assuming a target location at $z = 0$, the ALICE muon spectrometer would access the mid- to backward rapidity in the centre-of-mass frame ($-2.3 < y_{\rm cms}$[6] < -0.8) considering an incident proton beam on the target. For an incident lead beam, the muon spectrometer rapidity coverage is $-1.8 < y_{\rm cms} < -0.3$. In addition, the absorber in front of the muon tracking stations is an asset for background rejection and Drell-Yan studies. The ALICE central barrel offers a complementary coverage to the muon arm by accessing the very backward rapidity region ($-5.7 < y_{\rm cms} < -3.9$ with the proton beam and $-5.2 < y_{\rm cms} < -3.4$ with the lead beam), reaching the end of the phase space for several probes. Thanks to its excellent particle identification capabilities, particle detection and identification down to low $p_{\rm T}$, unique measurements of soft probes and open heavy flavours can be pursued. Another asset of the ALICE apparatus is the capability to operate with good performance in a high particle density environment. Access to the most central AA collisions at $\sqrt{s_{\rm NN}} = 72$ GeV should be possible if the detector occupancy does not exceed the one expected in Pb–Pb collisions at 50 kHz. In addition, the ALICE Collaboration could potentially devote a significant data taking time to a fixed-target programme (especially with the proton beam), allowing the collection of large integrated luminosities and the investigation of several target species.

Two main solutions are being investigated to deliver fixed-target collisions to ALICE: an internal gaseous target or an internal solid target (coupled to a bent crystal to deflect the beam halo). On the one hand, a gas-jet or a storage cell with levelled gas pressure would allow to deliver about 45 pb^{-1} of proton-polarised hydrogen collisions to ALICE (260 pb^{-1} in case of unpolarised H_2 collisions), and 8 nb^{-1} of Pb–Xe collisions per year. For the luminosity calculation, a time duration of 10^7 s and 10^6 s, corresponding to one LHC year, is considered for the proton and lead beams, respectively. With a gas system the target can be polarised, but requires large space to be installed, most likely outside the ALICE barrel magnet, 7 metres from the nominal Interaction Point (IP). In that case, additional detectors for vertexing are needed as well as studies of the tracking performances of the TPC in such conditions. A simple unpolarised storage cell might potentially be used closer to the current ALICE IP. On the other hand, the usage of an internal solid target coupled to a bent crystal has the advantage of more portability, allowing one to install the target closer to the IP, from 2.75 to 4.7 m to the IP, and thus benefiting of better performances from the current ALICE apparatus. With such a device 37 pb^{-1} (6 pb^{-1}) of p–C (p–W) collisions, and 5 nb^{-1} (3 nb^{-1}) of Pb–C (Pb–W) collisions could be registered in ALICE per year. One of these solutions could be installed during LS3.

The performance for several key probes has been investigated using fast simulations [507] and it is summarised in the following.

- Quarkonia: Very large yields are expected for charmonia (up to $\sim 10^6$ J/ψ) in the ALICE muon spectrometer both in pp and Pb-A collisions[7] considering one LHC year of data taking. The $\Upsilon(1S)$ will also be within reach. Looking at quarkonium suppression as a function of rapidity and the system size would allow one to search for the onset of the QGP formation, and to determine the in-medium modification of the QCD forces for centre-of-mass energies between the ones probed at RHIC and the SPS. In pA collisions, $\Upsilon(1S)$ could be used to probe large-x gluons in the target ($0.1 < x < 1$), in order to constrain the anti-shadowing and EMC effects.
- Drell-Yan: A precise measurement of the Drell-Yan process with the muon spectrometer can probe initial state effects on quarks of momentum fraction $0.05 < x < 0.8$ at a mass scale of $M_{\mu\mu} > 4$ GeV/c^2 from pA to A- collisions. The correlated background from $\rm b\bar{b}$ and $\rm c\bar{c}$ pairs in the dimuon decay channel is largely reduced at the lower centre-of-mass energy of the fixed-target mode, with respect to the TeV energy range.
- Open heavy flavour: At $y_{\rm lab} \sim 1$ about 3000 (up to 100) D^0 are expected to be produced per 0.1

[6] The rapidity is calculated assuming massless particles.

[7] The largest atomic mass number considered here is W for the solid target and Xe for the gas target.

rapidity unit per year in pp (Pb-A) collisions, respectively. The ALICE central barrel probes the end of the D meson phase-space, in particular if the vertex is located at $z < 4$ m from the IP. This would allow one to reach very large-x gluon close to 1 at low mass scale, where the contribution of the intrinsic charm component in the proton could largely increase the D meson yield. Hence the ALICE central barrel is well suited to study the large-x intrinsic charm component in the proton.

– Identified charged hadrons: In few hours of Pb–A data taking, it would be already possible to collect up to 10^6 minimum bias events with the ALICE central barrel which would allow one to reach an absolute statistical uncertainty of 0.01 on the elliptic flow coefficient v_2 for pions and protons, 0.02 for kaons, and 0.05 for antiprotons in semi-central events. Measurements of identified particles up to very large rapidities would complement the limiting fragmentation studies carried out by the BRAHMS and PHOBOS experiments at RHIC. In addition, particle yields and flow coefficients measured at large rapidities are powerful tools to constrain the temperature dependence of the medium shear viscosity [1028]. Thermal model calculations also indicate that the temperature and baryonic chemical potential depend on the rapidity [1029–1031] suggesting that one can perform a rapidity scan of the QGP phase diagram in a complementary approach to the Beam Energy Scan programme of RHIC.
– Antiproton production: Measurements of antiproton production cross sections in p–H, p–He, p–C, p–N and p–O collisions are important inputs for theoretical calculations of the secondary cosmic antiproton spectrum [1032–1034], where secondary antiprotons originate from the high energy scattering between the interstellar matter and the primary cosmic rays. The measurement of a cosmic antiproton excess with respect to expectations from secondary antiproton production would open new perspectives on the indirect detection of dark matter or unknown astrophysical mechanisms of cosmic ray acceleration. Complementarily to LHCb [1006], the ALICE central barrel can measure very slow antiprotons down to few hundred MeV momentum. Measuring slow antiprotons produced with the LHC proton beam on a nuclear target is equivalent to the case where the nuclear target travels at TeV energies, hit an interstellar proton at rest and produces an antiproton with high energy. Thanks to the large antiproton yields expected in p–H_2 collisions (larger than 10^8 per 0.1 rapidity unit per year), the ALICE central barrel is well placed to help constraining the uncertainty on the cosmic antiproton spectrum.
– Strangeness: Thanks to the large yields ($\sim 10^8$ per 0.1 rapidity unit per year at $y_{\rm lab} \sim 1$) of Λ hyperons expected to be produced in the ALICE central barrel by using a longitudinally polarised target with the proton beam, a precise measurement of the longitudinal spin transfer D_{LL} of the Λ hyperon could be carried out. So far only limited experimental results exist with poor precision [1035, 1036]. Measurements with ALICE would give a unique opportunity to study the spin-dependent strange quark (antiquark) densities at $0.35 < x < 0.7$.
– Charmonium and pentaquark photoproduction: Exclusive J/ψ photoproduction is known to be sensitive to gluon Generalised Parton Distributions (GPD) at leading order [1037]. ALICE in fixed target mode would have a unique opportunity to study the yet unknown GPD $E_{\rm g}$ thanks to the measurement of single transverse spin asymmetries of photoproduced J/ψ by using a transversally polarised H target with the proton beam [1038, 1039]. About 200 photoproduced J/ψ per year are expected to be produced in the muon spectrometer acceptance. Moreover, the photoproduction of hidden charm pentaquark states [1040] might be possible in the central barrel acceptance which allows for the access to low photon-proton centre-of-mass energies ($W_{\gamma p} \sim 5$ GeV). About 2 to 20 pentaquarks are expected to be produced in the ALICE central barrel per year in p–H_2 collisions.

Note that these studies were performed assuming a vertex position at the ALICE IP for the quarkonia, identified hadron production, as well as for charmonium and pentaquark photoproduction, and a vertex position at 4.7 m from the IP for the antiproton and strangeness production.

Studies are ongoing to address the technical feasibility of the target system integration in the

experiment, as well as simulation studies to evaluate the ALICE apparatus tracking performance for target positions displaced by a few metres from the IP. Moreover, investigations are ongoing to extend the ALICE rapidity coverage for several observables thanks to combined measurements of muons detected both in the ALICE central and the muon spectrometer (see as an example the work in [1041] in collider mode).

12 Summary of luminosity requirements and proposed run schedule

The physics programme presented in this report requires data-taking campaigns with various colliding systems with centre-of-mass energies and integrated luminosities $L_{\rm int}$ as outlined in the following. In some cases the requirements are updated or new with respect to the present baseline LHC programme (see Sec. 2.2 and Ref. [2]). The main variations are: a much larger $L_{\rm int}$ target for p–Pb collisions, motivated by high-precision studies of both initial and final-state effects, following the surprising discoveries of collective-like effects in small collision systems; a large sample of pp collisions at top LHC energy to reach the highest possible multiplicities with the smallest hadronic colliding system; moderate-statistics samples of O–O (as mentioned in 2.5, this would be a limited "pilot-run" scenarion that could not achieve the values listed in Tables 4 and 5) and p–O collisions, to study the onset of hot-medium effects and to tune cosmic-ray particle production models, respectively. Finally, as discussed in Sec. 11.1, extended LHC running with colliding intermediate-mass nuclei (as, for example, Ar–Ar or Kr–Kr), offers the unique opportunity of a large increase in nucleon–nucleon luminosity to access novel probes of the QGP and to open a precision era for probes which are still rare with the Pb–Pb system. The working group considers the high-luminosity Pb–Pb and p–Pb programmes to be the priorities that should be pursued in Run 3 and Run 4. High-luminosity runs with intermediate-mass nuclei are regarded as an appealing case for extending the heavy-ion programme at the LHC after LS4. This case, including the choice of the optimal nuclear species, should be studied further from the theoretical and operational points of view, both of which could be informed with one or two pilot runs with different species.

- **Pb–Pb at $\sqrt{s_{\rm NN}} = 5.5$ TeV**, $L_{\rm int} = 13\ {\rm nb}^{-1}$ (ALICE, ATLAS, CMS), $2\ {\rm nb}^{-1}$ (LHCb)
- **pp at $\sqrt{s} = 5.5$ TeV**, $L_{\rm int} = 600\ {\rm pb}^{-1}$ (ATLAS, CMS), $6\ {\rm pb}^{-1}$ (ALICE), $50\ {\rm pb}^{-1}$ (LHCb)
- **pp at $\sqrt{s} = 14$ TeV**, $L_{\rm int} = 200\ {\rm pb}^{-1}$ with low pileup (ALICE, ATLAS, CMS)
- **p–Pb at $\sqrt{s_{\rm NN}} = 8.8$ TeV**, $L_{\rm int} = 1.2\ {\rm pb}^{-1}$ (ATLAS, CMS), $0.6\ {\rm pb}^{-1}$ (ALICE, LHCb)
- **pp at $\sqrt{s} = 8.8$ TeV**, $L_{\rm int} = 200\ {\rm pb}^{-1}$ (ATLAS, CMS, LHCb), $3\ {\rm pb}^{-1}$ (ALICE)
- **O–O at $\sqrt{s_{\rm NN}} = 7$ TeV**, $L_{\rm int} = 500\ \mu{\rm b}^{-1}$ (ALICE, ATLAS, CMS, LHCb)
- **p–O at $\sqrt{s_{\rm NN}} = 9.9$ TeV**, $L_{\rm int} = 200\ \mu{\rm b}^{-1}$ (ALICE, ATLAS, CMS, LHCb)
- **Intermediate AA**, e.g. $L_{\rm int}^{\rm Ar-Ar} = 3$–$9\ {\rm pb}^{-1}$ (about 3 months) gives NN luminosity equivalent to Pb–Pb with $L_{\rm int} = 75$–$250\ {\rm nb}^{-1}$

Based on these requirements, the proposed updated running schedule is reported in the following table. It can be seen that the physics programme for Run 3 and Run 4 discussed in this report is achievable by a modest increase of the "heavy-ion running" time from 12 to 14 weeks per run.

Year	Systems, $\sqrt{s_{\rm NN}}$	Time	$L_{\rm int}$
2021	Pb–Pb 5.5 TeV	3 weeks	$2.3\ \mathrm{nb}^{-1}$
	pp 5.5 TeV	1 week	$3\ \mathrm{pb}^{-1}$ (ALICE), $300\ \mathrm{pb}^{-1}$ (ATLAS, CMS), $25\ \mathrm{pb}^{-1}$ (LHCb)
2022	Pb–Pb 5.5 TeV	5 weeks	$3.9\ \mathrm{nb}^{-1}$
	O–O, p–O	1 week	$500\ \mu\mathrm{b}^{-1}$ and $200\ \mu\mathrm{b}^{-1}$
2023	p–Pb 8.8 TeV	3 weeks	$0.6\ \mathrm{pb}^{-1}$ (ATLAS, CMS), $0.3\ \mathrm{pb}^{-1}$ (ALICE, LHCb)
	pp 8.8 TeV	few days	$1.5\ \mathrm{pb}^{-1}$ (ALICE), $100\ \mathrm{pb}^{-1}$ (ATLAS, CMS, LHCb)
2027	Pb–Pb 5.5 TeV	5 weeks	$3.8\ \mathrm{nb}^{-1}$
	pp 5.5 TeV	1 week	$3\ \mathrm{pb}^{-1}$ (ALICE), $300\ \mathrm{pb}^{-1}$ (ATLAS, CMS), $25\ \mathrm{pb}^{-1}$ (LHCb)
2028	p–Pb 8.8 TeV	3 weeks	$0.6\ \mathrm{pb}^{-1}$ (ATLAS, CMS), $0.3\ \mathrm{pb}^{-1}$ (ALICE, LHCb)
	pp 8.8 TeV	few days	$1.5\ \mathrm{pb}^{-1}$ (ALICE), $100\ \mathrm{pb}^{-1}$ (ATLAS, CMS, LHCb)
2029	Pb–Pb 5.5 TeV	4 weeks	$3\ \mathrm{nb}^{-1}$
Run-5	Intermediate AA	11 weeks	e.g. Ar–Ar 3–9 pb^{-1} (optimal species to be defined)
	pp reference	1 week	

13 First considerations on a heavy-ion programme at a High Energy LHC (HE-LHC)

Coordinators: Andrea Dainese (INFN Padova), David d'Enterria (CERN) and Carlos A. Salgado (Instituto Galego de Fisica de Altas Enerxias (IGFAE) Universidade de Santiago de Compostela)

Contributors: L. Apolinario (LIP and IST Lisbon), N. Armesto (Instituto Galego de Fisica de Altas Enerxias (IGFAE) Universidade de Santiago de Compostela), J. Jowett (CERN), G. Milhano (LIP and IST Lisbon, CERN), U.A. Wiedemann (CERN)

13.1 Introduction

In this section the physics opportunities associated with the operation of the HE-LHC with heavy-ion beams are discussed. These first considerations are based on studies carried out in the scope of the Future Circular Collider (FCC) Study group [411, 1042]. For a centre-of-mass energy $\sqrt{s} = 27$ TeV for pp collisions, the relation $\sqrt{s_{\rm NN}} = \sqrt{s}\sqrt{Z_1 Z_2 / A_1 A_2}$ gives the energy per nucleon–nucleon collision of $\sqrt{s_{\rm NN}} = 10.6$ TeV for Pb–Pb ($Z = 82$, $A = 208$) and 17 TeV for p–Pb collisions. The present estimate of the integrated luminosity per month of running is larger by a factor two with respect to the current projection for the future LHC runs, i.e. $L_{\rm int} \approx 6\ {\rm nb}^{-1}$ per experiment, see Section 2.2. The possibility of using nuclei smaller than Pb, like e.g. ^{40}Ar or ^{129}Xe, to achieve larger instantaneous luminosity is also under consideration. For example, the integrated nucleon–nucleon (NN) luminosity per run for Xe–Xe collisions at $\sqrt{s_{\rm NN}} = 11.5$ TeV could be 2–3 times larger than for Pb–Pb collisions (see integrated $L_{\rm NN}$ values in Tables 4 and 5).

The increase in the centre-of-mass energy and integrated luminosity at the FCC with respect to the LHC opens up novel opportunities for physics studies of the Quark-Gluon Plasma (QGP) described in a recent CERN Yellow Report [411]. Most of these opportunities also apply to the HE-LHC scenario, although with more moderate reach in terms of available probes and kinematics coverage. The main scientific motivations for a heavy-ion programme at the HE-LHC can be summarized as follows.

Novel access to QCD thermodynamics and QCD equilibration processes. Substantially increasing the centre-of-mass energy leads to the creation of initially denser and hotter strongly-interacting systems that expand for a longer duration and over a larger volume, thereby developing stronger collective phenomena. Extrapolations of LHC measurements indicate that the initial energy density increases by a factor about 1.4 from $\sqrt{s_{\rm NN}} = 5.5$ TeV to 10.6 TeV, up to values of about 22–24 GeV/fm^3 (at $\tau = 1$ fm/c). These estimates are presented in Section 13.2. The QGP formed at the HE-LHC collision energies reaches closer to a range of temperatures ($T \sim 1$ GeV) where charm quarks start to contribute as active thermal degrees of freedom in the QGP equation of state, thus playing a novel role in QCD equilibration processes.

Characterisation of dense QCD matter through hard-scattering processes. As detailed in Section 13.3, the HE-LHC would provide a much larger abundance of hard-scattering processes than the LHC, as well as novel probes like the top quark and, potentially, the Higgs boson [942, 944, 1043]. A notable example is provided by high-momentum (thus, highly boosted) $\mathrm{t} \to \mathrm{W} \to \mathrm{q\bar{q}}$ decay chains, which are promising probes of the QGP time evolution and of the role of colour coherence [944]. The secondary production of charm quarks in scatterings between quark and gluon constituents of the hot QCD medium could reach a substantial fraction of the initial production in partonic hard scatterings and be observed for the first time.

Exploration of saturated parton densities in a previously-uncharted, ultra-dense kinematic domain. As discussed in Section 13.4, the higher centre-of-mass energy of the HE-LHC allows one to explore a wide previously-uncharted kinematic range at low x and Q^2, where parton saturation is expected to set in. Proton–nucleus collisions would have a coverage down to $x \sim 5 \times 10^{-6}$ in the Pb nucleus at a rapidity of $y \approx 5$.

Table 17: Global properties measured in central Pb–Pb collisions (0–5% centrality class) at $\sqrt{s_{\rm NN}} = 2.76$ TeV and extrapolated to 5.5, 10.6 and 39 TeV. The values for Pb–Pb collisions at the LHC and FCC are from Ref. [411]. The values for Pb–Pb collisions at the HE-LHC are estimated using the same parametrisations as used for the FCC. The values for Xe–Xe collisions at the HE-LHC are all estimated on the basis of the multiplicity extrapolation from the measurement by the ALICE Collaboration [1045] (it is assumed that the transverse energy density scales only with the multiplicity, neglecting possible differences of the average energy per particle between Pb–Pb and Xe–Xe and between the LHC and the HE-LHC).

System, $\sqrt{s_{\rm NN}}$ (Tev)	Pb–Pb, 2.76	Pb–Pb, 5.5	Pb–Pb, 10.6	Xe–Xe, 11.5	Pb–Pb, 39.4
$\mathrm{d}N_{\rm ch}/\mathrm{d}\eta$ at $\eta = 0$	1600	2000	2400	1500	3600
$\mathrm{d}E_{\rm T}/\mathrm{d}\eta$ at $\eta = 0$ (TeV)	1.7–2.0	2.3–2.6	3.1–3.4	≈ 1.5	5.2–5.8
Homogeneity volume fm^3	5000	6200	7400	4500	11000
Decoupling time (fm/c)	10	11	11.5	10	13
ε at $\tau = 1$ fm/c (GeV/fm^3)	12–13	16–17	22–24	≈ 15	35–40

13.2 Global characteristics of nucleus–nucleus collisions at the HE-LHC

Extrapolating measurements of charged particle multiplicity, transverse energy and femtoscopic correlations at lower energies, one can obtain estimates for the growth of global event characteristics from the LHC to the HE-HC and the FCC. In particular, up to the top LHC energy, the growth of charged-particle multiplicity per participant pair per unit rapidity in nucleus–nucleus collisions is consistent with a slowly-rising power-law: $\mathrm{d}N_{\rm ch}/\mathrm{d}\eta\,(\eta = 0) \propto (\sqrt{s_{\rm NN}})^{0.3}$ (see e.g. [1044]). As shown in Table 17, for Pb–Pb this amounts to an increase of a factor ~ 1.2 from the LHC to the HE-LHC. The multiplicity in central Xe–Xe collisions is expected to be lower by 35% with respect to Pb–Pb collisions at the HE-LHC, and similar to that of Pb–Pb collisions at 2.76 TeV.

In general, the global event characteristics listed in Table 17 determine the spatio-temporal extent QGP system, and they constrain the thermodynamic conditions that apply after thermalization. The measured transverse energy per unit rapidity $\mathrm{d}E_{\rm T}/\mathrm{d}\eta$ (see Table 17) is of particular importance since it constrains the initial energy density. The energy density is expected to increase by a factor 1.4 from the LHC to the HE-LHC, reaching a value of 22–24 GeV/fm^3 at the time of 1 fm/c [411]. Using the arguments presented in Ref. [411], an initial temperature as large as $T_0 \approx 600$–800 MeV is expected at the time $\mathcal{O}(0.05\,\mathrm{fm}/c)$ after which both nuclei traverse each other at HE-LHC energies. In the case of Xe–Xe collisions the energy density is estimated to be significantly lower than that for Pb–Pb and similar to that of Pb–Pb at LHC energies.

13.3 QGP studies with hard probes

13.3.1 Hard processes in nucleus–nucleus collisions at the HE-LHC

The increase in energy and luminosity (in the case of Xe–Xe) from the LHC to the HE-LHC provides new tools to study the matter created in the collisions of heavy ions. In Fig. 106 (left), cross sections for different processes and different energies are computed with MCFM [1046] at the highest available order. The increases amount to a factor ~ 2 for charm, beauty, W and Z production, ~ 4 for jets with $p_{\rm T} > 100$ GeV/c and for Higgs, and ~ 6 for top-pair production.

The motivations for measurements of top quarks in heavy-ion collisions are multifold. In p–Pb collisions the cross sections efficiently probe the nuclear gluon PDFs in a wide range in momentum fraction x at high scale $Q \sim m_{\rm t}$ [942] (see Section 10.4.4). In Pb–Pb collisions, the top-quark observables are sensitive to the energy-loss of heavy quarks [1047] and by selecting boosted (very high $p_{\rm T}$)

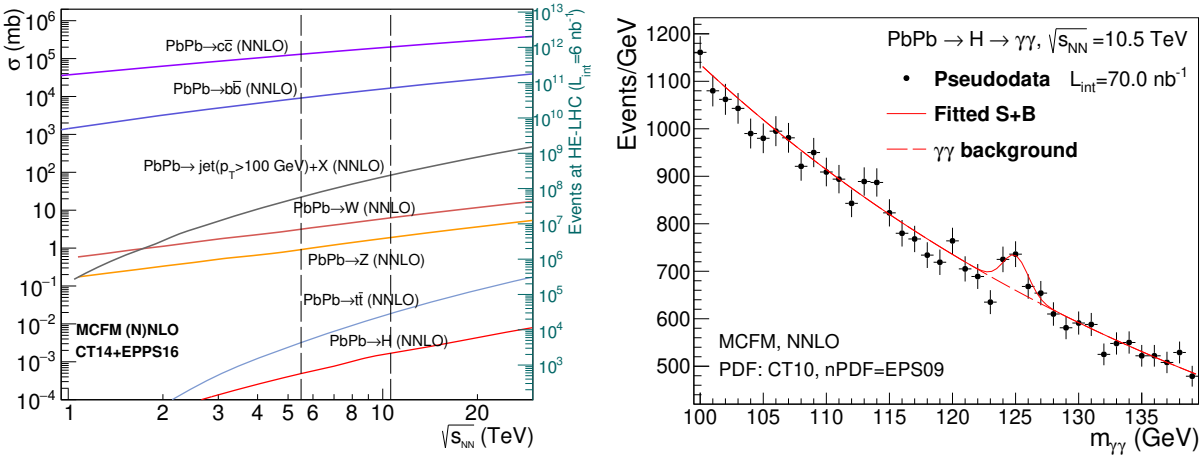

Fig. 106: Left: $\sqrt{s}$-dependence of the cross sections for hard processes of interest for a heavy-ion programme, calculated with MCFM [1046] at the highest available order. The yields for a one month Pb–Pb run ($L_{\rm int} = 6\ {\rm nb}^{-1}$) are also shown. Right: invariant mass distribution for Higgs boson search in the $\gamma\gamma$ decay channel in Pb–Pb collisions at the HE-LHC with $L_{\rm int} = 70\ {\rm nb}^{-1}$ using the selections described in Ref. [1043].

top quarks one could also probe the QGP medium at later times as the decays of boosted top quarks get Lorentz time dilated (see next section). For example, the estimated measurable yields for $\rm t\bar{t} \to b\bar{b}\,\ell\ell\,\nu\nu$ (using the per-month luminosities discussed in Section 13.1) with realistic analysis cuts and conservative 50% efficiency for b-jet tagging are about 10^4 in Pb–Pb collisions and 3×10^4 in Xe–Xe collisions (for the case of three-fold increase of NN integrated luminosity with respect to Pb–Pb).

Another potential novel probe of the QGP medium at HE-LHC and FCC energies is the Higgs boson. The Higgs boson has a lifetime of $\tau \approx 50$ fm/c, which is much larger than the time extent of the QGP phase [1048, 1049]. In Ref. [1048] it has been argued that the Higgs boson interacts strongly with the quarks and gluons of the QGP and the interactions induce its decay in the gluon–gluon or quark–antiquark channels, thus depleting the branching ratio to the most common "observation" channels $\gamma\gamma$ or $\rm ZZ^\star$. More recent detailed theoretical calculations, including virtual corrections, predict however no visible suppression of the scalar boson [1050]. The cross section for Higgs boson production in Pb–Pb collisions is expected to increase by a factor about 4 when going from $\sqrt{s_{\rm NN}} = 5.5$ TeV to $\sqrt{s_{\rm NN}} = 10.6$ TeV [1043]. A statistically-significant Higgs boson observation in the $\gamma\gamma$ decay channel in Pb–Pb collisions at the HE-LHC requires an integrated luminosity of 70 ${\rm nb}^{-1}$ (estimated as in Ref. [1043]), which corresponds to about 12 months with the present machine performance projections. The analysis used similar photon selections as used by ATLAS and CMS in pp collisions: $p_{\rm T} > 30, 40$ GeV/c, $|\eta| < 4$, $R_{\rm isol} = 0.3$. The backgrounds included the irreducible QCD diphoton continuum plus 30% of events coming from misidentified γ-jet and jet-jet processes. The corresponding invariant mass distribution is shown in the right-hand panel of Fig. 106. With Xe–Xe collisions the same statistical significance could be reached in 4 months.

13.3.2 Boosted tops and the time evolution of QGP opacity

The HE-LHC would provide large rates of highly-boosted heavy particles, such as tops, Z and W bosons. It is expected that when these particles decay the density profile of the QGP has already evolved. It has been argued that the hadronically-decaying W bosons in events with a $\rm t\bar{t}$ pair can provide unique insights into the time structure of the QGP [944]. This is because the time decays of the top and the W bosons are

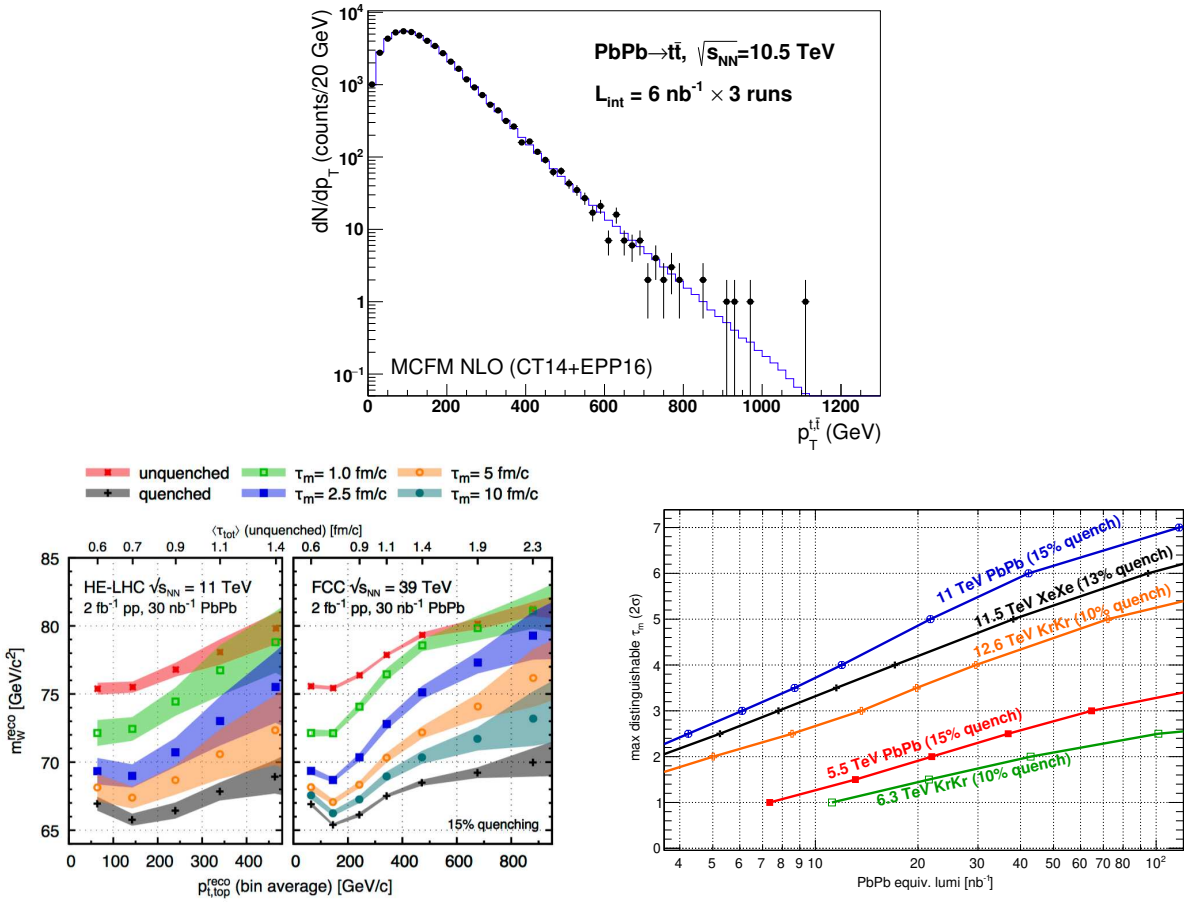

Fig. 107: Upper panel: expected top-quark p_{T} distribution in Pb–Pb in the decay channels of interest for the boosted top analysis at $\sqrt{s_{\mathrm{NN}}} = 10.6$ TeV after acceptance and efficiency cuts with the statistical uncertainties for $L_{\mathrm{int}} = 18$ nb^{-1}, corresponding to three months of data taking (adapted from [942]). Lower-left panel: reconstructed W boson mass at HE-LHC and FCC energies, as a function of the top p_{T}. The upper axis refers to the average total time delay of the corresponding top p_{T} bin. Lower-right panel: maximum medium quenching end-time, τ_m, that can be distinguished from full quenching at two standard deviations, as a function of luminosity for various species at LHC and HE-LHC energies. The luminosity for nuclei lighter than Pb is scaled to the Pb–Pb equivalent nucleon–nucleon luminosity. Figures adapted from Ref. [944].

followed by a time-delay in the interaction of the decay products of the W boson with the surrounding medium due to a colour coherence effect. The sum of these three times, several fm/c for boosted tops, would be the time at which the interaction with the QGP begins, providing a unique way to directly measure the time structure of the QGP evolution. In addition, due to colour coherence effects, energy loss would be initially absent for the colour-singlet $\mathrm{q\bar{q}}$ decay products of a highly-boosted W boson: the two quarks would start to be quenched only when their distance becomes larger than the colour correlation length of the medium, which depends on the transport coefficient $\hat{q}$ (the average transverse momentum squared that particles exchange with the medium per unit mean-free path) [1051]. The effect on the reconstructed masses of the top and W was studied with different energy loss scenarios as a proof of concept of the potential of these observables to access completely novel quantities in heavy-ion collisions [944].

For this study, the p_{T} reach of top quarks in Pb–Pb collisions is of special importance, because it determines the maximum time delay for probing the QGP. The upper panel of Fig. 107 shows the estimated p_{T} distribution of the reconstructed top yields in Pb–Pb collisions at the HE-LHC with an integrated luminosity of 18 nb^{-1}, corresponding to three months of data taking. The figure indicates that events with top p_{T} up to about 500 GeV/c can be studied. The reconstructed W-boson mass as a function of top transverse momentum is shown in Fig. 107 (lower-left panel), together with the FCC case. For details on the simulation and reconstruction procedure see [944]. The scale on the upper horizontal axis shows that a p_{T} reach of 500 GeV/c corresponds to an average total time delay $\langle\tau_{\mathrm{tot}}\rangle \sim 1.5$ fm/c. The shaded region corresponds to the statistical uncertainty estimated in central Pb–Pb collisions for $L_{\mathrm{int}} = 30$ nb^{-1} (corresponding to 5 Pb–Pb months or 1.5 Xe–Xe months with the present luminosity estimates) and $L_{\mathrm{int}} = 2$ fb^{-1} for the pp reference. Energy loss was simulated by assuming that all particles, except the W-boson decay products, lose 15% of their initial momentum. Average time delays $\tau_m = 1; 2.5; 5$ and 10 fm/c were considered as effective QGP time evolution profiles. Fig. 107 (right) shows the maximum medium quenching end-time, τ_m, that can be distinguished from full quenching with two standard deviations, as a function of luminosity for various collider energies and species. For Pb–Pb with $L_{\mathrm{int}} = 30$ nb^{-1} (5 months) at the HE-LHC a maximum time of 5–6 fm/c can be accessed, which is much larger than the time up to 1.5 fm/c that can be probed at the LHC with the nominal programme of 10 nb^{-1}. For Xe–Xe collisions, with equivalent NN luminosity larger by a factor 2–3 with respect to Pb-Pb, a time range longer by $\sim$ 1–2 fm/c can be covered in the same running period.

13.3.3 Heavy flavour and quarkonia

Heavy quarks (charm and bottom) are among the hard probes that have provided important insights on the formation and the characterics of the QGP, see Sections 5 and 7, and Ref. [258]. In this section, a few selected aspects that could represent novel or particularly remarkable observations at HE-LHC energy are discussed, namely: i) large production of thermal charm from interactions of light quarks and gluons within the QGP; ii) observation of an enhancement of charmonium production with respect to the binary scaling of the yields in pp collisions, as consequence of (re)generation; iii) observation of a colour screening and (re)generation for the most tightly-bound quarkonium state, the Υ(1S).

Interactions between gluons or light quarks of the QGP can lead to the production of $\mathrm{c\bar{c}}$ pairs if the energy in the centre of mass of the interaction is of the order of twice the charm quark mass $\sqrt{\hat{s}} \sim 2\,m_c \sim 3$ GeV. In Section 13.2 we have estimated that an initial temperature T_0 of 600–800 MeV could be reached at the HE-LHC. With these QGP temperatures a sizeable fraction of the gluons and light quarks have energies larger than the charm quark mass and $\mathrm{c\bar{c}}$ pairs can be produced in their interactions. Figure 108 shows the prediction [1052] for the time-dependence of the $\mathrm{c\bar{c}}$ rapidity density at mid-rapidity in central Pb–Pb collisons at the HE-LHC. The value at the initial time τ_0 corresponds to the initial hard-scattering cross section. Both calculations show a rapid increase after τ_0 with a final value that is larger by up to 20% than the initial production. This enhancement could be observed for the first time at the HE-LHC and provide a handle on the initial temperature of the QGP. The abundance of charm quarks also has an effect on the QGP equation of the state: the inclusion of the charm quark in lattice-QCD calculations results in a sizeable increase of $P/T^4 \propto n_{\mathrm{d.o.f.}}$ for $T > 400$ MeV, as discussed in the context of the FCC [411].

The measurements of the nuclear modification factor of J/ψ at the LHC [745, 749, 1053] are described by models that include dissociation caused by colour-charge screening and a contribution of recombination (usually denoted (re)generation) from deconfined c and $\mathrm{\bar{c}}$ quarks in the QGP [461, 1054, 1055]. The (re)generation contribution the charmonium yield is expected to be proportional to the square of the rapidity density of $\mathrm{c\bar{c}}$ pairs in the QGP. Therefore, it is predicted to be much larger at HE-LHC than LHC energies, as a consequence of the larger hard-scattering production cross section of $\mathrm{c\bar{c}}$ pairs and the possible sizeable thermal production. This could lead to the observation of an enhancement of

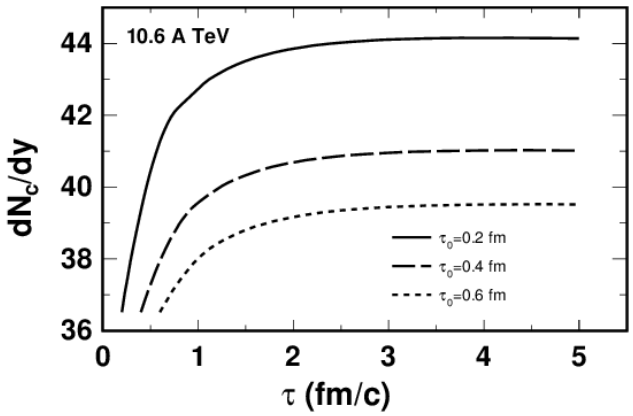

Fig. 108: Time-evolution of the $\mathrm{c\overline{c}}$ yield (per unit of rapidity at midrapidity) for central Pb–Pb collisions at $\sqrt{s_{\mathrm{NN}}} = 10.6$ TeV, obtained as described in Ref. [1052].

J/ψ production with respect to binary scaling of the yield in pp collisions, i.e. $R_{\mathrm{AA}} > 1$, which would be striking evidence of $c\overline{c}$ recombination from a deconfined QGP.

The measurement of Υ production would be particularly interesting at the high energies and temperatures reached at the HE-LHC. The LHC data are consistent with a scenario in which the excited states 2S and 3S are partially or totally suppressed by colour screening, while the 1S, which is the most tightly bound state, has no or little direct melting. Its suppression by about 60% could be explained by the lack of feed-down from the (melted) higher states and the effect of nuclear PDF suppression (see e.g. Ref. [258] for a recent review). At HE-LHC energies, on the one hand, the temperature could be large enough to determine a full melting even of the tightly-bound 1S state, on the other hand the large abundance of $\mathrm{b\overline{b}}$ pairs in the QGP could induce substantial Υ (re)generation. The role of the two effects —degree of survival of initial bottomonia and contribution of (re)generation— could be separated by means of precise measurements of the $\mathrm{b\overline{b}}$ cross section and of the B meson and Υ R_{AA} and elliptic flow v_2 (the regenerated Υ states could exhibit a v_2 such that $0 < v_2^{\Upsilon} < v_2^{\mathrm{B}}$).

13.4 Nuclear PDF measurements and search for parton saturation

Parton saturation [780, 781] is based on the idea that standard linear parton branching leads, at small values of momentum fraction x, to parton densities so high that non-linear dynamics (like gluon recombination) becomes important and parton densities are tamed to grow from power-like to logarithmically. Non-linear effects are expected to become important when the density of gluons per unit transverse area exceeds a certain limit, the *saturation density*.

In the framework of QCD collinear factorization, Parton Distribution Functions of nucleons inside nuclei (nuclear PDFs) can be obtained in standard global fit analysis with usual linear evolution equations. The differences with respect to free nuclon PDFs are parametrized in a nuclear modification factor $R_i^{\mathrm{A}}(x, Q^2)$ with $i = \mathrm{g}$, $\mathrm{q_{valence}}$, $\mathrm{q_{sea}}$ (see e.g. Ref. [1056]). Collinear factorization is expected to break down when the gluon phase-space becomes saturated. The onset of saturation is usually discussed in terms of the saturation momentum Q_{S}^2, defined as the scale at which the transverse area of the nucleus is completely saturated and gluons start to overlap. It can be shown that $Q_{\mathrm{S}}^2 \sim A^{1/3}\left(\sqrt{s_{\mathrm{NN}}}\right)^{\lambda} e^{\lambda y}$, with $\lambda \approx 0.3$ [411]. Therefore, the regime of high gluon density is best accessed at a high-$\sqrt{s_{\mathrm{NN}}}$ hadron collider with measurements at low p_{T} and forward rapidity, which probe small x and small Q^2. In order to firmly establish the existence of this new high-energy regime of QCD and clarify the validity of the different approaches to factorisation and evolution, new kinematic regions must be explored using

higher collision energies in order to have a large lever arm in Q^2 in a region that, while perturbative, lies inside the saturation domain. The HE-LHC extends the small-x coverage by a factor of two with respect to the LHC, as shown in Fig. 109.

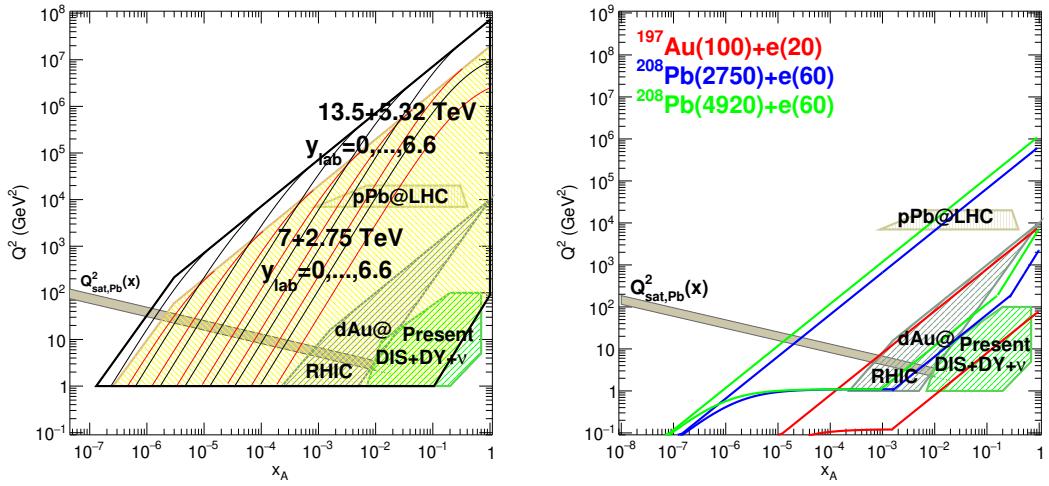

Fig. 109: Regions of the x–Q^2 plane covered by the data used for present nuclear PDF fits (nuclear DIS and Drell-Yan, p–Pb and d–Au at the LHC and RHIC), shown in both panels, by p–Pb collisions at the LHC and the HE-LHC (left) and by e–A collisions at the EIC, LHeC and HE-LHC (right). In the left panel, the thin lines correspond to different rapidities in the laboratory frame $y_{\rm lab}$ = 0,1, 2, 3, 4, 5, 6 from right to left, with the left edge defined by $y_{\rm lab} = 6.6$. Values of $Q^2_{\rm S}(x)$ for Pb are shown for illustration in both panels.

There is a strong complementarity between the physics programmes at hadron colliders and at the proposed electron–hadron colliders (Electron-Ion Collider in the USA [798], Large Hadron Electron Collider LHeC [797]). With kinematic reach at the TeV scale in the c.m.s. (Fig. 109, left), the electron–nucleus option at the HE-LHC would be well-positioned to reach conclusive evidence for the existence of a new non-linear regime of QCD. It would be clearly complementary with the p–Pb case, providing a precise knowledge on the partonic structure of nucleons and nuclei and on the small-x dynamics. A specific discussion can be found in the electron–nucleus part of the FCC Conceptual Design Report.

13.5 Photon–photon collisions

Photon–photon collisions in UPCs of proton [1057] and lead (Pb) beams [587] have been experimentally observed at the LHC [819, 1058–1060]. The future prospects at the LHC are extensively discussed in Sect. 11.2. Although the γ spectrum is harder for smaller charges –which favours proton over nuclear beams in the production of heavy diphoton systems– each photon flux scales with the squared charge of the hadron, Z^2, and thus $\gamma\gamma$ luminosities are extremely enhanced for ion beams ($Z^4 = 5 \cdot 10^7$ in the case of Pb–Pb). The Pb beam Lorentz factor at HE-LHC ($\gamma = 5\,650$) determines the "maximum" quasireal photon energy $\omega_{\rm max} = \gamma/{\rm R_{Pb}} \approx 160$ GeV, leading to photon–photon collisions up to centre-of-mass energies of $\sqrt{s_{\gamma\gamma}} \approx 320$ GeV, twice larger than those reachable at the LHC.

The very rare elastic scattering of two photons in vacuum $\gamma\gamma \to \gamma\gamma$ was recently observed for the first time in UPCs at the LHC [809, 810]. At the HE-LHC, due to the higher diphoton masses reached, this process may be sensitive to physics beyond the SM through new heavy charged particles contributing to the virtual loop such as, e.g., from SUSY particles [1061]. Light-by-light (LbyL) scattering has also been proposed as a tool to search for monopoles [1062], axions [1063], unparticles [1064], low-scale

gravity effects [1065], and non-commutative interactions [1066].

Acknowledgements

We would like to thank the LHC experimental Collaborations and the WLCG for their essential support. We are especially grateful for the efforts by the computing, generator and validation groups who were instrumental for the creation of large simulation samples. We thank the detector upgrade groups as well as the physics and performance groups for their input. Not least, we thank the many colleagues who have provided useful comments on the analyses.

Specific authors acknowledge the following forms of support:

- Nestor Armesto, Elena G. Ferreiro and Carlos Salgado acknowledge the support of the Ministerio de Ciencia e Innovación of Spain under projects FPA2014-58293-C2-1-P, FPA2017-83814-P and Unidad de Excelencia María de Maetzu under project MDM-2016-0692, by Xunta de Galicia (Consellería de Educación) within the Strategic Unit AGRUP2015/11, and by FEDER.
- Raphaelle Bailhache acknowledges the support of the German Federal Ministry of Education and Research (BMBF).
- Zvi Citron acknowledges the support of the ISRAEL SCIENCE FOUNDATION (grant No. 91/6491).
- Torsten Dahms acknowledges the support of the DFG cluster of excellence "Origin and Structure of the Universe".
- Stefan Floerchinger acknowledges the support of the DFG Collaborative Research Centre SFB 1225 (ISOQUANT).
- Iwona Grabowska-Bold acknowledges the support of the Polish National Science Centre grant DEC-2016/23/B/ST2/01409, of the AGH UST statutory tasks No. 11.11.220.01/4 within subsidy of the Ministry of Science and Higher Education, and of the PL-Grid Infrastructure.
- Ilkka Helenius acknowledges the support of the Carl Zeiss Foundation and the Academy of Finland, Project 308301.
- Peter Jacobs and Mateusz Płoskoń acknowledge the support of the U.S. Department of Energy, Office of Science, Office of Nuclear Physics, under contract DE-AC02-05CH11231.
- Jiangyong Jia, Peng Huo and Mingliang Zhou acknowledges the support of the U.S. National Science Foundation under grant number PHY-1613294.
- Spencer Klein acknowledges the support of the U.S. DOE under contract number DE-AC02-05-CH11231.
- Filip Krizek acknowledges the support of the Ministry of Education of the Czech Republic (grant InterExcellence LT17018)
- Mariola Klusek-Gawenda acknowledges the support of the Polish National Science Center Grant No. DEC-2014/15/B/ST2/02528.
- Nirbhay Kumar Behera acknowledges the support of National Research Foundation of Korea (NRF), Basic Science Research Program, funded by the Ministry of Education, Science and Technology (Grant No. NRF-2014R1A1A1008246).
- Constantin Loizides acknowledges the support of of the U.S. Department of Energy, Office of Science, Office of Nuclear Physics, under contract number DE-AC05-00OR22725.
- Laure Massacrier acknowledges the support of CNRS under the grant RFBR/CNRS 18-52-15007.
- Christoph Mayer acknowledges the support of the Polish Ministry of Science and Higher Education and from the Polish National Science Center.
- Alexander Milov acknowledges the support of the Israel Science Foundation (grant 1065/15), and the MINERVA Stiftung with the funds from the BMBF of the Federal Republic of Germany.
- Soumya Mohapatra acknowledges the support of the Division of Nuclear Physics of the US Department of Energy under grant DE-FG02-86ER40281.

– Petja Paakkinen acknowledges the support of the Magnus Ehrnrooth Foundation.
– Hannu Paukkunen acknowledges the support by his Academy-of-Finland project 308301.
– Dmitri Peresunko acknowledges the support of the Russian Science Foundation grant 17-72-20234.
– Ralf Rapp acknowledges the support of the U.S. National Science Foundation under grant number PHY-1614484, and in part by the ExtreMe Matter Institute EMMI at the GSI Helmholtzzentrum für Schwerionenforschung (Darmstadt,Germany).
– Kristof Redlich acknowledges the support of the Polish National Science Center NCN under Maestro grant DEC-2013/10/A/ST2/00106.
– Mark Strikman acknowledges the support of the U.S. Department of Energy, Office of Science, Office of Nuclear Physics, under Award No. DE-FG02-93ER40771.
– Adam Trzupek acknowledges the support of the National Science Centre, Poland under the grant no 2016/23/B/ST2/00702.
– Michael Weber acknowledges the support of the Austrian Academy of Sciences and the Nationalstiftung für Forschung, Technologie und Entwicklung, Austria.
– Michael Winn acknowledges the support of the European Research Council (ERC) through the project EXPLORINGMATTER, funded by the ERC through a ERC-Consolidator-Grant.
